Patients with substance use disorders are more challenging and risky to treat for pain for multiple reasons. For patients who are actively using, there is naturally a high risk that the opioids will simply add into the mix of drugs that are being abused, with potentially lethal results, particularly in the presence of sedatives or alcohol. Active substance use also decreases adherence to treatments, and these patients are more likely to be lost to follow-up.

For patients whose substance use disorder is in remission, reexposure opioids may be a trigger for relapse in their drug of choice, and they are at increased risk of iatrogenic opioid use disorder.

37.3 Diagnosis and Assessment of Addiction in the Pain Treatment Setting

The diagnosis of addiction in psychiatry has been complicated by a distinction between substance abuse and substance dependence. This has always been a poor fit for the particulars of opioids, which cause a withdrawal syndrome in everyone who takes them chronically, regardless of addiction issues. In the DSM-5, the categories of substance abuse and substance dependence have been collapsed into substance use disorder [44]. Both the DSM-5 criteria for substance use disorder and the ASAM-APS-AAPM criteria for addiction address similar symptoms of impaired control over use or compulsive use, continued use despite harm, and preoccupation with use or cravings [23]. The DSM-5 criteria for opioid use disorder specifically exclude consideration of opioid tolerance and withdrawal, since these will develop in all patients who take opioids chronically [1]. The DSM-5 also specifically excludes this diagnosis in patients who are only taking their prescribed opioid medication, which provides diagnostic clarity but may result in underdiagnosis of patients with iatrogenic OUD.

Addiction can be challenging to recognize in many settings but is particularly difficult in pain clinics, where the majority of patients are in some degree of emotional distress; there is high psychiatric comorbidity with depression and anxiety, frequent occupational and interpersonal problems, and many patients are seeking or are already prescribed habit-forming medications. Studies suggest that clinicians may overestimate their ability to recognize substance abusers "by feel" and that they are prone to fall into prejudicial misapprehension, overestimating prevalence of substance abuse in minority patients and failing to detect it in other population groups. The use of best practices for safe opioid prescribing has risen from a low baseline in an uneven manner, for example, laws have been passed in many states mandating that opioid prescribers check the prescription monitoring program report before writing a new prescription, but the actual adoption of this evidence-based practice has varied [52].

However clinicians can reliably observe two important sets of clues to addiction: risk factors

Table 37.1 Opioid aberrancies

Escalation of medication dosage
Requesting early refills
Doctor-shopping
Losing prescription medications
Tampering with prescriptions

and aberrancies. Aberrancies cover a wide spectrum of undesirable, unsafe, or boundary-transgressing patient behavior (see Table 37.1). The use of prescription monitoring programs and urine drug screenings can also be very helpful in identifying aberrant behavior. Once identified, whether by a physician, support staff, or lab, it is important to consider the anomalies in context of the clinical picture. The differential for addiction includes major mental disorders, delirium, misunderstanding, and interference by family members, roommates, or romantic partners.

Risk factors can be obtained from the patient, his other providers, and family. Several standardized questionnaires, such as the SOAPP and ORT, allow providers to identify known risk factors for addiction by self-report at time of intake.

It is important not only to make an accurate pain diagnosis and detect substance abuse in patients but also identify any other psychiatric comorbidities they may have. Once a patient has been identified as having a complex pain problem with addiction or dual diagnosis issues, they need to be evaluated more thoroughly to develop a good understanding of their psychosocial situation, their social and other resources, and significantly their limitations and challenges, including limited resources, legal issues, and family problems [12].

37.4 Acute Pain in Addicted Patients

The evidence suggests that nonaddicted patients in acute pain who have not had opioids before are at low risk for developing addiction during a short course of treatment with low-potency opioids [50]. However, brain changes of unclear significance are observable after as little as a month of treatment with opioids [56]. Clinical observations suggest that it is quite difficult for patients to discontinue opioids after 90 days of continuous treatment, which is also the threshold for pain conditions to be considered chronic. It is not unusual in academic pain centers to encounter patients who have undergone procedures and been prescribed pain medication for 1, 2, or even 3 months before they are referred to the pain service for a subacute problem which is rapidly becoming a chronic condition. Particularly when discharge is looming, the patient may not be safe to be discharged on high doses of opioids, but abrupt taper prior to discharge may result in a crisis and failure of disposition planning.

This situation requires close assessment to determine what is happening, as this clinical picture may represent reactivation of addiction and medication overuse, an inadequately treated pain condition, or diversion. Ideally, in the case of elective procedures, these issues can be identified beforehand and incorporated into treatment planning; however, a significant proportion of acute pain patients, particularly those with substance abuse issues, will present with pain secondary to trauma occurring due to assault, injury, or motor vehicle collision with no advance warning. When these issues are identified, they should be incorporated into treatment planning for their care of that acute pain episode and beyond. This can also be an excellent time for substance abuse interventions, particularly if the patient's injury was related in some way to their addiction, as this provides a clear adverse consequence to use as a platform for motivational interviewing or other interventional techniques. Motivational interviewing (MI) has been beneficial for preventing alcohol-related reinjury [18] and for increasing exercise in fibromyalgia patients [3], but there is no solid evidence for MI-based interventions for opioid dependence at this time. At the same time, further psychiatric assessment may be indicated, particularly if there is concern for suicidality prior to hospitalization or during the hospital stay. Some hospitals will have 12 step-based program meeting on their grounds, and this may also be an option for motivated and mobile patients to attend.

For pain specialists, the greatest challenge in acute pain in patients with substance use is finding safe and adequate treatments in patients who may have elevated opioid tolerance, lower pain threshold, and difficulty coping with stress and discomfort. Perioperative management must take into account patients' use of prescribed opioids, illicit opioids such as heroin, and potentially patients on chronic buprenorphine or methadone for opioid dependence who will have high tolerance and, in the case of the buprenorphine patient,

some initial difficulty in getting adequate analgesia due to the partial antagonism of the buprenorphine [38]. The provider must also be watchful for signs of other substance toxicity or withdrawal, such as stimulant-inducted psychosis or benzodiazepine withdrawal.

For the pain relief provider, it is important to determine, or at least estimate, their baseline opioid dosage and then maintain them on a regimen of opioids close to this in potency, with additional opioids available as needed for the acute pain. This may require conversion to parenteral opioids, and frequently the use of IV PCA analgesia is the safest and most effective strategy for managing their acute pain needs. In cases of thoracic or abdominal surgery or trauma, neuraxial anesthesia using epidural catheters to deliver local anesthetics or opioids can be very effective. Epidural morphine, for example, is ten times more potent than systemic morphine. Where the pain has a focal source, particularly in an extremity, regional anesthesia, such as using nerve catheters, can block much of the nociception from the injury and thus reduce the need for opioids overall as well as improve perfusion and recovery time. When patients with extremely high opioid tolerance require systemic opioids, a switch to methadone can often allow a decrease of overall dose. Very high doses of opioids raise the risk of respiratory depression and opioid-induced hyperalgesia, a condition characterized by whole-body pain that only worsens with increased opioid dosing.

37.5 Treating Chronic Pain with Opioids

Chronic pain is a highly significant and growing problem as the world's population gets older and more people are surviving significant illness or injury. Addicts are more likely to have all kinds of comorbidities, psychiatric and physical, and have a higher rate of physical injury and chronic pain as well [29]. The phenomenon of so-called self-medication for chronic pain is another mechanism by which patients may be exposed to these medications and develop addiction [46]. Chronic pain has been defined variously as pain lasting more than 3 or more than 6 months; for our purposes, the ASA description of chronic pain as pain lasting longer than "the expected temporal boundary of tissue injury and normal healing and adversely affecting the function or well-being of the individual" is most germane [2]. Perhaps the most important fact about chronic pain is that it is chronic; in other words, it should be managed without the expectation of complete resolution, a quick return to premorbid function, or a short horizon for treatment. The effectiveness of chronic pain treatments is also less than those for acute pain, with average effect size of 40–50% and a substantial minority of patients who receive no benefit from treatment. Any treatments offered for chronic pain should be safe and sustainable in terms of availability and affordability.

The most vexing question in the treatment of chronic pain, particularly chronic pain in addicts, is that of chronic opioid therapy. Patients prescribed opioids for pain are also likely to use opioids nonmedically. This finding has been seen in military veterans and in the general population [5, 17]. A history of substance use disorder makes it less likely that primary care patients will have good relief after 12 months of treatment for musculoskeletal pain including opioids [42]. Some systematic reviews of chronic opioid therapy for non-cancer pain have failed to present strong evidence for the effectiveness of chronic opioid therapy [9].

"Adverse selection" is the phenomenon of the sickest and highest-risk patients receiving more opioids for longer and often receiving the bulk of opioid prescriptions in any given population. This phenomenon has been demonstrated in multiple settings [54]. Similar findings have also been reported among US military veterans and HIV patients [41, 48].

The APS-AAPM guidelines published in 2009 for treatment of non-cancer chronic pain may be helpful in guiding treatment, although they are not specifically focused on substance abuse patients [10]. These patients are often more complex, with layered conditions including substance use disorders, one or more primary pain conditions, and frequently psychiatric comorbidities as well. Although these complex pain patients have been shown to respond better to intensive treat-

ment, the healthcare system rarely allows them to receive it [43]. Interdisciplinary pain care, which includes treatment by allied professionals and mental health, is rarely available in the USA due to coverage and access issues. The more recent and conservative CDC guidelines for opioids in chronic pain are also helpful and recommend low doses of opioids on a trial basis, with a ceiling dosage of 40 mg morphine equivalents [14, 15].

37.6 Treating Chronic Pain in the Setting of Substance Use Disorder

In this patient population, opioids should be prescribed cautiously if at all, in the knowledge that this is intrinsically risky, and more as a last resort than a first step. Providers without the requisite training or experience, or who do not have adequate support, are recommended to avoid opioid prescribing entirely in this population. If the patient is enrolled in substance treatment, or about to enter treatment, opioids may be incompatible and actually sabotage the patient's placement in a treatment program and should be avoided. These patients should first have the benefit of alternative treatment methods to the greatest extent possible, including non-opioid pain medications, nerve medications that are not addictive, behavioral interventions, and physical interventions such as physical therapy, TENS units, and injections where appropriate.

The initial intake for pain treatment should routinely include risk assessment, and this should be repeated regularly during treatment. Once risk factors such as a past history of SUD have been identified, or current aberrancies suggestive of SUD are seen, the decision must be made how to respond. Seeing potential problems of this nature or taking no action is not ethical or professionally advisable for the prescriber; in an older study of disciplinary actions taken against physicians related to opioid prescribing, 12% of the charged physicians had recognized SUD issues in their patients and continued prescribing without taking any action.

If opioids are felt to be a necessary part of pain treatment, they should be prescribed at the lowest dose possible. Many experts recommend short-acting opioids used on a schedule. If the patient is converted to a longer-acting opioid, it is recommended that they are not also prescribed short-acting opioids on an as-needed basis. This practice of treating "breakthrough pain," while very helpful in cancer pain, often results in patients taking both their scheduled and as-needed medications daily to the maximum extent possible, increasing risks and total opioid dosage [33]. It is predictable that some patients will overuse or misuse their medications. Many patients, after an initial good response, will quickly develop tolerance to at least part of the analgesic effect of the opioids and will escalate use on their own or request dosage increases. Increasing opioid doses tends to be a temporary solution only and increases morbidity and mortality risks.

Treatment should be individualized; however, there are many best practices that should be routinely followed in pain treatment, particularly as these risk factors and aberrancies may not be identified initially. Patients with fewer risk factors and less severe aberrancy may not require specific changes in treatment beyond closer monitoring. For high-risk patients and those whose aberrancy is more concerning, practices including a written, explicit treatment agreement, compliance checklists, and randomized urine drug screens may be helpful and should be used in every case. Early intervention with behavioral treatments may also be helpful [27], but there is little strong evidence to guide treatment in these high-risk patients. For patients with ongoing substance use issues or serious aberrancies, such as obtaining opioids from multiple prescribers for routine care or diversion, there may be no better option than stopping the opioids entirely. A taper should be done if safety allows, possibly with referral for consideration of medication-assisted treatment.

37.7 Problems with Tapering and Stopping Opioids

When opioid therapy is tapered or discontinued in patients who have been on opioids chronically, patients often experience at least transitory distress and increase of pain symptoms. Patients

with comorbid depression or anxiety may have exacerbations of these symptoms. A particularly challenging constellation of symptoms occurs in those pain patients who have been on chronic opioids for some time and have developed aberrancies or behavioral complications, which only seem to worsen when the opioid dosage is decreased. At worst, this can lead to a catastrophic scenario where the patient's distress becomes uncontrollable, placing patient and provider in a dilemma as neither further taper nor return to high-dose opioids seems a workable option [34]. This is hypothesized to result from physiological changes in the nervous system with prolonged opioid which make the patient unable to tolerate opioid tapering. This has been called "complex persistent dependence" and has been observed to respond well to buprenorphine therapy. In the USA, this treatment may be difficult to access, particularly if the patient does not meet formal criteria for OUD; some patients are also understandably resistant to this diagnosis, which is highly stigmatized and may have negative impacts on their employment and access to health insurance. In addition, relatively few pain specialists prescribe buprenorphine, and most addiction treatment programs do not feel comfortable addressing pain in addition to SUD.

If not treated with buprenorphine or methadone, chronic pain patients with SUD histories are more likely to relapse, particularly those with OUD [24]. A manualized treatment program emphasizing behavioral treatment including cognitive-behavioral therapy and acceptance and commitment therapy has been developed for veterans with comorbid pain and SUD [26]. Some patients in this position will complain that they are being driven to seek illicit drugs. For ethical and professional reasons, it is recommended to continue to offer these patients the full panoply of non-opioid pain treatments to the extent that they are appropriate.

37.8 Palliative Care in Addicted Patients

Palliative care was defined by the WHO as an approach to treatment which improves the quality of life of patients and their families facing the problems associated with life-threatening illness [47]. In this specialized arena of healthcare, the mandate to provide comfort may take precedence over concerns about addiction. While it is rare for patients in this clinical context to develop new addiction issues, preexisting psychiatric and addiction issues may be reactivated or worsen under the stresses of serious illness and may go unrecognized by providers. Untreated alcohol dependence, for example, is linked to other substance misuse and worse outcomes in pain patients [13]. Some cancer patients are provided with pain medications in larger quantities and dosages toward the end of life than any other types of patient. In addition to addiction, misuse or simple incorrect use due to misunderstanding can put patients at risk. These patients, who may be dependent on others for the management and administration of their medications, are also more vulnerable to diversion of medications by people near them. At the same time, many cancer patients do not receive adequate pain treatment due to access to care issues and also due to patient reluctance to use these medications for fear of addiction [49].

Following best practices in these patients can help track their medication use and identify aberrancies earlier. Close monitoring of symptoms and more frequent dispensing of opioids can be useful in harm reduction approaches. In larger, well-staffed cancer care centers, even daily dispensation of pain medications may be a useful intervention for selected patients. Pill safes and enlisting family members to dispense daily dosages can also improve safety and reduce the risk of misuse/overuse/diversion. In many cases, the medication misuse is also being driven by complex physical and emotional distress, with combined factors of depression, anxiety, worry about the future, impending death, being a burden on family, how family will fare after the patient's death, and non-pain forms of suffering such as dyspnea, fatigue, constipation, or immobility [32].

37.9 Best Practices for Risk Management

All patients may be potentially at risk for addiction, and current approaches to risk stratification are very limited. For example, there is consensus

that there is a large genetic component in predisposition to addiction, with abnormalities of the endogenous opioid system in particular being linked to increased risk of opioid abuse. However, no standard, evidence-based genetic testing protocol has been introduced. While family history may provide some clues to genetic predisposition, addiction is well known to "skip generations" and is often not openly discussed within families, so that the patient may not be aware of relevant history.

Therefore, the concept of universal screening in pain medicine, similar to the use of universal precautions for infection control, is becoming more popular [20]. This universal approach may also serve to reduce stigma and improve the detection of misuse. For example, opioid dependence is more likely to be overlooked in older adults and in Whites [6, 55]. This screening and risk stratification may also help use scarce community mental health, pain management, and substance abuse treatment resources more effectively, as low-risk patients remain in the primary care setting as long as they are doing well, while riskier patients are able to access more specialized and interdisciplinary care. Patients with serious psychiatric issues, substance dependence, or both should generally be seen in a setting with the availability of mental health consultation. This model tends to apply most to large cities and areas near academic medical centers; however, telemedicine applications may extend the reach of these specialties into rural areas and isolated regions [36].

Several useful screening tools for determining risk factors for patients include the COMM, SOAPP, and ORT. These are all brief, self-administered tests. The COMM has 17 items, while the ORT 8 and the SOAPP come in a full 24-item version and briefer versions [37]. The full version of the SOAPP may be the most effective at predicting future aberrancy [40]. Note that even a high score does not automatically translate into "do not prescribe opioids"; these tests must always be interpreted using clinical judgment. Since they are self-reported screens and do not attempt to conceal the nature of the assessment, they may underestimate risks in patients who are unreliable historians or deliberately deceitful.

The use of an opioid treatment agreement is also widespread, although there is very little evidence to support its efficacy. The greatest usefulness of this measure is to provide a transparent means of disclosing treatment policy to patients in advance. It is important to discuss the agreement with patients, along with obtaining fully informed consent for any treatments and documenting same. Since the risks of opioid therapy are much better appreciated now than they were even a decade ago, it is not safe to assume that a patient who is seen already on chronic opioids has full understanding of the implications and risks of this treatment. Any specific policies regarding prescription monitoring, pill counts, and urine drug screens should also be discussed at this time.

Urine drug testing (UDT) offers the promise of letting the prescriber know what the patient is exactly taking. Simple immunoassays have high false-positive and false-negative rates and should be followed up with confirmatory gas chromatography/mass spectrometry testing. Since even monotherapy with some opioids may result in numerous metabolites, these results should be reviewed with an expert, such as a pain specialist, pharmacist, or pathologist, before taking clinical action. UDT is most helpful in demonstrating that patients are not taking prescribed medications or taking additional, non-prescribed medications or illicit drugs. A policy should be developed to guide providers consistently on what actions to take in the event of an unexpected UDT result. Some studies have shown that even when UDT is obtained and shows unexpected results, prescribers continue to prescribe opioids [21]. In some states, where state law recognizes a role for medical marijuana, providers may choose to obtain UDT without checking routinely for THC. UDT is not able to reliably determine whether a patient is taking the full dose of their prescribed medication. These limitations aside, UDT helps providers recognize aberrancy that would not be identified by behavioral monitoring [30]. In the USA, many health insurances will not cover the cost of UDT, so providers must make smart choices about when and how often to order them. Systematic reviews suggest that the benefit for patients of standard UDT policies is modest [51].

37.10 Cooperation with Allied Providers

Primary care providers and pain specialists cannot be expected to master the fields of psychiatry and addiction but must understand enough to recognize patients with these issues, make appropriate referrals, and collaborate with the appropriate allied providers. It is important to provide solid information to colleagues about the nature of the patient's pain diagnoses and their treatment. For patients with addiction issues, some medications such as benzodiazepines and opioids may be both inadvisable and incompatible with their addiction treatment. In this case, prescribing these medications for the patient may unknowingly sabotage their addiction treatment or provoke relapse.

In patients who have been diagnosed with opioid dependence, a possible option for them may be opioid agonist therapy, namely, methadone or buprenorphine. In the USA, methadone may be prescribed freely for pain but only prescribed for the treatment of addiction by federally recognized methadone clinics. In addition, methadone clinics provide patients with a single larger daily dose of methadone, rather than dosing three times a day as is done for pain. Buprenorphine, in the form of Suboxone, may be prescribed for opioid dependence and (off-label) for pain. Buprenorphine is also available without the combination of naloxone and as a long-acting transdermal patch, Butrans. Both of these forms are more prone to abuse. Since buprenorphine is a partial opioid agonist, it may be less prone to abuse than other opioids, and it is also not suitable for combining with other opioids and may precipitate withdrawal in a patient who has been taking other opioids chronically. Bupropion treatment has been shown to be an effective treatment of opioid dependence and also reduces the rush experienced by patients who do relapse and use other opioids on top of the buprenorphine [28]. Naltrexone is also effective for OUD but has no analgesic effect and may worsen mood disorders; this medication, particularly in its long-acting injectable form, will complicate acute pain treatment due to the opioid blockade. A recent review by Harrison et al. provides an excellent overview of perioperative care in patients receiving medication-assisted treatment [22].

37.11 Conclusion

Substance dependence is a large and growing problem in developed countries. Prescription opioid misuse appears to have crested as a public health problem but remains significant, and the wider opioid crisis continues unabated as of this writing. Pain medicine has become intimately involved with this opioid crisis. Many pain patients have comorbid conditions including depression, anxiety, and SUD which complicate their treatment and worsen their prognosis. These patients should be offered the full range of pain management services, with particular emphasis on behavioral interventions; opioids should only be considered, if at all, after reasonable trials of other, safer treatment approaches. Early recognition of the patients by identifying their high-risk status and detecting aberrancies can help with early referrals to mental health and substance abuse providers and cautious, closely monitored prescribing practices. Many patients fall into this overlap between disorders, and there is an acute need for providers who are able to manage these challenging conditions. Specifically, a subset of patients who seem unable to tolerate opioid weaning and discontinuation has been identified. While they may not meet formal criteria for OUD, they may respond to behavioral treatment and buprenorphine.

Part IV

Main Systems Components in Addictions Treatment

Ambros Uchtenhagen and Giuseppe Carrà

38 Main Elements of a Systems Approach to Addiction Treatment: An Introduction

Ambros Uchtenhagen and Giuseppe Carrà

Abstract

The focus of this section is mainly on the treatment system and on the community, at a regional or national level, as a comprehensive network of different approaches, services, and actors, covering all types of addictive behaviors. This implies the preference for a public health perspective, combining the care for the individual patients in their diversity with the intention to cover the treatment needs in a specific catchment area and for a given population. In addition, there are some chapters focusing on diagnostic issues and reviews of specific therapeutic approaches.

This aim has to consider the availability, affordability, and accessibility of appropriate and qualified treatment. It has to build on effective treatment, provided in an efficient and cost-effective way. It has to stress connections among services, shared concepts of different indications, and routine rules for patient pathways through treatment phases, ranging from first contact, screening, and assessment to treatment planning and monitoring, rehabilitation, and aftercare. Pathways may also follow models of stepped care in an attempt to avoid misplacement of patients and to make best use of the available human and financial resources. Quality of intervention is embedded in evidence based also in the field of drug addiction treatment.

A comprehensive network goes beyond formal therapeutic regimes, by including low-threshold approaches for establishing contact by outreach activities and by harm reduction interventions in support of those still actively engaging in addictive behavior. This includes measures to reduce the risks of injecting, of acquiring blood-borne infectious diseases, and of overdose-related mortality. Such interventions are not in contradiction to others offering a structured regime of substitution medication (e.g., for opiates or nicotine) or even aiming at abstinence from substance use and full recovery. The system has to integrate all these approaches in order to best meet the needs and preferences of the equally diverse people with substance use disorders. Everyone should be able to find what is appropriate and suits him or her best under present conditions.

Such a comprehensive network is work in progress, as addictive behaviors and treatment populations change over time. New therapeutic methods and instruments also ask for adaptation

and suited implementation at the system level. Where no such network is in place, the relevant steps for building up a system responding to the needs are recommended. All this goes not without a political support to provide adequate and sustainable resources, in the framework of a treatment policy which is in line with an overall drug policy.

The structure of this section in its revised format can be divided into two parts: The first is about the principles and aspects of the systems approach to addiction treatment, presented in the text above. In the second part, the reader will find information on the individual chapters in this section. This is presented in the following text.

Chapter 39 by Babor TF, "Treatment Systems for Population Management of Substance Use Disorders: Requirements and Priorities from a Public Health Perspective," is a systematic analysis of what has to be considered in a treatment system, in order to best serve all in need of treatment in a given population. *Method:* It is based on relevant previous publications by the author and others, providing additional information on the various aspects, also in a historical perspective. The *Text* focuses on concepts, requirements, and priorities recommended for building up an adequate treatment system, starting out with definitions and rationale, going on to conceptual developments, and finally listing priorities. The *Conclusions* ask for an appropriate resource allocation if the treatment system should allow to cover the treatment needs, including good service quality and access to care.

Chapter 40 by Saunders JB and Latt NC, "Screening, Early Detection, and Brief Intervention for Alcohol Use Disorders," starts out from the observation that alcohol problems are frequently diagnosed too late before becoming chronic and disabling conditions. Therefore, secondary interventions such as providing help for self-recognition, early diagnosis, self-management of use, and therapeutic approaches to change behavior are essential. *Method:* The aim is to provide screening instruments and information on their usefulness, with bibliographic details, rather than a systematic literature search. *Text:* Besides providing evidence for the observations made, the focus is how to implement the use of screening instruments and of brief intervention techniques into clinical practice, including Internet and mobile phone techniques for interactive support.

Chapter 41 by Bobes-Bascaràn T et al., "Clinical Assessment of Alcohol Use Disorders," describes how to evaluate the type and extent of alcohol use and the type and extent of psychiatric comorbidities, of neuropsychological performance, and of psychosocial functioning and quality of life. *Text:* Besides reviewing the necessary elements of a comprehensive clinical procedure, a description of the most relevant psychometric instruments is provided, covering symptomatology; legal, economic, and occupational problems; coping behaviors; and readiness to change.

Chapter 42 by Wurst FM et al., "Biological State Marker for Alcohol Consumption," has a strong focus on the various direct ethanol metabolites and the use of their measurement, adding an overview of the traditional biological markers on consumption. *Method:* systematic description of the various biomarkers and their advantages and limitations. *Text:* Epidemiological data justify the need for better implementation of how to assess alcohol consumption by using biological markers. The main part is a detailed, literature-based description of direct ethanol metabolites and their assessment and value for clinical use. *Conclusion:* advancements in diagnosis and therapy, new perspectives for prevention, and interdisciplinary cooperation due to extended use of direct biomarkers.

Chapter 43 by Assanangkornchai S and Edwards G, "Clinical Screening for Illegal and Prescription Drug Misuse and Nicotine Use," covers screening instruments used in detecting substance use in medical, psychiatric, and forensic services, with a view of providing subsequent treatment. Specific tests utilized are discussed, along with their psychometric properties, intended screening populations and validity, as well as the importance of proper and ethical use. Conclusion: Despite its limitations, screening is a first, small step toward providing successful treatment outcomes.

Chapter 44 by Tremonti C, "Drug Testing in Addiction Medicine," explains in detail how a range of psychoactive substances can be detected in body fluids and tissues for medical and legal purposes, how findings are interpreted on the basis of appropriate knowledge about pharmacokinetics, and characteristics of the various samples to be analyzed. *Method:* Technologies and their applicability are described on the basis of best known standard procedures. *Text:* Drug screening is explained in a range of different contexts, such as hospital toxicology, workplace drug testing, forensic toxicology, postmortem toxicology, sports toxicology, and drugs of abuse testing. *Conclusion:* Close collaboration with laboratory specialists is essential for obtaining adequate results.

Chapter 45 by Harland J, Henry-Edwards S, Gowing L, and Ali R, "Brief Interventions for Illicit Drug Users," focuses on brief interventions as an effective and targeted tool, in the interest of the individual and of public health. *Method:* extended use of updated literature. *Text:* concise description of the nature and the effectiveness of brief interventions, for both legal and illegal substances of abuse, adding specificities of working with illicit drug users and the key principles to be followed. Settings for brief interventions are described. *Conclusion:* Including knowledge and training of brief interventions in medical school and nursing schools, as well as continued education later on, is considered a must.

Chapter 46 by Rush B, "Screening and Assessment of People with Substance Use Disorders: A Focus on Developed Countries," is about best practice procedures including a staged approach and subsequent monitoring of outcome, in order to maximize efficiency. *Method:* selected essential literature. *Text:* Various collaborative models in screening and assessment facilitate such procedures early in contact of persons with psychiatric and especially substance use problems with the treatment system. Best practices are based on an individual's needs and strengths, adhering to a bio- and psychosocial model of understanding disorders, cultural differences and characteristics of a given service, and research evidence of usefulness. *Conclusion:* A more proactive concerted effort to screening for mental health problems and at-risk consumption of alcohol and other drugs is recommended.

Chapter 47 by Uchtenhagen A, "Stepped Care in Addiction Treatment," deals with models and procedures on how treatment intensity can be determined by a systematic screening of patient characteristics, in order to make best use of available human and financial resources in a given treatment system. *Method:* Available literature describes and compares two models. *Text:* Procedures to start out with the least intensive intervention, progressing to more intensive ones if ineffective, are known from psychiatry and other medical disciplines. In the case of addiction treatment, two outstanding models have been developed, one by the American Society of Addiction Medicine ASAM and the other by a Dutch group as a national project MATE (Measurements in the Addictions for Triage and Evaluation). The first developed special models for adolescents and patients with psychiatric comorbidity and the later for patients with legal problems. The implementation meets some resistance from services used to take on patients even if those do not need this type of service. *Conclusion:* Further use and development of stepped care models needs political support.

Chapter 48 by De Leon G et al., "Therapeutic Communities for Addictions: Essential Elements and Cultural and Current Issues," describes community as a method, its various applications worldwide, its outcomes according to research, and challenges and how to meet those. *Method:* based on the extensive knowledge of the authors. *Text:* Besides the explanation of the TC model and its unique role in the treatment system as a recovery-oriented therapeutic method, available knowledge on its effectiveness and adaptations and modifications for special populations and settings are presented. Details on implementing a TC include funding, workforce, duration of treatment, research, challenges, and fidelity to treatment. *Conclusion:* defending the TC model and its unique mission for a recovery-oriented treatment.

Chapter 49 by Galanter M, "Spiritual Aspects of the Twelve-Step Method in Addiction," is

directed at defining the nature of spirituality and its relationship to empirical research and clinical practice. *Method: based* on the extensive knowledge of the author. Text: Diverse theoretical and empirically grounded sources provide an initial understanding of spirituality. More concretely, the movement of Alcoholics Anonymous illustrates the impact of spirituality on addiction in different cultural and clinical settings. Subjective spiritual experience can be assessed systematically by employing empirical techniques, thereby studying an important aspect of recovery. *Conclusion:* more integration into professional treatment needed.

Chapter 50 by Best D and Hamer R, "Addiction Recovery in Services and Policy: An International Overview," emphasizes the growing role of recovery as a treatment goal and a policy vision, aiming at healthy lifestyle and good quality of life. *Method*: based on the authors' knowledge of relevant literature. *Text:* Addiction is a chronic condition, and recovery needs a continuing care approach. Emerging service models and peer-driven recovery supports are described. The aim goes beyond changes in addictive behaviors, to improved overall functioning of the person and his/her quality of life. *Conclusion:* strategies recommended for medical professionals on how to promote recovery in substance-using patients.

Chapter 51 by Smith DE and Davidson LD, "Strategies of Drug Prevention in the Workplace: An International Perspective on Drug Testing and Employee Assistance Programmes (EAPS)," describes the diverse regulation mechanisms and instances for drug testing in the workplace, in the USA and Europe, especially for improving workplace safety by preventing or reducing substance use in staff. *Method:* based on the authors' knowledge of relevant literature. *Text:* A detailed and extensive description of regulation diversity and practices, including statistical information on findings from workplace testing, is provided, as well as much background information in graphs and figures. Same for employee assistance programs. *Conclusion:* The advantages of employee assistance programs for employers and employees are highlighted.

Chapter 52 by Hedrich D and Hartnoll R, "Harm Reduction Interventions, Policies, Settings, and Challenges," is a comprehensive description of all approaches to minimize the impact and negative consequences of substance use in persons unable to quit their substance use or having no access to effective treatment. *Method:* based on the authors' knowledge of relevant literature. Bibliography includes recommendations for further reading. *Text:* Main types of drug use-related interventions to reduce harm are described in detail. Best policy favors combination interventions, illustrated by integrated approaches at the local level. Further topics are enabling environments, prison settings, and ways to overcome barriers. *Conclusion:* Single interventions have best outcomes if they are part of a comprehensive policy to reduce harm from substance use and other addictive behaviors.

39 Treatment Systems for Population Management of Substance Use Disorders: Requirements and Priorities from a Public Health Perspective

Thomas F. Babor

Contents

Abstract

This chapter describes the requirements and priorities of service systems designed to treat persons with substance use disorders. Research and theory are reviewed to inform policymakers, program administrators, and treatment providers about the best ways to organize or to expand treatment services using a public health systems approach, which is concerned primarily with how services contribute to the health and welfare of a population. The requirements of a service system include sound policies (especially stable financing); appropriate structural features, such as facilities and trained personnel; and services that are effective, accessible, affordable, and integrated. The priorities for establishing such a system will depend on the assessment of population needs, as well as needs-based planning and the support of mutual help organizations. It is concluded that a public health approach to the development of treatment systems provides a useful way of responding to the changing needs of the population in relation to substance use disorders.

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment*, https://doi.org/10.1007/978-3-030-36391-8_39

critical that services for persons with alcohol and drug problems be delivered in the most effective as well as in the most efficient manner. The focus on treatment system issues represented in the title of this chapter is designed to direct attention at the growing body of research and theory that can be used to inform treatment planning and quality improvement at the community and national levels. The development of an effective treatment system is a crucial part of a country's public health response to the problems associated with substance use disorders. Although a great amount of research has been conducted on treatment of substance use disorders, most of it deals with clinical issues, such as the efficacy of different psychotherapies or pharmacotherapies, rather than the larger treatment service issues that often result from tradition, budget constraints, procurement procedures, or political decisions. As described in a conceptual paper by Babor et al. [8], what is now needed is a comparable effort to use systems-level research to inform policymakers and program administrators about the best ways to configure and expand their treatment services to maximize their impact at the population level.

This chapter deals with the requirements and priorities of the treatment system, which are approached from a public health perspective. The requirements of a service system include sound policies (especially stable financing); appropriate structural features, such as facilities and trained personnel; and services that are effective, accessible, affordable, and integrated. The priorities of such a system include the accurate estimation of population needs through service mapping and needs assessment, as well as rational service planning that includes an emphasis on community support networks such as mutual help organizations.

39.2 Concepts, Requirements, and Priorities

39.2.1 Definitions and Rationale

A treatment system for persons with substance use disorders is an arrangement of facilities, programs, and personnel that is designed to function in a coordinated way. Such an arrangement includes linkages between specialized care and other types of services, such as mental health, primary health care, social welfare, criminal justice, and mutual help organizations [8]. The focus on the arrangement and coordination of services, rather than just the personnel, programs, and therapeutic aspects of treatment, raises a new set of questions for clinicians, program administrators, and policymakers. Can systems concepts help to reduce the gap between population needs and the current availability of substance abuse services? How can treatment services be made more accessible to those in need? Are the needs of affected populations being met by the current array of services? Are services being distributed and accessed appropriately? Are screening and referral conducted at gateway institutions, such as primary health care, schools, and employment settings? Are there appropriate diagnostic capabilities? What are the most effective administrative linkages between substance abuse services and criminal justice, mental health, primary care, and other human services? Are specialized services coordinated in a continuum of care? Are evidence-based services available and relevant? What is the policy support for integrated structures? What can be done to build stronger community support networks (e.g., Alcoholics Anonymous (AA), family social clubs)? To what extent can mental health and general medical services be better integrated with addiction treatment? Are there advantages to having separate systems for substance abuse, or should they be integrated administratively with mental health care or services for other health conditions or social problems?

These questions define issues that can be addressed by a public health systems perspective, which is concerned primarily with how services contribute to the health and welfare of a population. Services for substance use disorders expanded dramatically in developed countries in the 1970s but often in a fragmented and arbitrary way. Resource allocation decisions and treatment policies have a major effect on the development of services for persons with substance use disorders, but there is little research to guide service planning or to indicate whether services achieve their public health objectives. Low- and middle-

income countries are now investing in services as substance use prevalence rates increase with new epidemics or rising national incomes, but there is little systematic knowledge to guide the development of service systems that would best address the needs of their populations.

39.2.2 History and Conceptual Developments

Conceptual, theoretical, and empirical work on treatment systems is a recent development, but substance abuse treatment has a long history that can be traced back at least 200 years in some countries [55, 63]. A rudimentary set of treatment services, mostly specialized residential programs, emerged from the nineteenth-century asylum movement originally designed for mental patients but which also served large numbers of alcoholics [63]. Since the 1960s in the industrialized countries, there has been a steady growth of specialized medical, psychiatric, and social services for individuals with substance use disorders [32]. Although each country developed a different mix of services and administrative structures, there were some commonalities across national systems in the types of service settings (residential, detoxification, and outpatient) and therapeutic approaches [25]. As treatment services became more numerous and specialized, new concepts were developed to describe how they related to the different types of population needs. These concepts include the continuum of care, broadening the base of treatment, the chronic care model, and service system levels.

The *continuum of care* concept, as described by Rush et al. [49], refers to the mix of services available to patients and the way patients are expected to pass through it. The services are generally arranged sequentially beginning with screening and diagnostic assessment. Patients are then assigned to different settings and services depending on acuity, severity, and complexity. The main services that have been incorporated into the systems framework in most countries are withdrawal management (including detoxification), residential rehabilitation, outpatient counseling, continuing care, harm reduction programs, and community support networks such as Alcoholics Anonymous. Variations of the continuum of care concept are the core-shell model and the stepped-care approach. In the core-shell model, core functions, such as intake assessment and treatment assignment to the most appropriate type of care (the shell), are facilitated by case management [15]. In the stepped-care approach, patients are assigned to the least intensive level of care initially. If outcomes are not optimal, they can be "stepped up" to a more intensive level, and if outcomes are positive, they can be "stepped down" to appropriate continuing services.

Another innovation that has contributed to the systems concept is SBIRT, which refers to screening, brief intervention, and referral to treatment, typically in the context of early intervention in primary health-care settings [5–7]. The SBIRT model grew out of a seminal report issued by the US Institute of Medicine [23], called *Broadening the Base of Treatment for Alcohol Problems*. SBIRT is a comprehensive and integrated approach to the delivery of early intervention and treatment services through universal screening for persons with substance use disorders and those at risk. Beginning in the 1980s, concerted efforts were made by the World Health Organization (WHO) to provide an evidence base for alcohol screening and brief intervention in primary health-care settings, in order to *broaden the base of treatment* in countries where specialized services were unavailable. With the development of reliable and accurate screening tests for alcohol, more than a hundred clinical trials were conducted to evaluate the efficacy and cost-effectiveness of alcohol screening and brief intervention in primary care, emergency departments, and trauma centers [5–7, 24].

Just as SBIRT attempts to integrate specialized substance abuse treatment services with outreach to the general health-care system, the *chronic care model* addresses the needs of more serious cases of substance dependence by coordinating specialized services over time under the assumption that once substance dependence has developed, there is a need for continuing care and management, as is done with chronic conditions like diabetes and hypertension. The chronic care model has been adapted to substance abuse by

Rush [48, 49] who has defined a series of "tiers" that constitute the most important elements of a continuum of services for the management of chronic substance users (see also Rush and Urbanoski [50]). Five tiers are defined on the basis of their functions, which are higher-order groupings of similar services or interventions, such as early intervention, detoxification, outpatient counseling, and residential programs. Tier 1 refers to health promotion and prevention functions targeted at the general population. This tier recognizes the likelihood that public policies, the regulatory environment, and lifestyle factors contribute to the risk of substance abuse and the need for treatment. Tier 2 consists of early intervention and self-management functions directed at persons at risk. This incorporates the SBIRT activities that have provided an important link to other health-care settings. Tier 3 consists of treatment planning, crisis management, and support functions for persons with identified substance-related problems. Tier 4 includes specialized care for people in need of more intensive services, such as residential programs, outpatient counseling, and pharmacotherapy. Finally, Tier 5 comprises highly specialized care functions for individuals with complex problems, such as inpatient withdrawal management, forensic services, and long-term psychiatric care. The tiered framework is designed to be used as a planning tool for the development of an integrated system of service functions for substance abuse, mental disorders, and gambling problems that takes into account problem severity and complexity.

Despite the growth of treatment services and systems of care in many countries, the services in most parts of the world are fragmentary and lack coordination. Four development levels have been proposed to account for the range of systems that have evolved in different countries [3]. Level I refers to services that are "minimal" in relation to population needs. If they exist at all, services tend to be fragmentary, with rudimentary care available in some settings (e.g., emergency departments or psychiatric wards) and perhaps specialized services in medical and psychiatric settings where a residential unit might provide care for a limited number of patients. Level II is described as "limited" in terms of systems development, with some specialized services in medical and psychiatric settings. Level III refers to a "modest" level of development where a variety of services are delivered in most settings and there is some regional coordination and planning. Level IV refers to "mature" systems, with a variety of integrated services in a range of settings and stable financing for these services. The specification of these levels is useful for suggesting ways in which a system at a particular level of development can be improved and for monitoring changes in systems development over time.

39.2.3 Requirements of an Optimal Treatment System

Babor et al. [3, 8] have described the components and dynamics of an optimal treatment system from a public health perspective. These are the basic "building blocks" of a service system [22]. As illustrated in Fig. 39.1, the first requirement is a set of policies that make the governance of the service system and its constituent parts possible. The second component is the system's structural resources, including infrastructure, technologies, personnel, programs, and facilities. The third component consists of system qualities, such as accessibility, economy, and efficiency, which contribute to the smooth functioning of the service system.

According to this model, the policies, resources, and qualities of the system should not only translate into the effectiveness of services on individuals exposed to them, it should also contribute to population health through reductions in death, disease, and disability.

The components of this model and the research supporting it are discussed in the remainder of this section in order to indicate how a systems model might best contribute to population health.

39.2.3.1 Policies

The first requirement of an effective treatment system is appropriate treatment policies that provide a statutory basis for designing treat-

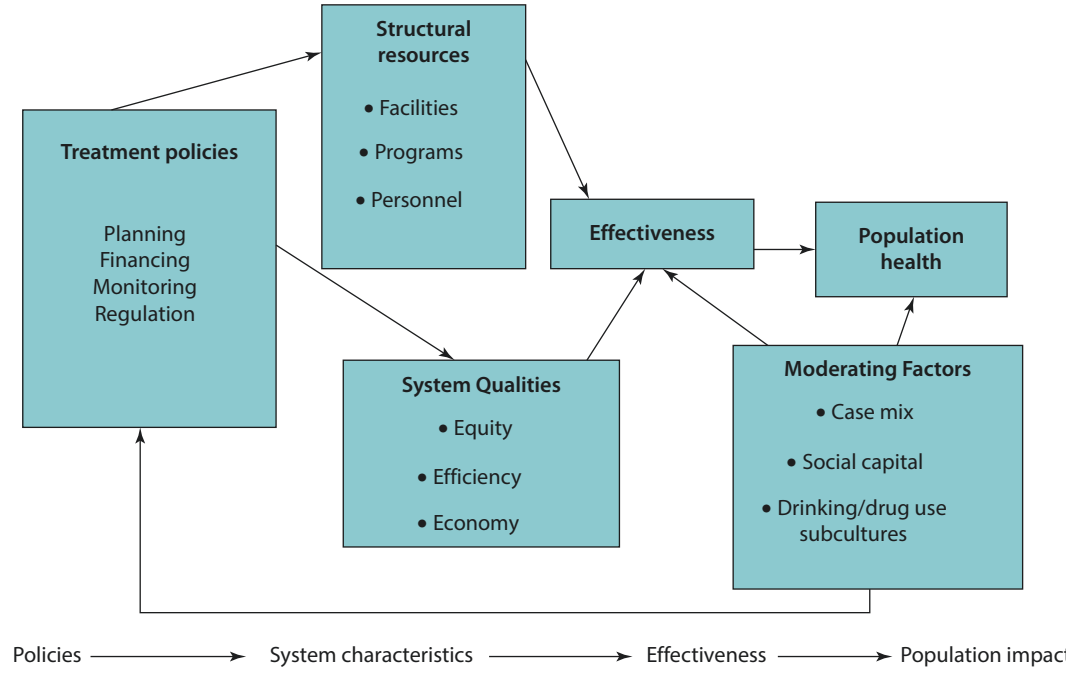

Fig. 39.1 Conceptual model of service system policies, resources, and qualities and their potential impact on population health. (Source: Adapted from Babor et al. [8])

ment programs, licensing of treatment providers, and funding for programs and personnel. Policies determine the size, the administrative location, and the organization of the treatment system. They provide a framework for the allocation of resources. There is a great deal of legislation for the treatment and rehabilitation of persons with substance use disorders, but much of the legislation is concerned with provisions for compulsory treatment or for treatment in lieu of jail [46]. Other kinds of policy include national standards for clinical practices and licensing requirements for treatment personnel.

According to a survey conducted by the World Health Organization [64], 66.2% of the 145 countries surveyed have a government unit or government official responsible for treatment services for substance use disorders, but fewer than half of these countries have a specific budget line for these services. Financing mechanisms vary but most countries use tax revenues, user fees, and private insurance to pay for alcohol and drug services. User-based funding models depend on private financing for services or insurance coverage. Population-based financing relies on public funding of services and is typified by the inclusion of addiction treatment in the social welfare systems of the Nordic countries.

Resource allocation and financing decisions have had a major effect on the development of these services. For example, the number and variety of services increased dramatically in the United States when the US Public Health Service invested in treatment services as part of a broader public health approach to reduce the burden of disease, disability, and social problems that accompany substance use [63]. The rapid development of federally supported residential and outpatient treatment programs, along with an expansion of insurance coverage for private programs, established the feasibility of serving large numbers of alcohol- and drug-dependent patients within a specialized set of services.

Treatment policies and financing mechanisms affect the degree of centralized management of treatment services and their incorporation into other human service areas, such as social welfare,

mental health, general medicine, and criminal justice. In Denmark, policies were used to decentralize treatment services, whereas in Norway, they moved the system toward a more centralized, medically oriented structure [57]. In Canada and the Netherlands, mental health and substance abuse treatment systems have been integrated [48]. In Finland, mental health and addiction outpatient services were merged, and patients were also managed in primary care [29]. Although policy changes designed to reform the organization of treatment services may have sound assumptions and a good rationale, they are rarely accompanied by systematic evaluation research to inform future decisions. One exception is a study of marketization trends in the Nordic countries [58], which found that public procurement guided by a business management model may not be appropriate for addiction services.

39.2.3.2 Structural Resources

The next requirement of an effective treatment system is to have sufficient resources to meet population needs and the demand for treatment services. The core structural elements are facilities, personnel, and programs. Alcohol and drug services in "mature" treatment systems form a continuum ranging from primary prevention activities designed to ensure that a disorder or problem will not occur, through secondary prevention activities (including early identification and management of substance use disorders), to tertiary prevention activities that aim to stop or retard the progress of a disorder. In many countries, these services have generally developed separately and are rarely integrated within a single service delivery system. Figure 39.2 summarizes data from the WHO *ATLAS on Substance Abuse* [64] describing the most common settings throughout the world for the treatment of alcohol and drug disorders. In the plurality of the responding countries (39.8%), mental health services are the most common treatment setting for alcohol use disorders, whereas the main setting for the treatment of drug use disorders (51.5%) is specialized treatment services.

Approximately 10% of the countries reported primary health care to be the most commonly used setting for treating alcohol and drug use disorders.

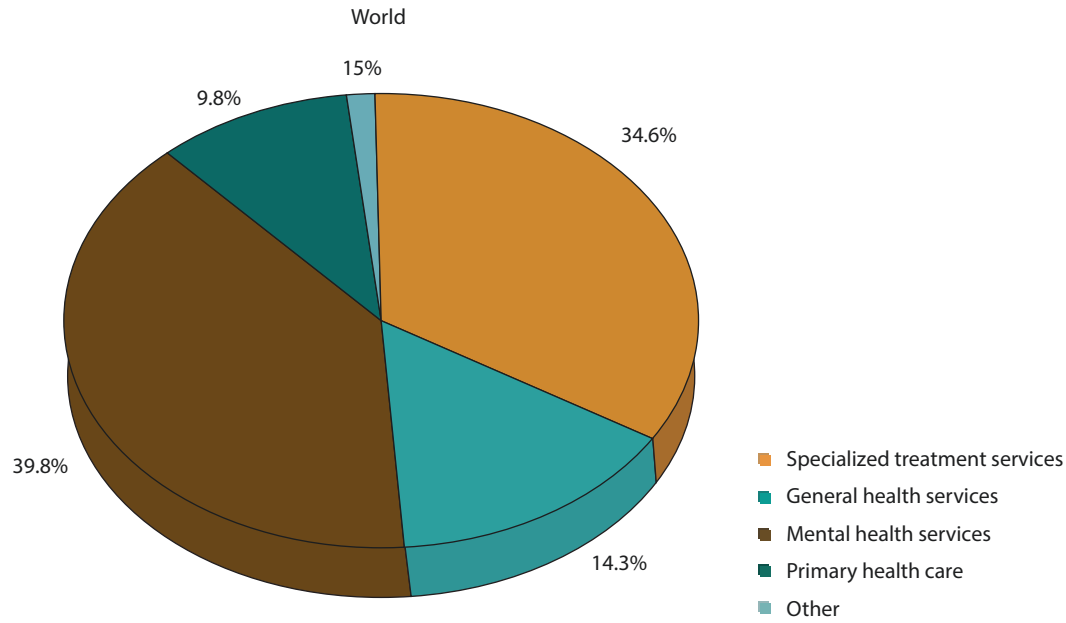

Fig. 39.2 Most common settings for treatment of alcohol and drug disorders in WHO member states. (Source: WHO ATLAS on Substance Abuse)

Another structural resource is the capacity of the system in terms of the number of beds and length of stay. The median number of beds for alcohol and drug use disorders globally was 1.7 per 100,000 population (range 0–52) [64]. The lowest number of beds was reported in the African regions, whereas the highest number was reported from countries in the European Region (10.3 beds per 100,000 population). Median length of stay for drug and alcohol detoxification was found to be 14.0 and 10.3 days, respectively, with low-income countries reporting a longer median length of stay than high-income countries.

Finally, treatment personnel have become a central feature of a country's treatment infrastructure. Among the various health professions involved in treating substance use disorders, the majority of countries reporting in the WHO ATLAS include psychiatrists, general practitioners, and narcologists as the most important [64]. That situation may be changing in the high-income countries of Europe and North America with the growth of specialized study programs for addiction treatment specialists, who are being trained at the bachelor, master, and doctoral levels to deliver services and manage programs [41, 42]. In addition to these professional addiction specialist groups, nonprofessional organizations have emerged as a critical part of the workforce in the formation of self-help organizations. Former alcoholics and drug addicts play an important role in providing community support services in many countries [64].

39.2.3.3 System Qualities

Over time, the collection of services used to manage persons with substance use disorders takes on the characteristics of a system, with unique configurations emerging not only in terms of policies and structural resources but also in terms of system qualities that characterize the functioning of a system. According to the model in Fig. 39.1, these qualities can be described in terms of equity, efficiency, and integration.

Equity refers to the extent to which services are equally available and accessible to all population groups. In South Africa, a study found inequitable access to substance abuse treatment services among the poor, with non-need factors, such as gender, mainly determining utilization [38]. Access to treatment may be as important as the type of treatment. Findings from large-scale treatment matching studies indicate that the decision to enter treatment is associated with considerable reductions in drinking, but once someone is admitted to a particular program, they do equally well regardless of the type of psychotherapy they receive [2].

Research [13] suggests that the key ingredient of the success of any therapy may be its ability to attract clients and generate enthusiasm among therapists. Instead of distinct nonoverlapping elements, different types of therapy may work through common mechanisms, such as empathy, an effective therapist-client alliance, a desire to change, ability to mobilize the client's inner resources, the creation of a supportive social network, and the provision of a culturally appropriate solution to a socially defined problem. Thus, the more that treatment services are made available to all population segments, the greater the system's effectiveness is likely to be.

Some therapeutic interventions are more cost-effective than others, suggesting that resources could be allocated more efficiently and economically without compromising effectiveness. One way to improve the efficiency of treatment is to organize treatment teams or sites to work together for a 12- to 24-month period with the aim of improving a specific area of care. This "improvement collaborative" approach combines traditional quality improvement methods of teamwork, process analysis, adoption of standards, training, and coaching. In a study by Gustafson et al. [16], the use of collaborative methods, especially coaching, was found to decrease waiting time, improve treatment retention, and increase recruitment of new patients. Humphreys and McLellan [21] found that process improvements can change the efficiency of treatment programs, but the link to better outcomes is weak, in part because outcomes are mainly influenced by environmental factors and life events outside of formal treatment.

System integration is a term that refers to the amount of interconnectedness among the organi-

zations in a network. Research suggests several ways to improve system integration: drug courts, SBIRT, integrated treatment programs for pregnant drug users, managed care, case management, and New Public Management (NPM), a market-oriented approach used in the Nordic countries to improve efficiency and lower costs [27]. There is some evidence to suggest that drug courts can increase social controls, lengthen the duration of treatment, reduce criminal behavior, and lower rates of recidivism [14]. The elements of SBIRT have been evaluated in clinical trials and found to be effective [5] to such an extent that programs have been initiated in large population areas of several countries, including Finland [53], Norway [1], Denmark [10], South Africa [52], Brazil [56], and the United States [31]. Despite some successes in primary health care [56], the results of programs relying on the training of physicians and other health personnel without adequate logistical support have not been encouraging.

In the United States, a large-scale program operating in 27 states since 2005 [6, 7] has been found to enhance the states' continuum of care to include universal, adult SBIRT services in primary care and other community settings (e.g., health centers, nursing homes, university health centers, hospitals, emergency departments, and military). In an evaluation of SBIRT's system effects, the program filled gaps in services for substance users in both the medical and specialty treatment systems of care. It was also associated with improved system equity (i.e., equal access to all population groups) and efficiency by extending services to underserved populations, expanding services within facilities and across tasks, and improving system linkages [6, 7].

Another way to improve system integration is through integrated treatment programs. Examples include treatment of pregnant women who have substance use disorders and the delivery of mental health services to patients with co-occurring mental disorders. Integrated women's programs providing pregnancy and parenting services have been associated with improvements in child development [39]. To the extent that clients with co-occurring disorders tend to have a more severe course of illness, more severe health and social consequences, more difficulties in treatment, and worse treatment outcomes than clients with a single disorder, research suggests that these outcomes might be improved when treatment modalities are offered in combination within an integrated treatment plan that simultaneously addresses substance abuse and psychiatric problems [36].

39.2.3.4 Effectiveness and Population Impact

When the requirements for an optimal treatment system are met, treatment services are available, affordable, and accessible. Under these conditions, the system should not only deliver effective services, it should also have a population impact. Effectiveness means the extent to which one or more services are responsible for positive changes in substance use and substance-related problems. Effective services should promote abstinence (or at least reduce substance use), prevent relapse, and address such substance-related problems as unemployment and marital adjustment. As suggested in Fig. 39.1, the impact of these services should translate into population health benefits, such as reduced mortality and alcohol-related disease rates, as well as benefits to social welfare, such as reduced unemployment, disability, crime, suicide, and health-care costs. One way this may happen is through the rapid diffusion of innovation within and across systems. To the extent that a new treatment innovation is perceived as being consistent with existing values, past experiences, and the needs of the country, the treatment system's communication processes may facilitate the transfer of evidence-based approaches [27].

Can the integrative effects of prevention, early intervention, and treatment systems reduce population rates of alcohol and drug problems? This issue has not been investigated extensively. There is suggestive evidence for such an effect with treatment services but not for screening and brief intervention [17]. For example, growth in the availability of opioid maintenance treatment is associated with reductions in illicit opiate use, crime, and HIV risk behaviors in the United Kingdom, France, Norway, and the United States [12, 34]. Increases in the proportion of alcoholics in treatment have been linked to decreases in liver cirrhosis morbidity [19, 33], and increases

in AA membership and amount of treatment linked to decreased alcohol problems [54].

Given the possibility that policies, resources, and system qualities, as core requirements, can be used to provide a more effective set of services and contribute to the system's public health impact, the next section of this chapter considers the main priorities for developing such a system.

39.2.4 Priorities

Substance use services have traditionally been established without the benefit of a comprehensive, quantitative planning process that is aligned with population needs. Priorities for developing an optimal treatment service system will vary according to a country's current level of services, as well as the nature of their alcohol and drug problems. Among the highest priorities are service mapping, needs assessment, and service planning. Another priority that is often neglected despite its recognized effectiveness is the establishment and support of mutual help organizations that provide a critical community resource for the initiation and maintenance of recovery.

39.2.4.1 Service Mapping

Treatment service mapping involves the documentation and description of system structures and qualities. Treatment mapping research has been conducted in Hungary, Poland, the Russian Federation, France, Switzerland, Germany, the United Kingdom of Great Britain and Northern Ireland, the United States of America, Finland, Sweden, and a variety of other countries [25, 26, 28]. Data collection tools have been developed for treatment mapping purposes, but most of these instruments do not examine the treatment system components described in this chapter.

To promote the orderly planning and dissemination of evidence-based addiction treatment within national health-care systems, the World Health Organization has designed a procedure for assessing, monitoring, and evaluating treatment systems for substance use disorders, in relation to population needs [3]. The WHO Substance Abuse Instrument for Mapping Services (WHO-SAIMS) was developed to provide information on prevention and treatment services that can be used for policy planning, service design, and service improvement. In its present form, the WHO-SAIMS has a primarily descriptive function that identifies gaps in service delivery and areas for system improvement. The primary purpose of the WHO-SAIMS is to examine the structure and functioning of alcohol and drug service systems in terms of resources, facilities, personnel, and programs. It can also be used at the national and subnational levels for monitoring and process evaluation to identify changes in the system over time and to assess the extent to which system improvement strategies have been implemented. The scope and configuration of the instrument are described in Table 39.1.

Table 39.1 Scope and configuration of the World Health Organization's Substance Abuse Instrument for Mapping Services (WHO-SAIMS)

Policy and legislative domain: This includes items about national alcohol and drug policies; legislation governing drug control, prevention, and treatment; strategic plans that address substance use disorders, workforce development for substance abuse professionals, and resource allocation to and the financing of alcohol and drug services
The substance abuse situation and current alcohol and drug service needs: This section is designed to (1) help identify whether current services match needs and (2) estimate service coverage of the current alcohol and drug treatment system. This domain described the type and mix of services provided, service integration, and system complexity
The alcohol and drug services domain. This section covers (1) other residential services for alcohol and drug problems such as halfway houses and sober living environments; (2) alcohol and drug services provided by other sectors such as mental health facilities, primary health-care services, and the criminal justice sector; (3) the linkages between these services; (4) the availability of psychosocial treatments and psychotropic medications; and (5) drug substitution therapies and harm reduction services for opioid users
The primary care domain. Items in this category refer to interventions used in primary care settings. The human resource domain. This describes the quantity of human resources as well as human resource development, including mutual help organizations and recovering communities such as AA and NA

39.2.4.2 Estimating Demand for Treatment and Treatment Needs

Demand for treatment refers to the number of people who want to access treatment, including those who receive treatment (met demand) and those who want treatment but cannot access it (unmet demand). Unmet demand may exist because services do not exist, are not available, are too expensive, or are inaccessible [44, 45]. Need for treatment refers to the number of people in a geographic region who meet the criteria for dependence or harmful use and who would benefit from treatment but do not access it. Some of these people want treatment but cannot access it (for the above reasons), while others do not want treatment nor do they seek it [44, 45]. The numbers of "unmet need" are likely to be greater than the numbers of "demand for treatment" because "unmet need" includes those people who do not perceive the need for or do not desire any treatment.

There are several methods to identify unmet treatment need, some involving primary data collection and others relying on secondary analysis of existing data sources. The simplest procedure is to use population surveys to estimate the number of people in need of treatment (see [43–45, 61]). If the rates of dependence and harmful use are used, these can translate into the potential demand for specialized services (residential and outpatient) as well as early intervention services in other health-care settings. These services can be directed at patients with dependence and harmful use, respectively. Because of the limitations of using survey measures of diagnostic criteria, population survey data should be supplemented by obtaining prevalence estimates from settings where substance users are likely to be encountered, such as prisons, emergency departments, and HIV clinics. The need for substance abuse services among the general population can also be estimated through the use of health and social indicators, such as substance-related mortality, morbidity, social problem statistics, and expert opinion on treatment needs. A major difficulty in using population data to estimate treatment need is the occurrence of "spontaneous remission," which refers to the changes in substance use that occur without treatment. Because of these problems, some experts suggest focusing on treatment demand, which can be measured through self-reported intentions to seek treatment or client perceptions of the need for treatment [44, 45]. Another option is to use waiting list data. If these data are not available or are difficult to obtain, harm indicators derived from administrative databases can be used as well. For alcohol, the harm indicators that have been used include arrests for alcohol-impaired driving and alcohol-related morbidity rates for different diseases and conditions. Although these indicators of treatment need or demand have limitations, a combined approach is sometimes used to provide greater confidence in the estimates [61] and to help direct resources to those services that conform best to the various indicators of severity (e.g., opiate withdrawal) and complexity (e.g., psychiatric co-morbidity).

39.2.4.3 Needs-Based Planning

For service systems at a modest (Level III) or mature (Level IV) stage of development, it may be more fruitful to use the "needs-based planning" approach described in Fig. 39.3. This model uses population prevalence data to estimate the types of treatment services to be received by subgroups in the population. As such, it is more advanced than the SAIMS methods because it takes into account different types of treatment and respective "need" by treatment type.

In the "Rush model," help-seeking populations are allocated across three treatment service categories: withdrawal management, community services and supports, and residential treatment services. Projections of need and required service capacity for Canadian health planning regions were derived by synthetic estimation according to age and gender. The model and gap analysis was piloted in nine regions of Canada, producing the following national distribution of need across the five categories: Tier 1, 80.7%; Tier 2, 10.4%; Tier 3, 6.1%; Tier 4, 2.6%; and Tier 5, 0.2%.

The "Rush model," initially developed in the early 1990s [47] to estimate treatment needs in Ontario, Canada, has been followed by similar

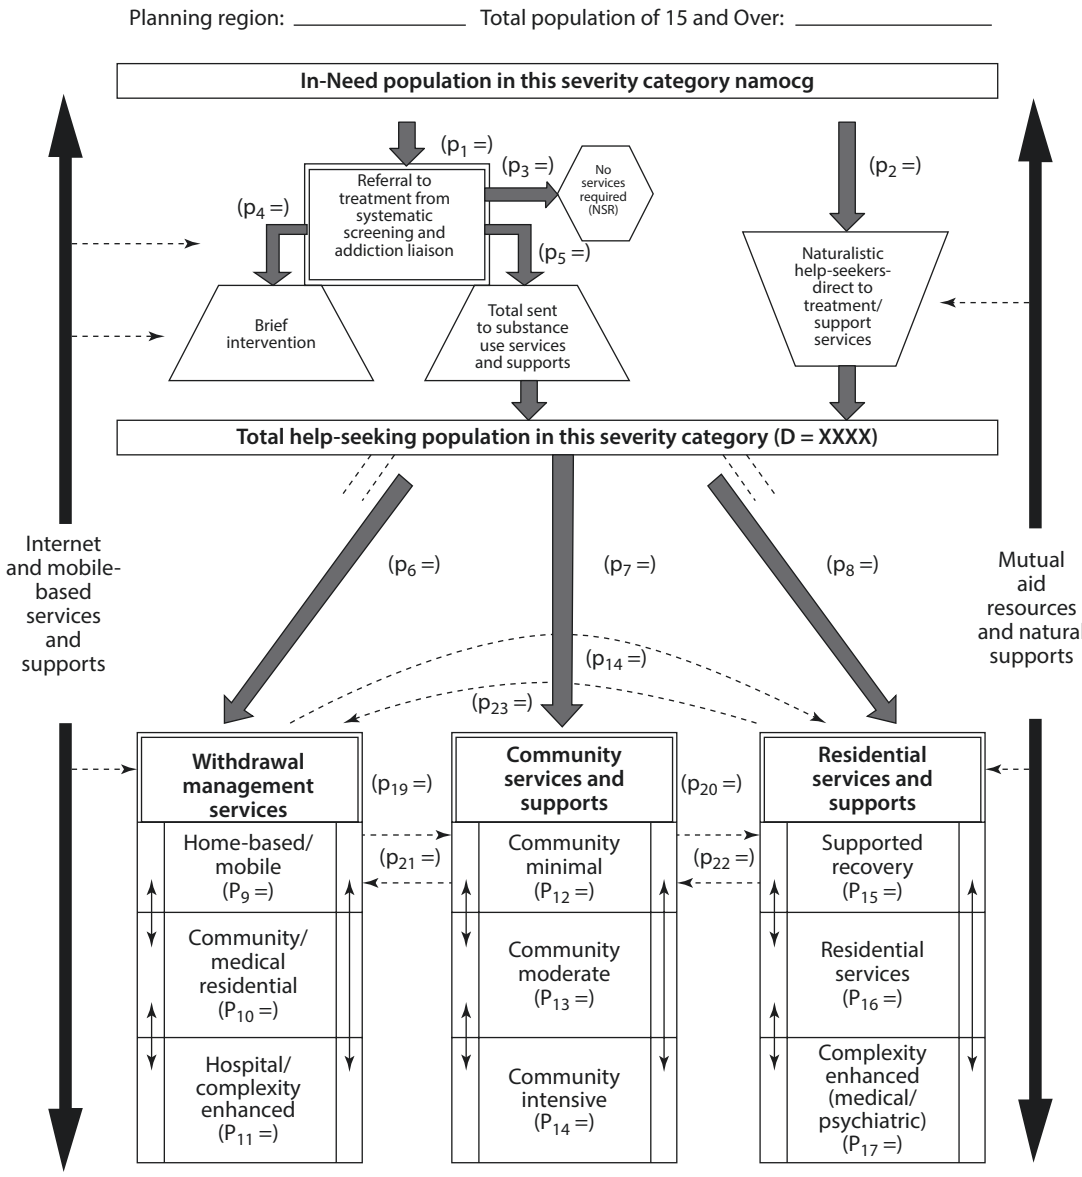

Fig. 39.3 Schematic diagram of needs-based planning model for substance use services and supports. (Source: Rush et al. [51])

approaches in Australia [44, 45]; the UK [11]; Brazil [37]; and Quebec, Canada [60]. As noted by Babor et al. [9], these initiatives differ in key features such as the substances of concern, populations of interest, criteria to define need for treatment, as well as methodological details. Nevertheless, they share several common features, such as the use of epidemiological measures of need and help-seeking to estimate the demand for treatment and postulating an "ideal" system design composed of evidence-based interventions.

Another commonality is the assumption that "treatment need" and the "treatment gap" should be estimated at the level of different services and client characteristics, rather than reported only as an undifferentiated measure of overall treatment coverage. In the past, diagnostic criteria derived

from health statistics or epidemiological surveys have typically been used as an indicator of the "treatment gap." In some cases, the estimates are so crudely constructed that they grossly overestimate total need without specifying how those estimates map on to specific service components and population groups [9]. An example is the use of the AUDIT and AUDIT-C that are sometimes used to estimate the need for early intervention services despite the number of false positives that can be included in such estimates [18].

39.2.4.4 Mutual Help Organizations

Alcoholics Anonymous and other mutual help organizations represent a critical resource both in countries with mature systems and in those with limited resources. Not only do these approaches provide continued support in the community, they do so at minimal cost. A variety of mutual help models have been developed throughout the world [20], many of them seemingly capable of managing some of the most difficult cases of drug and alcohol dependence. With an estimated 2.2 million members affiliated with more than 125,000 groups in 180 countries, AA is by far the most widely utilized source of help for drinking problems in the world [20, 30]. And the AA recovery program has been applied to a variety of other addictive behaviors, including drug use and problem gambling [30].

Although it is regarded as one of the most useful resources for recovering alcoholics, the research literature supporting the efficacy of AA is limited [35]. Attendance at AA tends to be correlated with long-term abstinence [20, 59], but this may reflect motivation for recovery. Several large-scale, well-designed studies [40, 62] suggest that AA can have an incremental effect when combined with formal treatment, and AA attendance alone may be better than no intervention. When AA is combined with a 12-week individual therapy called Twelve-Step Facilitation (TSF), one study [2] found that TSF not only increased affiliation with AA, it also had a demonstrable effect on clients whose social networks contained many drinking companions. This study suggested that AA is effective because it helps to change the drinker's social environment rather than through some form of spiritual conversion.

Similar mutual help organizations have been developed in a number of other countries, such as Danshukai in Japan, Kreuzbund in Germany, Croix d'Or and Vie Libre in France, Abstainers Clubs in Poland, Family Clubs in Italy, Links in the Scandinavian countries, Pui Hong self-help organizations in Hong Kong, Oxford House in North America and Australia, and Narcotics Anonymous worldwide [4, 20, 63].

39.3 Conclusion

Treatment systems for substance use disorders are a significant part of national responses to the burden of disease and disability resulting from substance abuse. In well-resourced countries, a relatively integrated system of services has been developed in response to population needs. In less-resourced countries, treatment services are often inadequate and fragmentary. Regardless of development level, appropriate population health-care management requires the allocation of resources to preventive, curative, restorative, and rehabilitative services, using the most effective and efficient evidence-based practices. By organizing service providers into networks, it should be possible to shift utilization to lower cost settings or the most appropriate level of care.

Despite the lack of systems research in low- and middle-income countries, some progress has also been reported in emerging economies where treatment services are expanding. For example, the implementation of needs assessment and performance measurement protocols has been found to be feasible and helpful for treatment systems planning in countries like Brazil and South Africa [9, 37]. These developments suggest a shift in the ability of governments and public health authorities to estimate need and plan services in countries where the epidemiological tools and the necessary service elements already exist.

A system-wide holistic approach to the planning and coordination of services for substance use disorders is more than the mere sum of gains attributable to discrete interventions and technologies, such as new screening tools, better diagnostic instruments, improved intervention

techniques, and more numerous services. The systems approach goes beyond capacity building and technical innovation. It is designed to coordinate services so that they are capable of responding to the changing needs of the population.

Abstract

Self-recognition of an alcohol use disorder is often late in the natural history of this condition. Because of this and the limited impact of treatment for patients with late-stage complications of their alcohol problem, there has been considerable effort made to identify alcohol consumption where it has reached a hazardous or risky stage or is starting to cause problems, before dependence becomes entrenched and complications irreversible. The approach of screening and brief intervention represents a secondary intervention approach, which aims to help people reduce their alcohol consumption to low-risk levels and thereby avoid progression to dependence and the development of harmful physical and mental sequelae and social problems. This chapter describes the development of screening instruments such as the Alcohol Use Disorders Identification Test (AUDIT) and several derivatives and alternatives. The performance and applicability of these screening instrument is reviewed. Following this, there is an account of brief intervention approaches which aim to provide succinct information on alcohol use and risks to the individual, often combined with brief motivational and behavioral strategies. There is considerable evidence from scores of randomized controlled trials and meta-analyses for the effectiveness of brief interventions in reducing hazardous alcohol consumption and alcohol-related problems. In the long-term follow-up studies, there is also evidence for reduced rates of hospitalization and mortality. The latest developments in screening and brief intervention are their presentation in various electronic formats. Online screening with feedback and brief intervention has shown to be efficacious and has the potential to be accessible to a greater section of the general population than face-to-face interventions in healthcare settings.

40.1 Broadening the Spectrum of Intervention for Alcohol Use Disorders

Self-recognition of an alcohol use disorder is often late in the natural history of the condition. Frequently, patients seen in healthcare services have well-established alcohol dependence and often physical, neurocognitive, psychiatric, and social complications when they present for treatment. At this stage, the road back to reasonable health and well-being is a long and sometimes uncertain one, requiring considerable personal resources and involvement in treatment, support, and lifestyle changes.

An important movement in recent years has been to broaden the spectrum of responses so that people with hazardous, harmful (or unhealthy) alcohol consumption and those with less severe alcohol use disorders, as well as those with alcohol dependence, have an opportunity to be alerted to the risks of their drinking and to change their consumption patterns in a healthy direction. Screening and brief intervention has its origins in the work of a World Health Organization (WHO) Expert Committee in the late 1970s. In its report, the Expert Committee recommended "the development of methods for identifying and modifying potentially harmful patterns of alcohol consumption before dependence developed and disease was entrenched."

Arising from this report was a WHO program of work on development of techniques for early detection and intervention for hazardous and

harmful alcohol consumption. Parallel work in the area was undertaken by pioneers such as Kristenson [41] and Heather [33]. Since those early days, there has been a substantial effort to develop screening instruments, such as the Alcohol Use Disorders Identification Test (AUDIT) [67], and brief structured therapies designed to be used at the time hazardous and harmful alcohol use is identified.

This approach has been endorsed by many authorities. In 1990 an influential report from the US Institute of Medicine [35] recommended that healthcare responses should extend beyond the provision of treatment for people with established alcohol dependence (or "alcoholism") to encompass early detection and treatments in primary care and in other nonspecialist settings. It noted the evidence accumulating for the effectiveness of opportunistic screening and brief intervention for hazardous and harmful alcohol consumption. Since that time, a national alcohol screening day has been introduced in the USA, and screening and brief intervention is identified as an essential approach for primary healthcare services. The US National Institute on Alcohol Abuse and Alcoholism (NIAAA) has issued a clinician's guide on "Helping patients who drink too much" [52]. The UK's National Institute for Health and Care Excellence's (NICE) guideline on the prevention of alcohol use disorders [53] and the World Health Organization's intervention guide for mental, neurological, and substance use disorders [80] support the widespread screening and implementation of brief intervention approaches in people with nondependent hazardous and harmful drinking.

Screening and brief intervention is analogous to screening for asymptomatic hypertension, hyperlipidemia, and a range of medical, mental, and social disorders. It is predicated on the basis that early detection and treatment of a disorder in its developmental stage has advantages over treatment of severe alcohol use disorder or dependence disorder in terms of reduced morbidity, better and more guaranteed response to treatment, and the avoidance of the costs of treating the advanced disorder and prevention of premature mortality.

This present chapter will (1) review the current criteria for nondependent hazardous/unhealthy alcohol consumption, harmful alcohol consumption, and mild alcohol dependence/mild alcohol use disorder, (2) examine the available screening instruments (focusing on instruments specifically derived to screen for a range of hazardous consumption and alcohol use disorders), (3) review the evidence for the effectiveness of brief alcohol interventions, (4) review the key therapeutic components of brief interventions, (5) examine the implementations of such interventions in healthcare systems, and (6) examine electronic screening and brief intervention approaches which have been developed to further broaden the access of people with hazardous or unhealthy patterns of alcohol consumption to information and advice, who otherwise might not be engaged in the healthcare system.

40.2 The Spectrum of Nondependent Alcohol Use Disorders

Alcohol use and misuse exists as a continuum, and an important realization is that harm can occur at many points along this continuum. Excess alcohol use is a significant cause of morbidity, mortality, and social problems. Accidents can occur due to a single episode of excessive consumption; they are more likely to occur with repeated bouts of drinking; social problems can arise due to intoxicated behaviors, and acute medical disorders may also arise from periodic binges. Many chronic disease states are linked to regular consumption of alcohol that may not reflect alcohol dependence. Although the risks of all these are multiplied in people who have alcohol dependence, and it is right that much attention be paid to this group, it is important to capture a broad range of consumption patterns and alcohol disorders.

Alcohol consumption may be facilitated by external factors such as cultural norms and practices, peer pressure, work culture, and work pressure or internal factors such as the person's feelings and mental state or desire to experience the euphoria and state of intoxication that alcohol can cause.

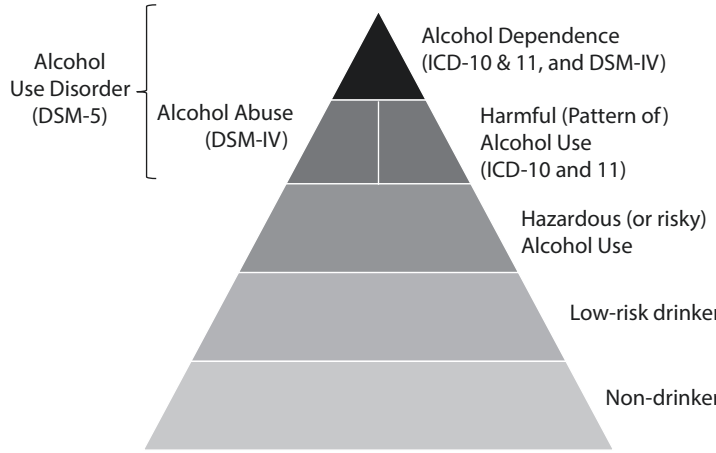

Fig. 40.1 The spectrum of alcohol use disorders

Nondependent alcohol use disorders include the following diagnostic terms from the World Health Organization's International Classification of Diseases (ICD) system: hazardous alcohol use [79], harmful alcohol use [78], and harmful pattern of alcohol use [79]. The American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders (DSM) includes alcohol abuse [1] and mild alcohol use disorder [2]. "Unhealthy alcohol use" is an umbrella term referring to that spectrum of alcohol use that can result in health consequences and broadly covers hazardous use, harmful use, and alcohol abuse and dependence and all grade of alcohol use disorder [64, 65] (See Fig. 40.1).

40.2.1 Hazardous Alcohol Use (ICD-11)

Hazardous alcohol use is defined as a pattern of alcohol use that appreciably increases the risk of harmful physical or mental consequences to the drinker or to others [79]. Hazardous use has not yet reached the level of having caused harm. "Risky use" is similarly defined as alcohol consumption in amounts that increase the likelihood of health consequences, e.g., injury, interpersonal problems, and medical consequences [64, 65].

The risk of harm is related to the level of alcohol consumption and the frequency and duration of consumption. In addition, psychosocial, environmental, and genetic influences may play a role [69, 72, 73]. Examples of national criteria for hazardous or risky alcohol use are as follows:

(a) *USA*: for women and men aged 65 years and older, drinking more than 7 drinks in a week or more than 3 drinks per day; for men under age 65 years, drinking more than 14 drinks in a week or more than 4 drinks in a day (1 drink being approximately 12–14 g of alcohol) [50, 52].
(b) *UK*: regular drinking of more than 14 units a week but less than 35 units a week for women; drinking more than 14 units a week but less than 50 units for men (1 unit is approximately 8 g or 10 ml of ethanol). Regular drinkers are advised to spread the amount evenly over 3 days or more, with some alcohol-free days per week [53]. In the UK risky drinking is sometimes graded as low risk, increasing risk, or higher risk. A single episode of heavy drinking, e.g., five to seven units in a 3–6-hour period (binge), increases the risk of accidents and injury two to five times [75].
(c) *Australia:* more than two standard drinks on any day (for both men and women) or more than four standard drinks on a single occasion (one standard drink being approximately 10 g of alcohol). For those under the age of 16 years or if a woman is pregnant or planning to become pregnant or breastfeeding, the safest option is not to drink alcohol [51].

Hazardous drinking includes any use of alcohol in pregnancy, when driving or working with machinery, when taking medications that interact with alcohol, and in certain medical conditions, e.g., chronic hepatitis C. Women should be warned that consumption of alcohol in early pregnancy carries the risk of fetal alcohol spectrum disorder (FASD) [68].

40.2.2 Harmful Alcohol Use (ICD-10) or Harmful Pattern of Alcohol Use (ICD-11)

Harmful (pattern of) alcohol use is a repetitive pattern of use at levels which have caused damage to a person's physical or mental health or resulted in behavior leading to harm to the health of others but does not fulfill the criteria for dependence of alcohol [78, 79]. The harmful effects may be acute (e.g., trauma) or chronic (e.g., alcoholic liver disease, depression). An episode of harmful alcohol use is a new ICD-11 diagnostic term for situations where harm has resulted from drinking, without information on whether the consumption represents a pattern of repeated use or a one-off episode [23, 29, 78, 79]. In DSM-IV TR, the term "alcohol abuse" is defined as a maladaptive pattern of alcohol use over a 12-month period leading to clinically significant failure to fulfill major obligations at work, school, or home and legal problems or interpersonal problems or which is physically hazardous [1].

40.2.3 Alcohol Use Disorder: Mild (DSM-V)

The DSM-V replaced the terms alcohol abuse and alcohol dependence under a broad term "alcohol use disorder." It is defined as a cluster of cognitive, behavioral, and physiological symptoms following a problematic pattern of alcohol use leading to clinically significant impairment or distress, manifested by at least 2 of 11 criteria within a 12-month period. The severity of the disorder is graded on the number of criteria met, viz., mild, two to three; moderate, three to four; or severe, six or more [2]. Nondependent alcohol use disorder lies in the lower end of this spectrum.

40.3 Alcohol Dependence (ICD-10, ICD-11, DSM-IV TR)

The DSM-V moderate to severe range of alcohol use disorder may conveniently be considered a counterpart to the ICD-10, ICD-11, and DSM-IV TR definition of alcohol dependence. Alcohol dependence is defined as a cluster of behavioral, cognitive, and physiological phenomena that develop after repeated alcohol use which tends to be self-perpetuating. The psychobiological syndrome is best understood as a disorder where there is impaired control over alcohol use and a persistent internal drive to consume alcohol such that alcohol increasing takes "center stage" or priority in the person's life and other enjoyments, activities, and responsibilities are pushed to the periphery. It reflects enduring changes in key neurocircuits that subserve reward, alertness, response control, and salience in the ventral tegmental area of the midbrain, the nucleus accumbens, and related structures of the lower forebrain and with projections to and from the prefrontal gyrus and the circulate gyrus of the cortex. It is more "disease-like" than any other form of repetitive alcohol use and tends to be self-perpetuating and to run true when active at different periods in the person's life. Physiological features indicative of neuroadaptation are manifested by tolerance, withdrawal symptoms following cessation or reduction of drinking, repeated use to prevent or alleviate withdrawal symptoms, and continued use despite harmful consequences.

Once alcohol dependence sets in, the patient may require prolonged treatment in a continuing care program. This includes inpatient or ambulatory detoxification followed by a comprehensive relapse-prevention program involving pharmacotherapy, a variety of psychosocial interventions, as well as self-help and mutual aid group therapy and family therapy. Where medical, psychiatric, or social complications have arisen, referral to appropriate specialties is required. In severe

cases, the patient may eventually require long-term residential or inpatient treatment.

There are more people with nondependent hazardous or harmful alcohol consumption than those with established alcohol dependence/moderate to severe alcohol use disorder. Approximately 15–20% of adults consume alcohol in a hazardous/harmful manner and 5% have alcohol dependence [68]. In England, alcohol dependence affects 2% of women and 6% of men, while over 24% of the English population consume alcohol in a way that is potentially harmful or actually harmful to their health and well-being [54] (see Fig. 40.1). Because of the greater prevalence of hazardous and harmful alcohol use in the population, more alcohol-related problems are attributable to hazardous and harmful alcohol use than to alcohol dependence. Screening and identification of nondependent hazardous and harmful drinking and provision of brief intervention are effective and cost-effective preventative approaches in preventing progression to more severe alcohol dependence, other alcohol-related harm, and death [31, 68].

40.4 Screening

For the spectrum of nondependent hazardous alcohol use, harmful alcohol use, and mild alcohol use disorder, there is a need for reliable methods of screening and brief intervention. Screening and early detection can also be applied to alcohol dependence, and brief interventions can be adapted and used in therapy at the start of treatment for persons with alcohol dependence. The 10-question Alcohol Use Disorders Identification Test (AUDIT) is a useful screening instrument in differentiating alcohol dependence from nondependent hazardous or harmful alcohol use: A score of 8 or more is associated with hazardous or harmful drinking, while a score of 15 or more is likely to indicate alcohol dependence [5, 7, 15, 18, 67, 68].

40.5 Development of the AUDIT

The modern era of screening for hazardous and harmful alcohol consumption and alcohol use disorders began with the development of the AUDIT [4, 5, 66, 67]. Prior to this, alcohol screening instruments focused on the detection of alcoholism. They were not designed to detect the range of alcohol use disorders or hazardous/unhealthy alcohol consumption, the reason being that these concepts had not gained general acceptance at the time the older instruments were introduced. These older instruments include the Michigan Alcoholism Screening Test (MAST), developed in 1971 which exists in several versions including brief ones, and the four-item CAGE, this being an acronym of Cut down, Annoyed, Guilty, and Eye-opener [30, 46]. The T-ACE is a variant of CAGE with guilt being replaced by tolerance (Tolerance, Annoyed, Cut down, Eye-opener), to identify excess drinking during pregnancy [71].

Given the increasing focus on identifying hazardous and harmful alcohol use before dependence has become entrenched, the MAST and the CAGE have become less widely used as they perform poorly as screens for less severe unhealthy hazardous or harmful drinking.

The AUDIT has its origins in the WHO collaborative work that was initiated by the Expert Committee and was derived from findings in a World Health Organization Collaborative Study [66, 67, 4, 5]. The AUDIT was developed from the empirical selection of items contained in a WHO assessment instrument, comprising more than 150 questions. Participating centers from six countries around the world (which represented different cultures, healthcare systems, stages of economic development and political systems) were involved. The 10 items which formed the AUDIT were those which had the following characteristics:

1. They had the highest or comparably high item-total correlations with the domains they represented.
2. Individually and collectively they had the greatest discriminatory value between patients who had hazardous or harmful consumption and/or alcohol use disorders and those who did not.
3. The questions not only conformed to the then bidimensional concept of alcohol dependence

and its consequences but extended it to a tridimensional concept of (i) intake measures, (ii) measures of the urge or drive to consume alcohol (and putative dependence), and (iii) direct or proxy measures of alcohol-related consequences.
4. The sensitivity and specificity and positive and negative predictive values for the AUDIT in clinical and also general populations indicated a high degree of accuracy of classification and therefore practical utility.
5. Likewise the sensitivity and specificity of questions in the three individual domains were psychometrically acceptable.
6. The questionnaire as a whole and questions within the three domains had acceptable psychometric performance as judged by measures such as Cronbach's alpha coefficient.
7. Each individual question had high-face validity, the meaning of the question was clear, and it explicitly mentioned the link with alcohol consumption.
8. Each question was suitable in providing a means of exploring further the patient's experiences with alcohol, and the questionnaire as a whole was suitable as a framework for intervention.
9. The individual questions could be translated readily and accurately (both grammatically and idiomatically) into major world languages.

Subsequent studies showed that the AUDIT:

1. Performed as well as a stand-alone questionnaire as it did when the questions were embedded in a general health screening instrument.
2. Had high acceptance among populations being screened.
3. It could be adapted easily to an electronic format including interactive media where feedback on the AUDIT score and on responses to individual questions could be provided.

The AUDIT questionnaire offers a simple and systematic way of assessing alcohol intake (Questions 1–3), alcohol dependence (Questions 4–6), and alcohol-related harm (Questions 7–10). The questionnaire may be self-administered while the patient is awaiting the consultation or may be used by the clinician during the assessment. Responses in the AUDIT are quantified from 0 (far left column) through to 4 (far right column) for Questions 1–8 and 0, 2, and 4 for Questions 9–10. The AUDIT score may range from 0 (for an abstainer of alcohol) to 40. A presumptive diagnosis of hazardous or harmful consumption is made if the AUDIT score is 8 or above. More severe harm and dependence is likely when the score is 15 or more and to be extremely likely if the score is 20 or more. The scores on the AUDIT can also point to the intervention required, if any. Scores of 0 and 1–7 may result in some feedback but otherwise no specific intervention. A score of 8 or more merits a brief intervention, with scores of 15 or more (and certainly 20 or more) alerting the clinician to the need for detoxification and referral for specialist treatment. Assessment by completion of the AUDIT questionnaire itself is reported to reduce hazardous drinking [42].

AUDIT screening for early diagnosis of hazardous and harmful alcohol use is recommended as part of a routine examination in the Accident and Emergency Department, during pregnancy, prior to prescribing medication that interacts with alcohol and where there is evidence of alcohol-related harm, e.g., cardiac arrhythmia, dyspepsia, liver disease, hypertension, depression, anxiety, insomnia, and trauma [13, 54].

40.6 Derivatives of the AUDIT and Alternative Screening Instruments

Several derivatives of the AUDIT have been published over the years. The most popular of these is the AUDIT-C, a three-item questionnaire which comprises simply the first three questions of the AUDIT consumption measures. The AUDIT-C and the single-item AUDIT-3 (which comprises the third question on heavy episodic drinking alone) have been shown to be more convenient, brief, and effective instruments for diagnosing alcohol use disorders in a primary care setting [15, 19, 70].

40.6.1 AUDIT-C

1. How often do you have a drink containing alcohol?
2. How many standard drinks containing alcohol do you have on a typical drinking day?
3. How often do you have four drinks (women) and six drinks (men) or more on one occasion?

A score of 3 or more in women and 4 or more in men has a sensitivity of 73% and 86% and a specificity of 91% and 89%, respectively [16]. A score of 7–10 or more suggests there may be alcohol dependence [60].

The Fast Alcohol Screening Test (FAST), a four-item questionnaire based on the AUDIT, is another useful screening tool. The first question is, "How often do you have eight (for men) or six (for women) or more standard drinks on one occasion?" A response of monthly or more is considered a positive answer. Three further questions make up the FAST [34] with a score of 3 or more indicating hazardous alcohol drinking.

The WHO Alcohol, Smoking and Substance Involvement Screening Test (ASSIST) is a combined screen for drug and alcohol misuse and is available for self-completion while the patient is in the waiting room or hospital clinic. It is designed to inquire about alcohol use in context of health enquiries to detect problem or risky alcohol and other substance use in primary healthcare. It is linked to a brief intervention based on the acronym FRAMES (Feedback, Responsibility, Advice, Menu, Empathetic interviewing and Self-efficacy) and incorporates motivational interviewing [57, 77].

40.6.2 Screening in Special Populations

Some alcohol screening instruments have been developed to identify hazardous consumption and alcohol use disorders within specific populations such as pregnant women, youth and adolescents, ethnic minorities, and the elderly. These include the TWEAK, a quick five-item screening and assessment tool for alcohol use during pregnancy [62, 63] and an acronym of Tolerance, Worried, Eye-opener, Amnesia and Cut down (K). A review of alcohol screening in women suggests that the TWEAK appears to be the optimal screening questionnaire for identifying women with excess alcohol use in racially mixed populations with the AUDIT as a reasonable alternative [14].

The CRAFFT, a six-item screening tool and an acronym for Car, Relax, Alone, Family, Friends, and Trouble, was developed specifically to screen for problematic substance use in teens [40] and found to be a suitable alternative to AUDIT in adolescents and young adults, with excellent sensitivity and no gender-based or race-based differences [22]. Another questionnaire for adolescents called the POSIT (an acronym for Problem-Oriented Screening Instrument for Teenagers and a lengthy 16-item screening questionnaire) was found to perform better than the CRAFFT [61]. The MAST-G, an "elderly-specific" questionnaire, and the CAGE were reported to be better than the AUDIT in a study of elderly male veterans [48]. The MAST-G and the CAGE are appropriate screening instruments for alcohol abuse and dependence in the elderly [10]. The CAGE is reported to be superior to the MAST in the elderly [6]. However, the AUDIT remains a more useful tool for identifying nondependent hazardous and harmful alcohol use in the elderly.

40.7 Brief Interventions: Background and Evidence

Once a person has been identified, through screening or clinical enquiry, as having unhealthy alcohol use, a brief, focused form of therapy is beneficial. The usual term to describe this is "brief alcohol intervention." As described above, brief intervention aims to engage with people who have hazardous or harmful alcohol consumption and offer simple advice on the harmful

physical, mental, and social consequences of excess alcohol. In the ICD system, this means people with hazardous alcohol use (use which confers the risk of future harm) or harmful alcohol use (use which has already caused physical, mental, or behavioral problems). In DSM-5, the nearest counterpart would be mild alcohol use disorder. The focused advice and therapy is provided before the person has developed a more severe alcohol use disorder or more severe physical, mental, or personal harm.

Brief intervention is therefore a proactive strategy comprising of provision of brief advice on the consequences of hazardous/harmful drinking or alcohol use disorder feedback of harm and relating this to the patient's excess drinking, setting goals for safe levels of drinking, outlining benefits obtained from cutting down drinking, and setting strategies to overcome "at-risk" times. The intervention may take only 4–5 minutes. If a structured brief intervention does not lead to reduction of hazardous or harmful drinking, it may be extended to 30–40 minutes to include motivational interviewing techniques [17, 47, 54].

While there is limited evidence on the effectiveness of brief interventions for young people under the age of 16 years [54], there is a wealth of evidence attesting to the effectiveness of brief alcohol interventions in reducing alcohol intake and alcohol-related problems in adults with alcohol use disorders. Approximately 50 randomized controlled trials of various forms of brief intervention compared with no intervention or an alternative form of intervention have been published. Furthermore, several meta-analyses have been published since the early 2000s.

Systematic reviews have shown that brief intervention reduces mortality over a 10-year follow-up, with a relative risk of 0.47 (95% CI 0.25–0.89) [24, 76].

Systematic reviews and meta-analysis confirm the effectiveness of brief intervention in reducing excess alcohol consumption and alcohol-related harm in a primary care setting [8, 58]. In a UK multicenter SIPS (Screening and Intervention Program for Sensible drinking) trial, 3562 primary care patients were screened for hazardous/harmful drinking using either the FAST or the single alcohol screening questionnaire. Patients randomized to three interventions were compared, each of which built on the previous one, namely, (i) a patient information leaflet control group, (ii) 5 minutes of structured brief advice, and (iii) 20 minutes of brief lifestyle counseling linked to motivational interviewing. The WHO screening instrument AUDIT (score of <8) was used as a primary outcome measure at 6 months**.** There was no difference in benefit between the three arms although patients in the 20-minute intervention reported greater satisfaction with treatment. The authors concluded that screening followed by simple feedback and written information may be the most appropriate strategy to reduce hazardous and harmful drinking in a primary care setting [27, 28, 39].

Meta-analysis of 22 randomized clinical trials of 5800 participants not seeking help for alcohol problems in a primary care setting showed that brief intervention was effective in reducing alcohol consumption in men with hazardous and harmful alcohol consumption but unproven in women [37]. Further supportive evidence was provided in a more recently updated Cochrane collaboration systematic review of 69 studies on a total of 33,642 participants with primary meta-analysis of 34 trials of 15,197 participants in general practices or emergency care. Brief intervention reduced alcohol consumption in hazardous and harmful drinkers compared to minimal or no intervention in both men and women, compared to controls after 1 year [11, 38].

Brief interventions, typically lasting 5–15 minutes (and no longer than 30 minutes), included feedback on alcohol use and health-related harms, identification of high-risk situations for heavy drinking, simple advice about how to cut down drinking, strategies to increase motivation to change drinking behavior, and the development of a personal plan to cut down drinking. Short advice-based intervention is as effective as extended counseling- based intervention [11, 37, 38, 49].

The efficiency of screening and brief intervention will vary according to the prevalence of hazardous alcohol consumption in general practice. A degree of effort is required to provide brief intervention in practice although information on alcohol consumption is relevant to much of the healthcare when other issues such as the potential for interactions with medications and advice needed for pregnant women and people with a range of chronic medical disorders are taken into consideration.

40.8 Implementation of Screening and Brief Intervention in Clinical Practice

There is a wealth of evidence that demonstrates that brief interventions reduce hazardous and harmful alcohol consumption, as judged by overall alcohol consumption, reduced frequency of binge drinking, alcohol-related problems, and various secondary measures such as healthcare utilization. Some of the findings vary from study to study and among the meta-analyses. However, the overall message is clear that for these interventions benefits are clear and the strength of the evidence would suggest that their general availability in the healthcare system should be assured. The reality is somewhat different.

Brief interventions are some of the most consistently effective and potent interventions directed at individuals, and considerable effort is being made to incorporate them into the healthcare system. This is proven to be more difficult than originally anticipated. Very often screening and brief intervention can be established as a brief project, but it tends not to be continued in systematic way when external support and interest ceases.

It is fair to say that screening and brief intervention remains under utilized. Certainly systematic screening in primary care and the delivery when appropriate of a brief therapy remain unusual, even in healthcare systems that have a strong primary prevention and population health orientation. Various barriers to implementation have been reported by health professionals and include (i) reluctance to inquire about alcohol consumption, (ii) poor role adequacy, (iii) inadequate resources to address alcohol use and problems, and (iv) poor role support [56]. There remain significant issues regarding training and confidence in providing brief interventions, issues of remuneration, and competition for the time of medical practitioners and other health professionals given their overall responsibilities. Ethical considerations have also been raised as to the appropriateness of introducing a health issue which is not on the patient's agenda when he/she booked the consultation. More broadly there is debate about which healthcare professionals have the capacity to provide these interventions.

Detection and diagnosis of alcohol use disorders remains low, and it is estimated that of the 15–30% of patients in primary care or hospital settings who have an alcohol use disorder, in only one-third of the cases is it diagnosed. It must be emphasis that screening and early detection therefore has a greater role than leading to a brief intervention. Early detection can often result in the correct diagnosis being expedited, with the patient being spared unnecessary investigations. Equally importantly, knowledge of the alcohol use disorder may prevent months or indeed years of inappropriate or ineffective treatment for patients who have disorders that may be related to alcohol consumption, such as hypertension, esophagitis and gastritis, anxiety, depression, and recurrent headache. It can also often provide an answer for patients who have multiple nonspecific and seemingly unconnected symptoms.

Examples of policy recommendations and directives include the expectation that screening and brief intervention will be provided in all healthcare settings in the recommendations of the US Preventive Services Task Force [50], the guidelines published by the UK National Institute of Clinical Excellence [53] and the British Medical Association (BMJ) Best Practice

Alcohol Use Disorder Guidelines [13], and the National Preventative Health Taskforce, Australia [55].

Opportunities for screening, early detection, and brief intervention for unhealthy alcohol use exist in many settings. These include general medical/family medical practice, other primary care settings (nurse, psychologist, social worker delivered), emergency departments and acute care clinics, student health services, work place health programs, and also certain public areas such as shopping centers.

In addition to these primary care or community contact settings, brief interventions can be offered in hospital wards (general and psychiatric) and in a range of specialist services such as diabetes, hypertension, and liver clinics. A large number of hospital outpatients who are not seeking treatment for their drinking could benefit from early intervention [36]. There is mixed evidence for the effectiveness of brief intervention in hospital wards, while significant reduction in alcohol consumption and less likelihood of alcohol-related injury have been reported following screening and brief intervention for alcohol use disorders in the emergency department [26, 32, 45].

These settings are of course quite diverse, and the extent to which a person can be engaged in any alcohol intervention will vary according to the primary task of a particular setting. Still, given that few people specifically request treatment and assistance in an alcohol use disorder, any attempt to identify these and to place alcohol on the healthcare agenda is to be welcomed.

Throughout this period, there has been a tendency for patients who have actual alcohol use disorders to present for care at an earlier stage than was the case a generation ago. Furthermore, developments in general practice mean that questions on alcohol as well as cigarette smoking are more commonly part of the routine enquiry when patients attend primary care for the first time or are part of a periodic annual or biannual assessment. Even though the systematic approach of brief intervention may be less common than had been anticipated by those working in the area, nonetheless in various areas of the world it is more common for inquiry about alcohol use to be made.

In addition to screening instruments, good history taking, physical examination, and laboratory tests help to provide useful diagnostic information. This includes measurement of alcohol levels in the breath or blood, full blood count (macrocytosis), and liver function tests: GGT (gamma-glutamyl transpeptidase), ALT (alanine aminotransferase), AST (aspartate aminotransferase), and CDT (carbohydrate-deficient transferase) [21].

40.9 Brief Intervention in Practice: The Techniques

Brief intervention techniques vary widely in content and duration [12, 52, 65]. A structured brief intervention begins with personalized feedback regarding a person's alcohol intake and/or experience of problems and an indication that the level of consumption puts them at risk of future harm and/or that problems have arisen due to their alcohol intake. This is followed by recommendation for behavior change and advice to reduce consumption to approved guidelines for low-risk intake. These latter vary from country to country but typically would be under 20 g daily for men and 10–20 g daily for women Finally, negotiation and confirmation of goals and arrangement for follow up is made. This information and advice is typically conveyed to the patient over 5 minutes.

Many brief interventions incorporate other strategies. They include:

- Normative feedback, in which the person's alcohol intake is compared to that of the population at large and the risk levels and harmful effects of excess alcohol
- Brief motivational enhancement approaches, which may employ techniques of empathic feedback and cognitive dissonance

– Strategies for limiting alcohol consumption which are typically brief, cognitive behavioral interventions and may focus on avoiding high-risk situations for drinking and managing emotions such as frustration and boredom
– Measures aimed at moderated or controlled drinking such as always eating some food before any alcohol consumption, spacing drinks and extending the interval between drinks and counting drinks, and having alternate alcoholic and nonalcoholic drinks.

Based on motivational interviewing techniques [47], two popular approaches to brief intervention are set out below.

The first, FLAGS, an acronym for Feedback, Listen, Advice, Goals, and Strategies [68], is derived from the intervention developed from the WHO brief intervention collaborative study [3, 5].

FLAGS

Feedback: Problems experienced or likely to occur and link this with unhealthy drinking

Listen: Listen to the patient's response and assess his/her readiness to change (use motivational interviewing techniques as required [59])

Advice: Give clear advice to change and/or reduce unhealthy levels of drinking; list the benefits of change

Goals: Negotiate goals to reduce drinking to recommended limits

Strategies: Discuss practical methods and strategies, for example, how to determine at-risk times, and develop coping strategies

The second, FRAMES, an acronym for Feedback, Responsibility, Advice, Menu, Empathetic interviewing and Self-efficacy, is an intervention which has a major component of motivational interviewing and enhancement. It is derived from the work of Miller and colleagues and is an abbreviated form of a more extended intervention which has been developed for psychological practice [68].

FRAMES: (brief intervention with motivational interviewing)

Feedback: about personal risk and impairment

Responsibility: emphasis on personal responsibility for change

Advice: to cut down, abstain if indicated, because of severe dependence or harm

Menu: of alternative options for changing drinking pattern and, jointly with the patient, setting a target; intermediate goals of reduction can be a start

Empathic interviewing: listening reflectively without cajoling or confronting, exploring with patients the reasons for change as they see their situation

Self-efficacy: an interviewing style which enhances peoples' belief in their ability to change

[12]

40.10 Electronic Screening and Brief Intervention

Worldwide, 70% of the adult population has ready access to the Internet typically through smartphones or numerous other electronic devices. In some countries, the coverage of the Internet reaches 98% of the population. Communication of information is easier than ever before. In addition, the interactivity that is possible electronically means that intervention can be offered in real time. In many areas of healthcare, this technology has been put to use for the provision of screening and assessment and the provision of relevant information and advice. Screening and brief intervention for alcohol use has been part of this.

Electronic screening and brief intervention (e-SBI) has its origins in the late 1990s when the

potential of the technology became apparent and also when there was interest in the widespread dissemination of health advice about alcohol. Soon, pioneering efforts in the provision of alcohol screening and brief intervention were made, and the first systematic studies appeared in the early 2000s. A series of controlled studies in student populations, both in individual campuses and national studies, have shown significant effect sizes on measures of overall alcohol consumption, binge drinking, alcohol-related problems, measures of academic performance, and healthcare utilization. The effect size does appear to be slightly less for electronic interventions than that seen for clinician-provided interventions [44]. In several other populations controlled trials have since shown electronic screening and brief intervention to result in significant changes in alcohol consumption and associated problems [25, 43]. However, given the high acceptability of electronic interventions and the potential reach to the at-risk population, electronic interventions have far greater capacity to be disseminated universally than could be achieved realistically through the dissemination of clinician-provided interventions.

Screening and brief intervention have high levels of acceptability particularly among populations (such as young people) who are electronically literate. Studies among university and college students show acceptability levels exceeding 80%, and receiving information electronically is preferred among young people to receiving such information from a health professional. A pilot project has shown that while implementation of self-administered electronic screening and brief intervention is acceptable and feasible in primary care practices, its use is rather limited without human support. This could be improved by training of desk personnel or practice nurses [9].

Based on evidence from a systematic review of 31 studies showing the effectiveness of electronic screening and brief intervention in reducing excessive alcohol consumption and alcohol-related problems [20, 74], the use of electronic devices (computers, telephones, or mobile devices) is recommended to facilitate screening and personalized feedback about the risks of excessive drinking. However, a randomized double blind controlled study of e-SBI to adults with hazardous and harmful drinking was not found to be effective in a hospital outpatient setting [36].

More broadly, screening and brief intervention including its electronic forms offers the prospect of reducing alcohol-related harm at a population level as an alternative to primary prevention approaches based on control of per capita alcohol consumption. These latter approaches, although empirically sound, are difficult for governments to enact into effective policy as they impact on the availability and access to alcohol of the entire population and not just those whose drinking is hazardous and causing problems. In the modern world, governments have been reticent to impose tax imposts and restrictive legislation on alcohol consumption generally for fear of electoral unpopularity and economic considerations, particularly in those countries where the production of alcohol drinks is a significant part of the national economy. Screening and brief intervention therefore offers a population-wide and more politically acceptable approach to reducing harm from alcohol in the population at large. Both clinician-provided and electronic interventions have important roles to offer in the fulfillment of this goal.

Abstract

Alcohol use disorder assessment needs different strategies depending on whether screening/early use or severity and depth of the condition is yielded. The former implies the simpler and agile instruments while the latter complex and sophisticated instruments that usually require specific training. An efficacious clinical treatment starts with an integrative comprehension of the individual. Ongoing assessment and monitoring are crucial because clients' symptoms and functioning may change throughout treatment and so do priorities and targets of intervention. Alcohol use is known to interfere with neuropsychological performance, psychiatric symptomatology,

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment*, https://doi.org/10.1007/978-3-030-36391-8_41

and social and personal functioning, so it is strongly recommended to conduct multiple evaluations to determine a better approach of patient's genuine mental health and cognitive performance. An all-embracing assessment should appraise multiple domains of need and delve into the following areas: historical and recent patterns of drinking, dependence and withdrawal symptomatology, alcohol craving and impulsiveness, alcohol-related problems (i.e., legal, economic, occupational), self-efficacy and confidence in relapse prevention, readiness to change, other drug misuse including prescribed and under-the-counter medication, comorbid mental health disorders, comorbid physical health conditions, neurocognitive performance, social and personal functioning, quality of life, and disability. This information may be obtained by a precise clinical interview, but standardized tools and measures should be administered as well. This chapter will enumerate and briefly describe the most relevant psychometric instruments to evaluate alcohol use disorders and related problems, psychiatric comorbid symptomology, neurocognitive performance, and social functioning and quality of life issues.

Keywords

Alcohol assessment · Alcohol clinical assessment · Alcohol screening test · Alcohol use detection · Alcohol evaluation · Clinical evaluation of alcohol use

Screening and early detection of alcohol use disorders should be the initial step in the process of identifying possible conditions (see Chap. 40)**.** After a person has been detected and diagnosed, an in-depth assessment, which involves both integrative comprehension of the patient and monitoring of patient's progress, is needed. Ongoing assessment and monitoring is important because clients' symptoms and functioning may change throughout treatment and so do priorities and targets of intervention. For instance, a patient may report anxiety symptoms or dysphoric mood upon treatment intake and have these symptoms attenuated after achieving abstinence. By the same token, another person could enter treatment with apparently no mental health symptomatology but develop them after a period of reduced use, if self-medication with alcohol existed [18]. At the same time, it should be noted that recent alcohol abuse may influence neuropsychological performance, psychiatric symptomatology, and social and personal functioning, so it is strongly recommended to conduct further evaluations to determine a better approach of patient's genuine mental health and cognitive performance. It is fundamental to bear in mind that the primary benefit of assessment is not only to accurately and efficiently determine the treatment needs of the patient but to build rapport. For this reason, it is the heart of the assessment to avoid confrontative approaches and adopt a motivational one instead (see Chap. 24).

An all-embracing evaluation should appraise multiple domains of need and delve into the following areas:

- Alcohol consumption:
  - Historical and recent patterns of drinking
  - Dependence and withdrawal symptomatology
  - Alcohol craving and impulsiveness
  - Alcohol-related problems (i.e., legal, economic, occupational)
  - Self-efficacy and confidence in relapse prevention
  - Readiness to change
- Other drug misuse, including prescribed and under-the-counter medication
- Comorbid mental health disorders
- Comorbid physical health conditions
- Neurocognitive performance
- Social and personal functioning
- Quality of life and disability

This information may be obtained by a precise clinical interview, but standardized tools and measures should be administered as well (see Table 41.1).

This chapter will enumerate and briefly describe the most relevant psychometric instruments to evaluate alcohol use disorders and related problems, psy-

Table 41.1 Distinctive features in instrument selection

Feature	Characteristics
Clinical utility	Screening Diagnosis Assessment of drinking behavior Treatment planning Intervention monitoring Outcome appraisal
Time frame	Recent/short-term/current use vs. chronic/long-term/lifetime use
Specific subgroup	Adolescent, adult, elderly Women (pregnant) Imprisoned Homeless Inpatient vs. outpatient Cultural issues/ethnicity
Sensitivity/ positive predictive value (PPV)	Proportion of patients with the condition correctly classified as "diseased"
Specificity/ negative predictive value (NPV)	Proportion of individuals without the condition who are correctly classified as "disease-free"
Validity (test measures what is intended to measure)	Content (comprehensiveness) Construct (conceptual components, internal structure) Convergent (similar to other tests to assess that construct) Discriminant (different to tests that assess other constructs) Criterion (correlation with gold standard measures) Concurrent (similar measures obtained to comparative tests at same time frame) Predictive (ability to predict future outcome)
Reliability (accuracy of assessment)	Test-retest (correlation at two different time points) Inter-rater (degree of agreement by different raters) Internal consistency (items of test measure same aspect)

chiatric comorbid symptomology, neurocognitive performance, and social functioning and quality of life issues. Chapter 40 on Screening, Early Detection & Brief Intervention for AUD and Laboratory Tests for Alcohol Chap. 42. Biological State Marker for Alcohol Consumption may be searched through for further information. Regarding physical and mental health comorbidities, Part VIII is an exhausted revision on Medical Disorders, Complications of Alcohol and Others, and Pain Section, and Part IX addresses Psychiatric Comorbidities and Complications of Alcohol and Other Drugs.

41.1 Evaluation of Alcohol Use

There are no specific instruments to diagnose alcohol misuse, so fundamental diagnostic methods consist of an accurate anamnesis and a meticulous clinical exam. Albeit this fact, psychometric tools are of considerable aid to appraise addictive disorders when used by trained specialists.

41.1.1 Clinical Severity of Addiction

- Addiction Severity Index [45]. The ASI is a semi-structured interview designed to address seven potential impairments and problem areas in substance-abusing patients: medical conditions, employment and support, drug use, alcohol use, legal issues, family/social relationships, and psychiatric disorders. It consists of 200 items, which gather information on recent (past 30 days) and lifetime problems in all of the problem areas. Last version (ASI 6.0) [13, 44] is composed of 15 scales: 9 primary scales (related to main problem areas) and 6 secondary scales (perceived support and conflicts with partner, family, and friends). There is a follow-up version (ASI-FU follow-up) designed to monitor patients' evolution and treatment outcomes and several adaptations to adolescent population: Teen-ASI [36], T-ASI-2 [11].
- Alcohol Use Inventory [35]. The AUI is a self-administered instrument which includes 24 scales that intend to describe different ways in which individuals use alcohol, benefits and negative consequences derived from such use, and awareness and readiness for help. It consists of 228 items grouped in primary scales regarding benefits, styles, consequences and concerns and acknowledgments of alcohol use, and other second-order factor scales.
- Comprehensive Drinker Profile [48]. The CDP is a structured interview that contains 88 questions inquiring different areas of interest: alcohol use, everyday problems, most common drinking settings, people with whom they drink, beverage preferences, reasons for drinking, effects and life problems related to alco-

hol use, and patient's concerns and issues. Three instruments were derived from the CDP: the Brief Drinker Profile (BDP), the Follow-up Drinker Profile (FDP), and the Collateral Interview Form (CIF).

41.1.2 Dependence/Withdrawal Symptoms

- Severity of Alcohol Dependence Questionnaire [69]. The SADQ is a self-administered questionnaire designed to measure severity of dependence. There are four items in each of the five scales that gather information on a 6-month time frame: physical withdrawal, affective withdrawal, withdrawal relief drinking, alcohol consumption, and rapidity of reinstatement. Scores range between 0 and 60 points, and scores greater than 30 are suggestive of severe alcohol dependence. It has demonstrated adequate content and criterion (predictive) validity and test-retest reliability.
- Alcohol Dependence Scale [66, 67]. The ADS consists of 25 items that interrogate alcohol withdrawal symptoms, impaired self-control over drinking, awareness of compulsive drinking, tolerance to alcohol, and salience of drink-seeking behavior. It has shown good predictive value, content and construct validity, and test-retest and internal consistency reliabilities. A computerized version is also available. It is an adequate instrument for clinical and research purposes.
- Short Alcohol Dependence Data [59]. This 15-item instrument was derived from the Alcohol Dependence Data (ADD) in order to accomplish an easier and faster measure profitable for seeking-help patients, current state dependence assessment, sensitive to change over time, and cultural-free influenced. It can be self- or hetero-administered in about 2–5 minutes and has provided good reliability and validity parameters.
- Clinical Institute Withdrawal Assessment [70]. The CIWA-AD is an eight-item scale for clinical quantification of the severity of the alcohol withdrawal syndrome. It is useful to monitor patients undergoing alcohol withdrawal as it focuses on both intensity and severity of symptoms. Scores over 20 indicate a severe withdrawal syndrome, and inpatient detoxification is strongly recommended.

41.1.3 Craving/Impulsiveness

- The Obsessive Compulsive Drinking Scale [4]. The OCDS is a 14-item scale developed to reflect obsession and compulsion related to craving and drinking behavior such as drinking-related thoughts and urges to drink and the ability to resist those thoughts and urges. The OCDS has been shown to be a reliable and sensitive monitoring tool and has proven content and predictive validity for relapse drinking. There is an adolescent version, the A-OCDS [19], which discriminates between problem drinkers and experimenters and detects functional impairment associated with alcohol abuse.
- Penn Alcohol Craving Scale [27]. The PACS is a five-item self-administered instrument for assessing frequency, intensity, and duration of thoughts about drinking and the ability to resist drinking. Although it was intended for adults, it may be used in adolescent population. Good reliability and validity measures have been obtained.
- Alcohol Craving Questionnaire [64]. The ACQ-NOW is a 47-item self-administered, multidimensional state measure of acute alcohol craving. It measures four dimensions: emotionality, purposefulness, compulsivity, and expectancy. There is a 12-item short form, the ACQ-SF-R. It has demonstrated adequate reliability and is sensitive to change.
- Impulsive Behavior Scale [76]. The UPPS is a 45-item scale designed to measure impulsivity across dimensions of the five-factor model of personality. It measures four domains: premeditation, urgency, sensation seeking, and perseverance. The revised version, UPPS-P, consists of 59 items and assesses an additional personality pathway to impulsive behavior, positive urgency [17].

- Barratt Impulsiveness Scale [5, 57]. The BIS is one of the oldest and most widely used measures of impulsive personality traits. The last version, BIS-11, contains 30 items grouped in 3 subscales: attentional impulsiveness, motor impulsiveness, and non-planning impulsiveness. This scale is intended to measure six factors: attention, motor impulsiveness, self-control, cognitive complexity, perseverance, and cognitive instability.

41.1.4 Self-Efficacy and Expectancy

- Alcohol Abstinence Self-Efficacy Scale [23]. The AASE was designed to evaluate self-efficacy in 20 situations that represent typical drinking cues associated to negative affect; social/positive, physical, and other concerns; and withdrawal and urges. It may be also used to assess an individual's temptation to drink. It has shown great utility to intervene over relapse potential situations, monitor progress in treatment, and assess outcomes.
- Drinking Refusal Self-Efficacy Questionnaire [81]. The DRSEQ is a 31-item measure of drinking-related self-efficacy. It is grouped in three factors: drinking in situations characterized by social pressure, opportunistic drinking, and emotional relief. Adequate reliability and validity have been analyzed.
- Alcohol Expectancy Questionnaire [12]. The AEQ is an empirically derived self-report form designed to assess the domain of alcohol reinforcement expectancies. It consists of six subscales: positive global changes in experience, sexual enhancement, social and physical pleasure, assertiveness, relaxation/tension reduction, and arousal/interpersonal power. Total scores are predictive of current and future drinking practices, persistence and participation in treatment, and relapse following treatment.
- Negative Alcohol Expectancy Questionnaire [46, 47]. The NAEQ is a 60-item questionnaire that assesses the extent to which negative consequences are expected to occur if that person were to "go for a drink now." The expected negative consequences are held to represent motivation to stop drinking. There are three different time frames: same-day, next-day, and long-term expected consequences. Responses are measured in terms of how likely it is that a person would expect them to occur and are measured on a five-point Likert scale. A short version composed of 22 items is also available. This instrument is very useful at intake and during treatment to intervene over motivational factors during therapeutic process.

41.1.5 Motivation to Change

- University of Rhode Island Change Assessment [43]. The URICA is a 32-item self-report measure used to assess motivation for change that includes four subscales: precontemplation, contemplation, action, and maintenance. These subscales can be combined in order to yield a second-order continuous readiness to change score (C + A + M-PC). It has demonstrated adequate internal consistency as well as content and criterion validity.
- Readiness to Change Questionnaire [63]. The RCQ is comprised of 12 items and focuses on readiness to change drinking behavior. It is based on the URICA questionnaire and is founded on Prochaska and DiClemente's theory on stages of change. It is clustered into three factors: precontemplation, contemplation, and action. It has good psychometric properties, including predictive validity. There is a treatment version, the RCQ (TV), for use in patients at treatment settings.
- Stages of Change Readiness and Treatment Eagerness Scale [49]. The SOCRATES consists of 40 items grouped into 5 stages of change: precontemplation, contemplation, determination/preparation, action, and maintenance. The SOCRATES 8A is a 19-item version that yields 3 factorial-derived scale scores: recognition, ambivalence, and taking steps. There are available other forms of the SOCRATES: 8D, a 19-item drug/alcohol questionnaire for clients; 7A-SO-M, a 32-item alcohol questionnaire for significant others of males; 7A-SO-F, a 32-item alcohol questionnaire for SOs of females;

7D-SO-F, a 32-item drug/alcohol questionnaire for SOs of females; and the 7D-SO-M, a 32-item drug/alcohol questionnaire for SOs of males. These SO forms are intended to measure motivation for change of significant others (rather than patient's motivation).

41.2 Psychiatric Comorbidity Assessment

Individuals with alcohol use disorders often suffer from one (comorbid) or more (multimorbidity) psychiatric disorders. This frequent phenomenon indicates the necessity of specific assessment and treatment in the field of addictive behaviors, which has been historically narrowed and focused to the addiction per se. This section yields over basic instruments to assess psychiatric comorbidity in patients with alcohol problems (see Table 41.2). For further information on psychiatric comorbidity, consult Part IX of this book, Psychiatric Comorbidities and Complications of Alcohol and Other Drugs.

41.3 Neuropsychological Performance

Scientific literature has well established that excessive alcohol use is associated to damage and impairment of brain structure and function, yielding to poor cognitive performance and behavior disturbances. Assessment and intervention over neuropsychological performance is fundamental as it involves assimilation and understanding of information, reasoning, and problem-solving in order to prevent oneself from relapse, to develop mnesic capacity to remember therapeutic guidelines, to learn new skills and maintain abstinence, and to develop more adaptable behaviors. This section enumerates the most

Table 41.2 Psychometric instruments to evaluate psychiatric comorbidity

Construct	Instrument	Author
Psychiatric comorbidity	Psychiatric Research Interview for Substance and Mental Disorders (PRISM)	[34]
	Composite International Diagnostic Interview (CIDI)	[78]
General symptoms	Symptom Checklist- 90- Revised (SCL 90-R)	[21]
	Minnesota Multiphasic Personality Inventory (MMPI-2)	[42]
Affective symptoms	Hamilton Depression Rating Scale (HDRS)	[33]
	Beck Depression Inventory-II (BDI-II)	[8]
	Young Mania Rating Scale (YMRS)	[80]
Autolytic risk	Scale for Suicidal Ideation (SSI)	[7]
	Hopelessness Scale (HS)	[9]
Anxiety	Hamilton Anxiety Rating Scale (HARS)	[32]
	State Trait Anxiety Inventory (STAI)	[68]
	Yale-Brown Obsessive Compulsive Scale (Y-BOCS)	[31]
	Clinician Administered PTSD Scale (CAPS)	[10]
Psychotic spectrum	Brief Psychiatric Rating Scale (BPRS)	[56]
	Positive and Negative Syndrome Scale (PANSS)	[38]
Personality	International Personality Disorder Examination (IPDE)	[41]
	Eysenck Personality Questionnaire-Revised (EPQ-R)	[25, 26]
	Millon Clinical Multiaxial Inventory-III (MCMI-III)	[50, 51]
Eating behavior disorders	Eating Disorders Inventory (EDI)	[29]
	Eating Disorder Examination (EDE)	[16]
Sexual dysfunction	Changes in Sexual Functioning Questionnaire (CSFQ)	[14]
	Derogatis Interview for Sexual Functioning-Self-Report (DISF-SR)	[20, 22]
ADHD	Conners' Adult ADHD Rating Scales	[15]
	The World Health Organization Adult ADHD Self-Report Scale (ASRS)	[39]

Table 41.3 Tests to assess neuropsychological performance

Function	Subcomponent	Instrument	Author
General mental function		Mini Mental State Examination (Mini-Mental)	[28]
Attention	Span and control	Digit span (WAIS-IV)	[72, 74]
		Mental control test	[72, 74]
	Sustained or vigilance	Visual Cancellation Test	[75]
	Selective	Stroop Color and Word Test	[30]
	Alternating	Trail Making Test- – Part B (TMT-B)	[60]
Executive function	Disexecutive syndrome	Behavioural Assessment of the Dysexecutive Syndrome	[77]
	Fluency	Verbal fluency	[40]
	Working memory	Letter-Number (WAIS-IV)	[72, 74]
	Flexibility and analogic reasoning	Wisconsin Card Sorting Test (WCST)	[53]
	Interference and inhibitory control	Go/No- Go Task	
	Planning	Key Search and Zoo Map (BADS) Plan	[77]
	Decision-making	Iowa Gambling Task (IGT)	[6]
Memory	Broad function	Wechsler Memory Scale (WMS-III)	[71, 73]
	Short-term/working memory	Letter-Number, Arithmetic, and Digit Span (WMS-III)	[71, 73]
	Episodic long-term	Rey Auditory Verbal Learning Test (R-AVLT)	[62]
	Semantic long-term	Boston Naming Test	[37]
	Procedural	Rivermead Behavioural Memory Test (RBMT)	[1]
Visuospatial and perceptual abilities		Rey-Osterrieth Complex Figure	[61]
Language and communication skills		Information and Comprehension (WAIS-IV)	[72, 74]
Premorbid and morbid intelligence		Wechsler Adult Intelligence Scale-IV (WAIS-IV)	[72, 74]
		National Adult Reading Test (NART)	[54, 55]

relevant tests to evaluate neuropsychological performance (see Table 41.3).

41.4 Psychosocial Functioning and Quality of Life

Alcohol and other drug use disorders are increasingly viewed as chronic conditions. This approach addresses the impact of disorder and resources on patient's overall well-being. From this perspective, integrative intervention in addictive behaviors should aim for the broad goal of recovery, which is defined as abstinence plus improved quality of life and psychosocial functioning. These social markers are essential in treatment planning and outcome assessment as they represent the abilities and skills of the individual to function independently in the community.

41.4.1 Disability

- Disability Assessment Schedule 2.0 [79]. The WHODAS 2.0 was developed through a collaborative international approach, with the aim of developing a single generic instrument for assessing health status and disability across different cultures and settings. It is short, simple, and easy to administer, and one first-level general disability factor and six second-level standardized domains may be obtained: cognition, mobility, self-care, getting along, life activities, and participation.

41.4.2 Quality of Life

- Quality of Life Enjoyment and Satisfaction Questionnaire [24]. The Q-LES-Q is a self-

administered scale of 93 items designed to measure satisfaction and enjoyment in various domains of functioning: physical health and activities, mood state, work, household duties, academic/occupational activities, leisure and hobbies, social relationships, and general activities. There are various short forms available.

- World Health Organization Quality of Life Assessment [58]. The WHOQOL-100 includes 24 facets relating to quality of life, which are grouped into 4 larger domains: physical, psychological, social relationships, and environment. It also includes one facet examining overall quality of life and general health perceptions. There is an abbreviated, self-administered, 26-item version, the WHOQOL-BREF [65], which produces only domain scores.

41.4.3 Functioning

- Global Assessment of Function [2, 3]. The GAF is a 100-point tool rating overall psychological, social, and occupational functioning of people over 18 years of age and older. It excludes physical and environmental impairment. Scores range from 100 (extremely high functioning) to 1 (severely impaired). It has been replaced in the fifth edition of the Diagnostic and Statistical Manual for Mental Disorders (DSM-5) with the WHO Disability Assessment Schedule (WHODAS) which is supposed to be more detailed and objective than this brief global impression.
- Personal and Social Performance Scale [52]. The PSP is a global measure of personal and social functioning based on four domains of function: self-care, socially useful activities, personal and social relationships, and disturbing and aggressive behavior. Scores may vary from 0 to 100, with a higher score indicating a higher level of social and personal functioning.

Abstract

Alcohol-related disorders are common, expensive in their entire course, and often underdiagnosed. To facilitate early diagnosis and therapy of alcohol-related disorders and thus prevent later complications, questionnaires and biomarkers are useful. Indirect state markers such as gamma-glutamyl transpeptidase (GGT), mean corpuscular volume (MCV), and carbohydrate deficiency transferrin (CDT) are influenced by age, gender, various substances, and nonalcohol-related illnesses and do not cover the entire timeline for alcohol consumption. Direct state markers such as ethyl glucuronide (EtG), phosphatidylethanol (PEth), and fatty acid ethyl esters (FAEEs) have gained enormous interest in the last decades, as they are metabolites of alcohol becoming only positive in the presence of alcohol. As biomarkers with high sensitivity and specificity covering the complimentary timeline, they are already routinely in use and contribute to new perspectives in prevention, interdisciplinary cooperation, diagnosis, and therapy of alcohol-related disorders.

Keywords

Alcohol biomarker · Ethanol metabolites · Traditional biomarkers · Ethyl glucuronide · Phosphatidylethanol · Gamma-glutamyl transferase

Introductory Paragraph

Alcohol biomarkers offer the opportunity to objectively assess alcohol intake. According to their specific characteristics, they provide different types of information: from abstinence monitoring to heavy use over time. If appropriately applied and used in conjunction with self-reports and questionnaires, they become an indispensable tool in the assessment and treatment of many conditions, such as alcohol use disorders, evaluation of liver transplant candidates, forensic evaluations, and others.

42.1 Introduction

Alcohol-related disorders are in the top ten of the most common diseases worldwide. The point prevalence for alcohol dependence in Germany, as in other comparable countries, is 5%, and the lifetime prevalence is 10%. Worldwide, approximately 4% of deaths are attributable to alcohol, greater than deaths caused by HIV, violence, or tuberculosis [1]. The yearly costs attributable to alcohol in Europe are approximately 270 billion €. Costs produced by alcohol include both direct costs (i.e., costs in which goods or services are being used or delivered such as medical care) and indirect costs (those stemming from lost productivity due to illness, death, or accidents). Another relevant source of costs attributable to alcohol is intangible costs (costs which are not related to any material loss: e.g., emotional suffering). Importantly, many of these costs are borne not only by the individual drinking alcohol but by society as a whole (the so-called social costs) [2].

Of all alcohol-dependent individuals, it is estimated that only about 10% receive specific treatment, most of them by their general practitioner (about 80%) and only a minority in specialized settings or general hospitals [3].

Thus, alcohol-related disorders are common, expensive in their entire course, and often underdiagnosed.

To facilitate early diagnosis and therapy of alcohol-related disorders and thus prevent later complications, questionnaires such as the CAGE questionnaire or the Alcohol Use Disorders Identification Test (AUDIT) are useful. Biomarkers also play an important role in many of the stages of alcohol use disorders, from screening and early detection to treatment monitoring, especially in abstinence-oriented settings [4, 5].

Indirect state markers as well as direct state markers are routinely used to detect alcohol. The indirect state markers such as gamma-glutamyl transpeptidase (GGT), mean corpuscular volume (MCV), and carbohydrate deficiency transferrin (CDT) are influenced by age, gender, various substances, and nonalcohol-related illnesses and do not cover the entire timeline for alcohol consumption, meaning that they need prolonged ingestion of relatively high amounts of alcohol to become elevated [6].

On the other hand, direct state markers have gained enormous interest in the last decades as they are metabolites of alcohol becoming only positive in the presence of alcohol. As biomarkers with high sensitivity and specificity covering the complimentary timeline, they are already routinely in use and contribute to new perspectives in prevention, interdisciplinary cooperation, diagnosis, and therapy of alcohol-related disorders.

42.1.1 Direct Ethanol Metabolites

Routinely used direct ethanol metabolites are as follows:

- Ethyl glucuronide (EtG) in serum, urine, and hair
- Ethyl sulfate (EtS) in urine and serum
- Phosphatidylethanol (PEth) in whole blood
- Fatty acid ethyl ester (FAEEs) especially in hair

Ethanol metabolites are detectable in serum for hours, in urine for up to 7 days, in whole blood over 2 weeks, and in hair over months.

42.2 Ethyl Glucuronide

Ethyl glucuronide (EtG) is a phase II metabolite of ethanol and has a molecular weight of 222 g/mol. It is metabolized by the UDP-glucuronosyltransferase.

Only about 0.5% of all the ethanol ingested undergoes this degradation pathway, but it can function as a biomarker as it is only detectable in the presence of ethanol. Moreover, EtG is non-volatile, water-soluble, and stable in storage and can, depending on the amount consumed and time spent for consumption, still be detectable in the body long after completion of alcohol elimination [7]. It can be detected of up to 90 hours in urine. There is no difference regarding the elimination rate between a healthy population and heavy alcohol consumers at the beginning of detoxification treatment [8]. Ethyl glucuronide can also be detected in postmortem body fluids and tissues such as the gluteal and abdominal fat, liver, brain, and cerebrospinal fluid and even in the bone marrow and muscle tissue.

Compared to traditional biomarkers, ethyl glucuronide displays a high sensitivity. Even small amounts like 0.1 L champagne can be detected up to 27 hours with this biomarker. Experiments with 1 g ethanol (champagne, whisky) as well as the use of mouthwash and hand sanitizer gels might yield positive ethyl glucuronide concentrations, usually with values of less than 1 mg/L in urine [9]. Measurable concentrations in urine can be found up to 11 hours after ingestion.

This aspect is of relevance regarding unintentional exposure of alcohol: Pralines, nonalcoholic beer, pharmaceutical products, fruit juice, sauerkraut, mouthwash products, and hand sanitizer gels may contain small amounts of alcohol. Even the intake of 21–42 g yeast with approximately 50 g sugar leads to measurable EtG and EtS concentrations in the urine.

Therefore, a patients' claim not having consumed alcohol may be the truth even when EtG is detectable in the urine. Since patients in withdrawal treatment should avoid even the smallest amount of alcohol, they have to be informed of such hidden sources of ethanol to avoid unintentional alcohol intake. A differential cutoff of 0.1 mg/L in cases where total abstinence is the goal and 1.0 mg/L if small amounts of alcohol intake are tolerated have been recommended for practical reasons. Applying these cutoffs, the probability of false-positive results is very low [10].

> Sometimes a positive ethyl glucuronide in the urine will be a true laboratory positive, but a false clinical positive, meaning that the patient has not intentionally ingested significant amounts of ethanol. However, using appropriate cutoffs, this would be a low probability situation.

42.2.1 Selected Applications for the Use of EtG

1. Outpatient addiction treatment programs

   Regular alcohol screening is a frequent intervention in many outpatient addiction treatment settings. Urine ethyl glucuronide has shown a higher sensitivity compared to traditional screening methods in this population, providing a more accurate feedback to both patients and professionals. In a former study, the percentage of urine positive samples screened with ethanol was less than 2%, whereas the same samples screened positive for ethyl glucuronide in almost 22% of the cases [11].
2. Specific high-risk group

   Many patients in opioid-maintenance therapy suffer from hepatitis C (HCV) infection. Alcohol consumption especially in large amounts leads to the progression of cirrhosis. Previous studies showed the usefulness and necessity of the determination of ethyl glucuronide in patients in opioid-maintenance therapy. For example, one study showed that, of all EtG positive patients, 42% ($n = 8$ of 19) would have not reported the alcohol consumption [12]. The use of direct ethanol metabolites in high-risk groups therefore allows more possibilities for therapeutic interventions,

consequently leading to improvement in the quality of life.

3. Monitoring programs

   One example for using ethyl glucuronide successfully in monitoring programs is the physician health programs in the USA which provide a non-disciplinary therapeutic program for physicians with potentially impairing health conditions as, for example, substance-related disorders. Being in the monitoring program, physicians with substance-related disorders are allowed to keep on working provided a regularly proof of abstinence has to be shown. Measuring EtG in urine, Skipper and colleagues showed that of 100 random samples collected, no sample was positive for alcohol using standard testing; however, seven were positive for EtG (0.5–196 mg/l), suggesting recent alcohol use. EtG testing can provide additional information and consequently may lead to further treatment and improvement for the patient [13].

4. Pharmacotherapeutic studies

   As an objective outcome parameter, EtG testing has shown to be useful in pharmacotherapeutic studies [14].

5. Liver transplantation

   Up to 30% of liver transplantations are related to alcohol. Postoperatively, 20–25% of patients lapse or relapse to alcohol intake. In 18 patients with ALD (alcohol liver disease), Erim et al. found no self-report of alcohol consumption. One out of 127 tests for breath alcohol was positive, whereas 24 of 49 urine samples were positive for EtG. Comparable results were reported by another study which found self-reported alcohol consumption in 3% in contrast to 20% positive urine EtG and EtS tests [15].

6. Pregnant women

   Alcohol intake during pregnancy is a well-established risk factor for developmental impairments, especially fetal alcohol spectrum disorders (FASD). It is also known that a relevant proportion of pregnant women drink alcohol. Therefore, alcohol screening during pregnancy should be routinely conducted. Alcohol intake during pregnancy can be investigated in maternal (including hair, blood, urine) and fetal specimens (meconium). Similarly to other groups, self-reports and other questionnaires tend to underestimate alcohol intake. Ethyl glucuronide both in urine and meconium has been shown to improve the detection of drinking [16].

The above mentioned applications show that ethyl glucuronide tests are complementary to self-reports and questionnaires, yielding valuable information on alcohol consumption which is relevant to diagnosis and therapy.

> Irrespective of the setting and population where it is applied, ethyl glucuronide always displays a significantly greater sensitivity for the detection of alcohol drinking when compared to questionnaires, self-reports, and traditional biomarkers. However, the information it provides must always be considered as complementary to that obtained from other sources.

42.2.2 Methodological Aspects

The gold standard for the detection of ethyl glucuronide is liquid chromatography-tandem mass spectrometry (LC/MS-MS), and it remains the only valid method of analysis in enquiries with medicolegal relevance [17]. However, availability and cost issues prevent this method to become ubiquitous.

Fortunately, a DRI ethyl glucuronide enzyme immunoassay ([DRI-EtG EIA) became commercially available a decade ago. It is a semiquantitative method with a clinical cutoff of 500 ng/ml. It also offers a low and clinically relevant analytical range (15.3–2000 ng/ml). Its validity is very similar to that of the gold standard.

The last available method of analysis has been the appearance of point-of-care EtG immunoassay dipcards, which are commercially available at a very low cost. A recent study suggests the validity of the method to be high [18].

42.2.3 Limitations

A potential problem with EtG is the potential false-negative results produced by urinary tract infections, especially *E. coli*, which is able to degrade EtG. That, however, does not happen with ethyl sulfate, which remains stable in spite of the infection. This leads some authors to recommend simultaneous analysis of both biomarkers when a false-negative result is suspected for EtG. Interestingly, a recent study reported that the bacterial degradation of EtG by *E. coli* can be prevented by the use of dried urine on filter paper.

Given the impact alcohol has on liver function, it is important to remark that liver disease does not influence on the validity of EtG, as has been shown in studies conducted in patients with liver disease, including cirrhosis. Similarly, previous studies also suggest that race, nicotine consumption, body mass index, and body water content do not influence EtG concentrations. Conversely, reduced renal function seems to prolong the elimination time of EtG. Other potential factors affecting EtG levels are age, gender, and cannabis consumption.

42.2.4 Clinical Impact of Ethyl Glucuronide

Traditional biomarker validation studies rely on cross-sectional designs where sensitivity and specificity are the cornerstone of the evidence-gathering process. Accordingly, EtG has shown a high sensitivity and also high predictive values, both positive and negative, both in experimental and clinical settings.

However, cross-sectional validation prevents linking biomarker properties to patient outcomes on a longitudinal basis. A recent publication of a diagnostic randomized clinical trial where ethyl glucuronide was compared to ethanol in a randomized design [19] enabled the connection of biomarker properties and diagnostic performance to patient outcomes, demonstrating that implementing ethyl glucuronide in the routine screening of alcohol-dependent outpatients leads to decreased drinking and increased rates of abstinence over time.

> Recent evidence suggest that the application of a highly sensitive biomarker such as ethyl glucuronide has therapeutic properties, leading to reduced drinking and increased abstinence rates, probably due to increased feedback to both professionals and patients about their drinking.

42.3 Ethyl Sulfate

Ethyl sulfate (EtS) presents a secondary elimination pathway for alcohol and is usually detectable in varying interindividual concentrations. An immunochemical detection test is currently not commercially available for EtS. For combined detection of EtS and EtG, the use of rapid LC/MS-MS procedures is routinely applied. It is normally measured in urine, although it can also be assessed in plasma.

The formation is effected by sulfonyl transferase and the breakdown by sulfatases. The molecular weight is 126 g/mol and the molecular formula $C_2H_5SO_4H$.

Currently, a LC/MS-MS method with pentadeuterium EtS as internal standard and two ion transitions can be used in forensic and medicolegal cases as well as in clinical routine. The fact that its formation route is different to that of EtG offers the opportunity of increased sensitivity when analyzing the two biomarkers together. However, the discrepancies between the two are usually low [20].

In summary, a cutoff of 0.05 mg/l for repeated alcohol intake has been suggested. As for ethyl glucuronide, there is evidence of prolonged elimination in reduced renal function. Importantly, bacterial degradation of EtS has not been described. Therefore, EtS should be analyzed in conjunction with EtG when degradation of this biomarker is suspected, in order to prevent the appearance of a false-negative result.

Ethyl sulfate is seldom analyzed alone. Usually, both EtG and EtS are assessed, in order to complement each other's information. EtS might help prevent false-negative results due to bacterial degradation of EtG, especially by *E. coli*, and it might also increase the sensitivity of EtG alone.

42.4 Fatty Acid Ethyl Esters

In recent years, the existence of fatty acid ethyl esters and non-oxidative metabolic products of ethanol in the blood and various organs with reduced or deficient capacity to oxidize ethanol after consumption has been proven. Since these esters were proven to cause damage to subcellular structures, they were postulated to be mediators of organ damage.

Two enzymes catalyze the formation of FAEE: acyl coenzyme a-ethanol o-acyltransferase (AEAT) and fatty acid ethyl ester-synthase. FAEE-synthase can be isolated from the rabbit myocardium, human brain, and rat fat tissue. Two of these FAEE-synthases were shown to be identical to rat liver carboxyl esterase. Furthermore, pancreatic lipase, lipoprotein lipase, and glutathione transferase were shown to possess FAEE-synthase activity.

Fatty acid ethyl esters are formed in the presence of ethanol from free fatty acids, triglycerides, lipoproteins, or phospholipids affected by specific cytosolic or microsomal FAEE-synthases or through acyl coenzyme a-ethanol o-acyltransferase. Detectable levels are found in the blood shortly after alcohol consumption and remain positive for more than 24 hours.

Of 15 different FAEEs in hair, the sum of four of these (ethyl stearate, ethyl oleate, ethyl myristat, and ethyl palmitate) is shown to function as a marker in hair analysis. With a cutoff of 0.5 ng/ml, a sensitivity and a specificity of 90% were reported. A differentiation between abstinent, social, and excessive drinkers appears possible [21]. However, the complex GC/MS method lacks practicability for routine use.

42.5 Phosphatidylethanol

Phosphatidylethanol is an abnormal phospholipid formed in the presence of alcohol via the action of phospholipase D. The precursor is the naturally existing lipid-phosphatidylcholine. PEth consists of glycerol which is substituted at positions sn1 and sn2 by fatty acids and a phosphate group at position sn3 esterified with ethanol. Due to the variations of the fatty acids, various analogs of PEth can be detected. The PEth analogs 16:0/18:1 and 16:0/18:2 are most prevalent, and their combined sum correlates better with PEth than PEth 16:0/18:1 or PEth 16:0/18:2 alone.

Using the original HPLC methods, repeated consumption of more than 50 g alcohol over 2–3 weeks yielded positive results, lately even with daily consumption over 40 g [22].

A drinking experiment [23] with healthy persons with a target blood ethanol concentration of 1 g/kg (1 per mille) once on each of 5 consecutive days yielded PEth values up to 237 ng/ml. Measurements were performed with LC/MS-MS. In contrast to alcohol-dependent patients, the values were reported to be up to 213,000 ng/ml [24].

Various studies found no false-positive results. A linear relationship between consumed amounts of alcohol with phosphatidylethanol values has been described [22].

Interestingly, and thanks to constant refinements in analytical methods, the sensitivity and specificity of current PEth analysis seem to be extremely high [25]. Also relevant is the fact that, besides its already known potential for abstinence monitoring, current evidence suggests PEth could be a suitable biomarker for the differentiation between light and heavy drinking, a feature that is lacking in other direct alcohol biomarkers [26].

Importantly, PEth values seem not to be influenced by liver diseases and hypertension [27].

Among the new direct alcohol biomarkers, PEth seems to be the only one capable of assessing abstinence and also differentiating between light, moderate, and heavy drinking.

42.5.1 Methodological Aspects

The current approach for PEth determination is LC/MS and LC/MS-MS methods. These methods facilitate detection and quantification of single analogs, if a reference is available.

For everyday practical use, the use of dried blood spots may be of significant relevance. This method is suggested to have results similar to whole-blood measures. Furthermore, there is no difference between venous or capillary blood collection [28]. Sampling is simplified as nonmedical staff can obtain capillary blood, the risks for HIV and hepatitis C infections are decreased, and storage and transport are simplified.

42.5.2 Clinical Applications

Similar to what has been described with ethyl glucuronide, phosphatidylethanol has shown a high degree of sensitivity and specificity for the detection of alcohol drinking. It has been applied to different populations and clinical settings, such as HIV populations, pregnant women, and alcohol-dependent patients [29].

Interestingly, it seems like PEth shows good correlations with AUDIT-C scores [30]. Therefore, PEth might be a potential biomarker of heavy alcohol consumption over time.

Finally, some authors suggest that PEth might have a role in patients who are tested for EtG and EtS, have low positive values, and deny alcohol consumption, as a further evaluation with an even more sensitive biomarker.

42.5.3 Limitations

In blood and tissues containing ethanol, the formation of PEth under certain conditions may be feasible. Without influencing the PEth levels, whole-blood samples can be stored frozen at −80 °C [31], and DBS can be stored for at least 30 days at −20 °C [32].

In vitro formation of PEth in erythrocytes has been reported after addition of ethanol. Further experimental studies in rats showed that ceramide is able to block the activity of phospholipase D and inhibits the synthesis of PEth.

42.6 Hair Analyses

Hair analysis has been established to assess ethanol intake. FAEE and ethyl glucuronide (EtG), two metabolic by-products of ethanol, are gaining attention as alcohol markers in the hair.

The time frame for the detection of alcohol consumption is longer in the hair compared to blood or urine. Due to head hair growth of 1 cm per month, depending on the hair length, evidence of alcohol consumption can be found for the respective time period. The deposit of lipophilic FAEE in the hair occurs in sebum, whereas hydrophilic EtG is incorporated through perspiration and/or from blood.

Measurement of FAEE and EtG allows differentiation between chronic excessive and moderate alcohol consumption as well as abstinence or very low levels of alcohol consumption.

In a last consensus from the Society of Hair Testing, an essential change of the consensus was accepted for the FAEEs, where the concentration of ethyl palmitate (EtPa) can be used autonomously for interpretation instead of the concentration sum (ΣFAEE) of the four esters ethyl myristate, ethyl palmitate, ethyl oleate, and ethyl stearate, as previously applied [33]. The EtPa cutoff for abstinence assessment was defined at 0.12 ng/mg for the 0–3 cm segment and at 0.15 ng/mg for the 0–6 cm segment. The cutoff for chronic excessive drinking was fixed at 0.35 ng/mg for the 0–3 cm segment and at 0.45 ng/mg for the 0–6 cm segment. The use of EtPa with these cutoffs in place of ΣFAEE for alcohol intake assessment produces only a minor loss in discrimination power, leads to no essential difference in the interpretation concerning chronic excessive alcohol consumption, and is suitable to confirm EtG results in abstinence assessment.

An EtG concentration of over 30 pg/mg hair is interpreted as definite evidence for excessive and regular alcohol consumption (>60 g EtOH per day), whereas an EtG concentration of more than 7 pg/mg is a marker of frequent alcohol use. If samples less than 3 cm or greater than 6 cm are used, the results should be interpreted with caution. The analysis of FAEEs alone is not recommended to determine abstinence from ethanol.

For abstinence assessment, EtG should be the first choice, and the analysis of FAEEs alone is not recommended to determine abstinence from ethanol. A positive FAEE result combined with an EtG below 7 pg/mg does not clearly disprove abstinence but indicates the need for further monitoring. The combined use of FAEE and EtG can be recommended to increase the validity of hair analysis [34].

In an alcohol drinking experiment, 32 women who consumed 16 g alcohol per day had EtG values of less than 7 pg in their scalp hair [27]. These divergent results may be explained by the fact that EtG values lower than 7 pg/mg do not exclude alcohol ingestion. Furthermore, scalp hair was pre-analytically cut in this study, while previous studies pulverized the specimen: The preparation pre-analytically has been reported to influence the results significantly [35].

42.6.1 Other Influencing Factors

Whereas only in one case a false-positive result for EtG in the hair after use of EtG containing shampoo has been reported, regular use of alcohol-containing hair tonic can lead to false-positive FAEE results. No such false-positive results are reported for EtG. Impaired kidney function may lead to higher EtG levels, as preliminary results indicate. BMI showed to have also an influence on EtG concentration in the hair.

False-negative results for both alcohol markers can also be caused by the use of hair cosmetics, such as alkaline hair cosmetics for FAEE [36] or oxidative treatment for EtG and hair straightening for EtG. Cleansing shampoos may also alter EtG and FAEE concentrations in hair.

The hair color and melanin content in hair play no role, in contrast to drugs and medications. In segmental investigations of hair samples, a chronological correlation to drink or abstinent phase with FAEE is not possible, but for EtG, two studies have shown this to be feasible.

Altogether, hair analysis for FAEE or EtG is currently a sensible tool to clarify past alcohol consumption, as demonstrated in many studies.

42.6.2 Practical Use

Hair analysis for FSEE or EtG is applicable in several contexts including judging driving ability and forensic psychiatry. Another clinical use of alcohol metabolite measures is the screening for alcohol use in medication- assisted treatment of opioid-dependent subjects as mentioned above

42.7 Summary

In summary, specific ethanol metabolites are available which can detect the spectrum between short-term intake of small amounts and long-term use of large amounts of alcohol (s. Table 42.1). Cutoff values and influencing factors are summarized in Tables 42.2 and 42.3. Appropriate methods of analysis and pre-analytics are crucial for a valid and reliable detection of markers. For ethyl glucuronide (EtG), the most frequently used marker, the best method for detection is chromatographic approach which is considered a standard method especially in forensic cases. A commercial test

Table 42.1 Clinically relevant options for determination of direct biomarkers, with respect to amount and duration of alcohol intake

Duration of consumption	Amount of consumption	
	>1 g/d	>40–60 g/d
<1 day	Serum, urine: EtOH, EtG, EtS	Serum and urine: EtOH, EtG, EtS; PEth in whole blood and dried blood spots (LC/MS-MS)
>1 day	Serum, urine: EtOH, EtG, EtS	Serum and urine: EtOH, EtG, EtS; PEth in whole blood and dried blood spots (LC/MS-MS)
>14 days	Serum, urine: EtOH, EtG, EtS	Serum and urine: EtOH, EtG, EtS; PEth in whole blood and dried blood spots (HPLC LC/MS-MS)
Weeks to months	Serum, urine: EtOH, EtG, EtS	Serum and urine: EtOH, EtG, EtS; PEth in whole blood and dried blood spots (HPLC LC/MS-MS), EtG and FAEEs in hair

Modified according to Thon et al. [37]
EtOH ethanol, *EtG* ethyl glucuronide, *EtS* ethyl sulfate, *PEth* phosphatidylethanol, *FAEE* fatty -acid ethyl esters

Table 42.2 Clinically relevant options for determination of direct biomarkers, with respect to amount and duration of alcohol intake

Biomarkers	Amount of consumption	Cutoff
EtG in hair	Abstinence and low intake (<10 g alc/d)	<7 pg/mg
	Social consumption (20–40 g/d)	7–30 pg/mg
	Excessive drinking (>60 g/d)	>30 pg/mg
FAEEs in hair	Repeated alcohol intake	≥200 pg/mg
	Excessive intake	≥500 pg/mg
EtG in urine	Total abstinence	0.1 mg/L
	Unintentional intake Recent alcohol use Longer back-dated alcohol intake in larger amounts	0.1 mg/l–0.5 mg/L
	Unintentional intake unlikely, but possible, active alcohol intake probable	0.5–1 mg/L
EtS in urine	Total abstinence	0.05 mg/L
PEth	>40 g/d, more than 2 weeks alcohol intake at least once with 1‰ detectable	HPLC, 0.22 μM; LC/MS-MS, 20/30 ng/ml; PEth, 16:0/18:1 or 0.05 μM

Modified according to Thon et al. [37]
EtG ethyl glucuronide, *FAEEs* fatty -acid ethyl esters in hair, *EtS* ethyl sulfate, *PEth* phosphatidylethanol

Table 42.3 Detection of direct biomarker, with respect to amount and duration of alcohol intake

Direct biomarkers	Potential influencing factor	Influence
EtG in urine	*E. coli*, dried urine spots	No
	Grade of liver disease, smoking, BMI, body water content, reduced kidney function	No
EtS in urine	*E. coli*, dried urine spots	No
PEth	Liver disease	No
	Hypertension	No
	Storage of ethanol blood samples Refrigerator temperature, −80 °C	No
EtG in hair	Hairsprays with ethanol, hair color, melanin content, age, gender, BMI	No
Direct biomarkers	**Potential influencing factor**	**Type of influence**
EtG in urine	*E. coli*, *C. sordellii*	Decrease
	Reduced kidney function	Longer detection
	Chloral hydrate	False positives
EtS in urine	Reduced kidney function	Longer detection
	Closed Bottle Test (OECD 301 D) Manometer Respiratory Test (MRT)	28 days' stable detection, depletion after 6 days
FAEEs in hair	Aggressive alkaline hairsprays	False negative
	Hairsprays with ethanol	False positives
PEth	Ethanol-containing blood samples, storage of ethanol blood samples at RT and − 20 °C	Increase
EtG in hair	Hairspray with EtG	Increase
	Reduced kidney function	Increase
	Bleaching, hairstyling products	False negative

Modified according to Thon et al. [37]
EtG ethyl glucuronide, *FAEE* fatty -acid ethyl esters, *EtS* ethyl sulfate, *PEth* phosphatidylethanol, *BMI* body – mass index, *RT* room ambient temperature, *E. coli Escherichia coli*, *C. sordellii Clostridium sordellii*

kit is available and contributed to wide distribution of the test. Of course, lab values always require critical reappraisal. However, EtG is detectable in urine using LC/MS-MS even after an ingestion of low amounts of alcohol (1 g), which also occurs in some food, drugs, and disinfectants. Individuals with the motivation to or obligation for abstinence have to be informed about these "hidden contents" to avoid involuntary intake of alcohol. For forensic purposes, the current cutoff value of 0.1 mg/L should be adapted to exclude cases of involuntary alcohol use. With respect to differences in formation and degradation, EtG and ethyl sulfate (EtS) should be analyzed together, if possible. In the absence of known influencing factors, EtG in the hair can be recommended as a marker for alcohol intake for the last 3 months. Further, guidelines for interpretations of values from international society (SOHT) are available. While positive urine values of EtG and EtS can be in accord with innocent/unintentional alcohol intake, positive values of PEth are related to previous intoxications of 0.5‰ and more. The use of "dried blood spots" is promising and may facilitate sample taking, storage, distribution, and decrease of infection risk.

42.8 Traditional Biomarkers for Alcohol Consumption

Many clinical-chemical parameters show pathological changes as evidence of the biochemical burden of ethanol metabolism. None of these conventional indicators show 100% sensitivity or specificity. Nonetheless, evidence of long-term alcohol consumption can be obtained from these state markers, especially a combination of several individual indicators. The currently used and potential alcohol biomarkers are shown in Table 42.4.

Table 42.4 Diagnostic characteristics of several conventional and potential alcohol biomarkers

Alcohol biomarker (abbreviation)	Window of assessment	Specificity/ sensitivity	Type of alcohol consumption	Application	Specific comments
Conventional alcohol biomarkers					
Ethanol (EtOH)	6 hours	High/high	Recent alcohol consumption/ alcohol intoxication	In traffic safety/ emergency department	In combination with clinical observations – monitoring alcohol habits
Gamma-glutamyl transferase (GGT)	2–8 weeks	Moderate/ moderate	Chronic, heavy	Screening/ monitoring	More specific for alcoholics ages 30–50 years
Aminotransferase ratio AST/ALT ≥ 2	Unknown	High/low	Heavy	Alcoholic hepatitis/ relapse	Less frequently used than GGT for screening heavy alcoholics
Mean corpuscular volume (MCV)	Up to several months	Moderate to high/low	Chronic	Screening/fetal alcohol effects	Show dose-dependent response to the intensity of alcohol intake
Carbohydrate-deficient transferrin (CDT)	2–3 weeks	High/ moderate	Heavy	Screening/ monitoring/ relapse	No elevation in single episodes of acute alcohol intoxication
GGT-CDT	2–3 necks	High-high	Heavy	Abstinence/ relapse	Useful for diagnostic alcohol-liver damage due to excessive and prolonged intake
Potential alcohol biomarkers and devices					
Ethyl glucuronide (EtG) and ethyl sulfate (EtS)	Several days	High/high	Recent alcohol consumption	Abstinence/ relapse	High inter-individual variations

(continued)

Table 42.4 (continued)

Alcohol biomarker (abbreviation)	Window of assessment	Specificity/ sensitivity	Type of alcohol consumption	Application	Specific comments
Phosphatidylinositol (PEth)	1–2 necks	Unknown/ high	Heavy	Screening/ relapse	Promising in differentiating alcohol – from non-alcohol-induced liver disease
Fatty acid ethyl esters (FAEEs)	24 hours (after ingestion)/99 hours (heavy drinking)	High/high	Recent heavy	Distinguishing social drinkers from heavy	Combination of FAEE and EtG in meconium – markers for fetal alcohol exposure
Whole blood-associated acetaldehyde assay (WBAA)	Unknown	High/high	Chronic/heavy	Monitoring abstinence	IgAs against acetaldehyde protein adducts – promising in differentiating alcohol – from non-alcohol- induced liver disease
Total sialic acid (TSA)	Unknown	Between GGT and ALT	Chronic, heavy	Relapse	Increased in high alcohol consumption and reduced during abstinence, especially among women
5-HTOL/5-HIAA	1 day	High/high	Recent alcohol consumption	Evaluation of treatment/ relapse	5-HTOL/5-HIAA > 20 marker of recent drinking
Transdermal devices (SCRAM, WrisTAS)	–	High/high	Record continuous alcohol consumption	By court monitoring of abstinence	Need product improvements

From Topic and Djukic [38]

42.8.1 Blood Alcohol Content Calculation

A mathematical estimation of blood alcohol content is useful when blood alcohol is not currently detectable or for prediction of alcohol level. While there are several ways to calculate it, the simplest is Widmark's equation: $Co = A/[p \times r]$, where Co is the theoretical maximum concentration of alcohol in the blood (mg/g), A is the amount of alcohol in the body (g), p is the body weight (kg), r is the correction factor corresponding to the ratio of total body water and blood water (0.6 for females and 0.7 for males).

Gender plays an important role in the total amount of water in the body. In general, men have less fatty tissue and higher percentage of water (58%) than women (49%); thus, volume of distribution (Vd) for ethanol is higher in men. According to its partition coefficient (Poct/water is 0.1), ethanol is ten times more soluble in water than in lipids. Thus, upon ingestion of the same amount of ethanol, the BAC will be higher in females than in males. The Widmark's equation has been improved subsequently by introducing individual r, based on the multiple linear regression equations:

$$\text{For females}: r\text{FI} = 0.31223 - 0.006446 \times \text{body weight}(\text{kg}) + 0.004466 \times \text{body height}(\text{cm})$$

$$\text{For males}: r\text{MI} = 0.31608 - 0.004821 \times \text{body weight}(\text{kg}) + 0.004632 \times \text{body height}(\text{cm})$$

There is no absolute accurate blood alcohol calculator because numerous factors influence the BAC, such as gender (male/female), rate of metabolism/elimination, health status, medications that might be taken, drinking frequency, amount and the type of food in the stomach and small intestine, time when food was eaten, and others [38].

42.9 Gamma-Glutamyl Transferase (γ-GT)

γ-GT is a membrane-bound glycoprotein enzyme which occurs ubiquitous in the organism but mainly in the liver, pancreas, and renal proximal tubules. γ-GT detectable in serum arises mainly from the liver so that an increase in serum enzyme activity would be a sensitive indicator for hepatobiliary diseases. Chronic alcohol consumption induces an increase in enzyme synthesis and, through direct activation of the enzyme from membrane binding, leads to increase of γ-GT in serum. The release of enzymes through liver parenchymal damage also presents a secondary mechanism in chronic alcoholic hepatitis. To exceed the normal values (4–18 U/l in women and 6–28 U/l in men) requires the chronic, daily alcohol intake over at least 4–6 weeks. A short-term, higher alcohol burden causes no such increase. Nevertheless, drinking intensity has more influence on γ-GT than drinking frequency. In absolute alcohol abstinence, normalization of the values occurs within 3 weeks to 60 days.

The sensitivity of γ-GT varies, according to age, gender, and body weight, from 35% to 85%. γ-GT increases with age in heavy alcohol drinkers as well as moderate drinkers. Contrarily, in young adults less than 30 years, even when these are alcohol dependent, the sensitivity of the markers is very low. In addition, the higher vulnerability of women to alcohol-associated liver diseases is well known. Other studies have shown that the relationship between overweight (BMI > 25) and an increase in γ-GT [39] is related. γ-GT levels can also be increased by various other causes, for example, the effects of medication and teratogens, adiposities, diabetes, cholestasis, or inflammatory liver diseases. Accordingly, the specificity of 63–85% is only satisfactory, and γ-GT, in spite of its practicability as solitary indicator of chronic alcohol misuse and current liver diseases, is deemed unsuitable [40].

42.10 Mean Corpuscular Erythrocyte Volume (MCV)

Measurements of MCV are common in standard investigations; an increase occurs in 4% of the general population and in 40–60% of patients with alcohol misuse. Koivisto et al. [41] reported definite evidence of marked dose-dependent relationship between MCV and the intensity of alcohol consumption. Increase in MCV is to be expected in long-term alcohol consumption; by contrast, the values normalize slowly during abstinence over a period of 2–4 months. Compared to γ-GT, the sensitivity of MCV in screening as evidence of alcohol misuse, at least in men, is inferior. In interpreting MCV values, other causes such as vitamin B12 or folic deficiency, nonalcoholic liver diseases, reticulocytosis, and hematologic diseases should be considered.

The mechanism responsible for increasing MCV is hitherto unclear, and direct hematotoxic damage or interaction of ethanol and its metabolites, especially acetaldehyde, with erythrocyte membrane has been suggested [42].

42.11 Carbohydrate-Deficient Transferrin (CDT)

Transferrin is the most important iron transport molecule in humans, and its synthesis and glycolization occur in hepatocytes. Depending on the iron load as well as the number and breakdown of carbohydrate chains, different isoforms can be detected. Differentiation occurs through measurements of isoelectric points (pl), whose values depend on the load of bound iron ions and number of sialic acid residues in carbohydrate chains. Abnormal isoforms with much increased pl-values over 5.65 in the liquor and serum of

alcohol-dependent patients were found and were traced back to small levels of bound sialic acid residues. In subsequent investigations, more precise differentiation in mono-, di-, and asialotransferrin was feasible, and all abnormal isoforms were subgrouped under CDT [43]. All abnormal transferrin molecules increase in chronic alcohol consumption. Measurements with HPLC showed that increased alcohol consumption leads to increased disialotransferrins, while increases in asialotransferrin occur in chronic increased alcohol consumption only. A variety of methods and respective reference levels for the detection of CDT are available. Hitherto, measurements of CDT using HPLC is the reference standard, with routine measurements of various enzyme immunoassays in use. For confirmation analyses, immune electrophoresis is employed, while direct CDT detection method using specific antibodies is still under development [44].

The underlying pathomechanism for CDT development is not exactly known. Inhibition of intracellular transmission of carbohydrates to change through toxic effects from ethanol or acetaldehyde is presumed. Ethanol's influence on the activities of membrane-bound sialine transferases and plasma sialidases in hepatocytes has been discussed, in which an imbalance in favor of sialine acid reduction enzymes occurred.

There has been no agreement in previous studies concerning the correlation between CDT concentrations in serum and the absorbed alcohol amounts. Though an increase in CDT with daily consumption of 60–80 g alcohol over 7 days has been shown, other studies have reported contradicting results. Additionally, contradicting results on the effect of moderate drinking (<40 g alcohol) are found. In alcohol-dependent patients, it is, however, sensitive enough for detecting relapses and monitoring sobriety [45].

The clinical strengths of CDT as a biomarker vary depending on gender, BMI, age, nicotine abuse, and anorexia [46]. Previous studies showed that CDT in men is a more sensitive indicator of alcohol-related diseases compared to women. CDT values in women might be increased under natural conditions but not much in increased alcohol use. Furthermore, hormonal factors appear to play a role – CDT values are definitely increased in pregnant women but reduced in postmenopausal women. Obviously in the female gender, differences in CDT serum activity depend on age as well.

Among the various conventional alcohol markers, CDT is currently considered the most useful and significant indicator [47]. Information on sensitivity and specificity varies, since no methodical standardization exists. Further, the heterogeneity of test populations concerning age, gender, alcohol consumption, duration of abstinence before serum extraction, as well as current liver diseases makes the comparison with other traditional markers difficult. In selected clinical patient groups, various test methods with specificity between 90% and 100% with high sensitivity (50–90%) have been reported.

In WHO/ISBRA study, the sensitivity of CDT with 60% in men was slightly less than that of γ-GT, and in women the sensitivity reached only 29% [6]. False-positive increased CDT values can occur in biliary cirrhotic, autoimmune hepatitis, genetically determined transferrin variants, or the autosomal recessive inherited CDG syndrome. Most patients with liver diseases have insignificantly increased CDT values so that the specificity, especially in comparison with other state markers, must be stated exceptionally high and usually reach at least 90%. Thus, CDT could be used for detection of chronic alcohol consumption and changes in drinking patterns in these patients. With a half-life of 14 days and normalization of CDT values in abstinence, evidence of drinking relapses in the post-acute phase after alcohol withdrawal treatment can be obtained.

42.12 Serum Transaminases (ASAT/ALAT)

Increases of aspartate aminotransferase (ASAT) and alanine aminotransferase (ALAT) in serum are unspecific signs of hepatocellular damage. While ASAT is produced in the liver, skeleton, and cardiac muscle tissues, ALAT is a liver-specific enzyme. Thus, an increase in ALAT practically indicates liver diseases (fatty degeneration, tumors,

metastases, cirrhosis, cholangitis). By contrast, measurements of ASAT must differentiate between alcohol-sensitive, mitochondrial (m-ASAT), and cytoplasmic isoform (c-ASAT). Conclusions on an alcohol-induced liver damage can only be drawn from increased m-ASAT/c-ASAT quotients. Increased ASAT values would be found in alcohol-dependent patients from 39% to 47%. In the WHO/ISBRA study, sensitivity of ASAT between 23% and 45% (women vs. men) could be found. The toxic effects of ethanol on mitochondria lead to increased release of ASAT compared to ALAT. Thus, measurements of de-Ritis-Quotient (ASAT/ALAT) increase the alcohol specificity of both markers – a quotient over 1 and even 2 would offer strong indications for an ethyl toxic etiology.

In summary, the sensitivity and specificity of both enzymes as indicators for alcohol misuse are considered variable so that an interpretation of an increased serum activity is mainly meaningful in the context of other liver values (bilirubin, alkaline phosphatase, γ-GT).

42.13 HDL Cholesterine and Apolipoprotein

Increases in HDL cholesterol and apoprotein I/II are described in many studies as specific and sensitive indicators of chronic alcohol strain; by contrast, triglycerides and total cholesterine are nutritionally influenced. Alcohol leads to an increase in the concentrations of cholesterol and phospholipids within the HDL particles and causes a shift to bigger portions of phospholipids in richer, larger HDL_2 particles [48].

Studies showed this phenomenon to be the basic principle for the observed cardioprotective character of moderate alcohol consumption [49]. Chronic alcohol load causes an increase in HDL over 50 mg/dl, and after withdrawal and with continuing abstinence, the values normalize within 1–4 weeks. The pathogenic cause of alcohol-related HDL and apoprotein increases is postulated to be an enzyme induction as well as increased lipoprotein lipase activity.

Increased HDL levels without alcohol can occur under the influence of medication (sedatives, lovastatin), pronounced underweight, and physical strain. Still, the specificity of this marker is highly esteemed. Moreover, it proved itself to be practicable. Particularly in patients without liver damage, HDL and apoprotein I/II can be used for monitoring abstinence since changes in alcohol consumption would be accurately reflected.

42.14 Cholesteryl Ester Transfer Protein (CETP)

Cholesteryl ester transfer protein is a glycoprotein synthesized in the liver and catalyzed out of HDL particles through lipid diffusion into LDL particles. Through alcohol consumption, the plasma concentration and activity of CETP are reduced, thereby increasing HDL concentration. Moderate drinking, by contrast, hardly influences CETP activity. The sensitivity and specificity of CETP as an alcohol marker can be compared to those of MCV, γ-GT, ASAT, and ALAT. Nonetheless, the use of CETP as an indicator for alcohol misuse is limited by the complex measurement method and by the influence of drugs and various diseases.

42.15 β-Hexosaminidase

β-Hexosaminidase is a lysosomal liver enzyme detected in serum or urine using spectrometric methods. Higher serum activity of this glycoprotein was reported in alcohol-dependent patients. A daily consumption of 60 g alcohol leads to significant serum increases; even short-term alcohol load is reflected in alcohol patients by its low half-life and resulting limited normalization in values (<6, 2 U/l) 2–4 days later. The pathological mechanism in rats is the reduction in biliary elimination of the enzyme in chronic ethanol intake. The specificity of β-hexosaminidase in serum is stated to be 91–98%, and the sensitivity is 69–94%. β-Hexosaminidase activity reflects recent alcohol consumption, while β-hexosaminidase in urine remains increased for longer periods after alcohol consumption (Fig. 42.1).

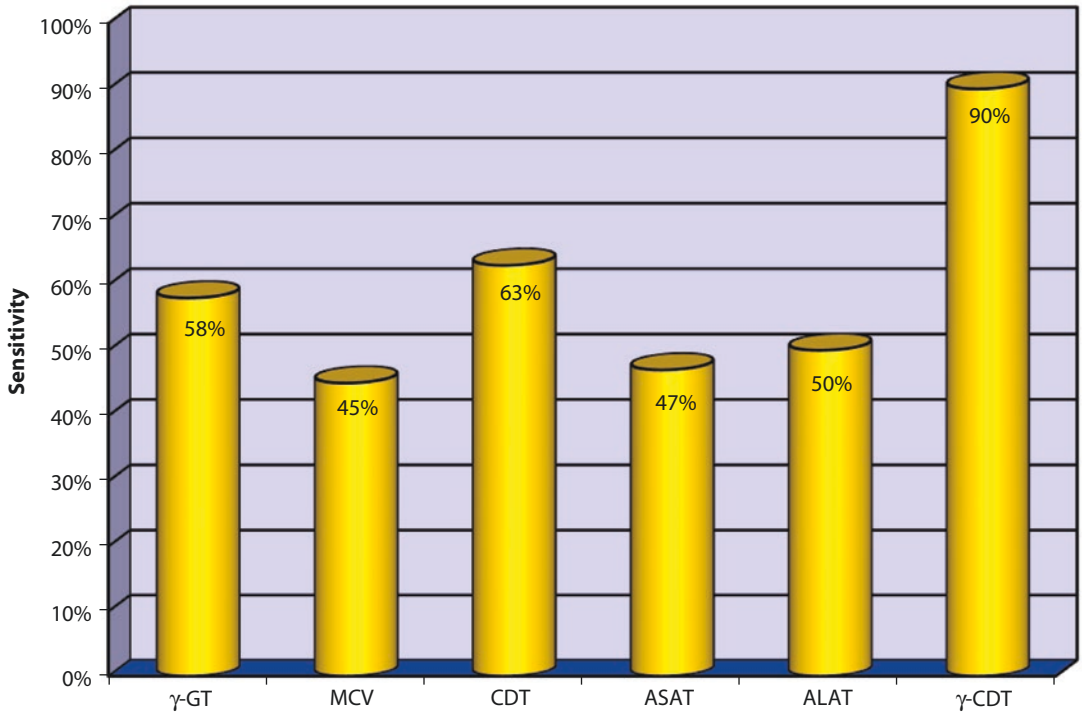

Fig. 42.1 Comparison of sensitivities of conventional markers with γ-CDT. (Modified from Niemelä [50]) [15]

42.16 Methanol (MeOH)

Methanol is a monovalent alcohol produced endogenously; under physiological conditions, the concentration in serum is between 0.5 and 1.0 mg/l. Methanol can be ingested exogenously through alcoholic drinks, fruit juice, and pectin-containing fruits (e.g., bananas or apples). The metabolism of methanol occurs in the liver through alcohol dehydrogenase (ADH), which shows a manifold increased affinity to ethanol compared to methanol even without alcohol ingestion. That being so, in the presence of ethanol in concentrations over 0.2–0.5%, a competitive inhibition of methanol breakdown occurs, which, in continuing ethanol availability, leads to accumulation of endogenous methanol. Should the ingested alcohol also contains methanol (e.g., fruit-flavored gin, whisky), the blood levels would be potentiated even more by endogenous accumulation. The methanol levels normalize itself in alcohol abstinence within several hours to several days. Early evidence of increased blood methanol levels after longer drinking periods was reported in the 1970s, among others. In numerous studies, a coincidence between increased methanol levels and blood alcohol levels has been found. Consequently, methanol values >10 mg/l, which were not caused by normal and short term, even high alcohol load over 1.5–2.0%, were estimated and considered as an indicator for recent alcohol misuse or longer alcohol consumption phase. Despite its high specificity, methanol is only suitable as a short-term state marker because it is rapidly normalized. Its significance lies primarily in screening alcohol misuse in clinical as well as forensic cases.

42.17 Acetone and Isopropanol

Physiologic levels of isopropanol in blood are up to 0.1 mg/l and acetone up to 7 mg/l. Both substances are not found in alcoholic drinks. Isopropanol and acetone are in reciprocal biotransformation process, meaning isopropanol is

reduced to acetone and formed, through oxidehydration, from acetone. Both processes occur via alcohol dehydrogenase. Alcohol load causes an increase in isopropanol in blood; conversely during withdrawal, acetone is increased. Higher isopropanol and acetone levels occur mainly in alcohol-dependent patients with concurrent eating disorders or reduced nutritional intake. It is established practice to pool both substances in serum concentration, and a level of 9 mg/l has been recommended. Still, isopropanol and acetone appear less convincing than methanol as alcohol markers because increased acetone levels also result from metabolic disorders such as ketosis in hunger, diabetes, cooling, and heavy physical strain (Fig. 42.2).

42.18 Combination of Individual State Markers

Since individual conventional alcohol markers were found to be insufficiently sensitive and/or specific for the recognition of alcohol misuse, several important parameters in varying combinations were investigated. The better known combinations comprised of CDT, γ-GT, MCV, and ASAT.

42.19 Gamma-Glutamyl Transferase and Carbohydrate-Deficient Transferrin

Some studies showed that the combined use of γ-GT and CDT resulted in higher sensitivity and specificity compared to use of either one alone. Sillanaukee et al. [52] reported a sensitivity of 75% and specificity of 93% for γ-CDT from 257 alcohol-dependent patients and 362 occasional drinkers. γ-CDT is estimated using the formula **[γ-CDT = 0.8 ln(γ-GT) + 1.3 ln (CDT)]**. Compared to CDT and γ-GT alone, ASAT, ALAT, or MCV showed the logarithmic transformation from γ-GT and CDT to have the best predictive value to differentiate between alcohol-dependent patients and occasional drinkers. Values for γ-CDT correlate to current amounts of consumption, regardless of whether a heavy alcohol-dependent individual or an occasional drinker was tested. γ-CDT can thus be used to monitor abstinence, though in continuing abstinence the values normalize within 2–3 weeks. Considering the cost efficiency and simple application, γ-CDT appears to be a suitable indicator in clinical routine work.

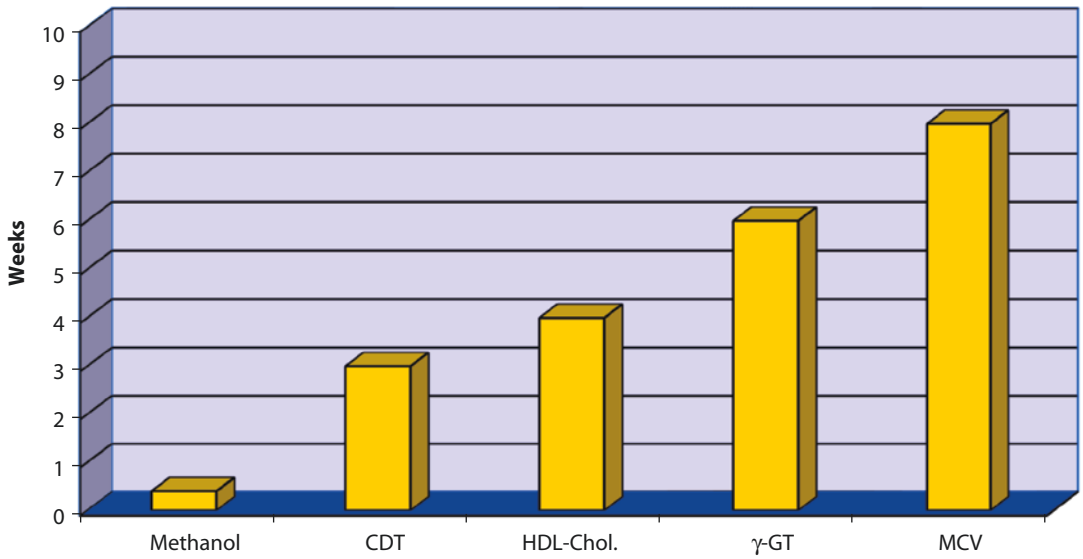

Fig. 42.2 Depiction of alcohol markers in appropriate time lines. (Modified from Gilg [51])

42.20 Alc Index

By combining methanol, acetone/isopropanol, γ-GT, and CDT in a logistic regression formula, Brinkmann et al. [53] developed the so-called Alc index to differentiate between alcohol-dependent patients and nondrinkers. The basic principle for the investigations was the hypothesis that each of these alcohol markers shows overlap in values in the collective with none or low alcohol consumption and alcoholics. From the results, an Alc index of 1.7 as cutoff was defined with a specificity of 100% and a sensitivity of 90% to differentiate between alcohol-dependent and nonalcohol-dependent individuals. The advantage of this index is the single cutoff point instead of four for individual markers, through which it can prevent false conclusions with raised values of an isolated marker.

42.21 Early Detection of Alcohol Consumption (EDAC) Test

EDAC uses results from a series of routine lab parameters to identify heavy drinkers and light drinkers in study groups. Already in the 1980s, attempts have been made, through multivariate statistical analysis with blood samples from conspicuous patients with alcohol, to differentiate between light alcohol misuse and heavy alcohol dependence. The multiple chemical and clinical parameters extracted should reflect alcohol's influence on various organs and organ systems. These studies were subsequently abandoned because of impracticable, partly costly statistical analysis. Harasymiw et al. [54] developed EDAC test to be an established procedure, in which a form of "mathematical fingerprint" for each tested patient could be created from 10 out of 30 routine lab values through a linear discrimination analysis. The fingerprint of an individual could possibly be that from a heavy alcoholic and presented as P-positive, representing the degree of concordance to the stereotyped alcoholic lab profile. In general, a P-positive value over 50% showed current heavy alcohol consumption, whereas values below or equal to 50% showed evidence of light alcohol misuse. The EDAC test was successfully used as screening for alcohol misuse and to identify heavy or risky alcohol consumption in various studies on different study populations. A higher sensitivity of 34–65% (women/men) for EDAC test compared to 23–30% for γ-GT in a population of 1605 heavy drinkers or probands with risky alcohol consumption has been reported. The specificity is 89% (men) and 98% (women). Sensitivity and specificity over 80% each was reported in the identification of alcohol misuse in heavy male and female drinkers. Considering these results, EDAC test in primary care can establish itself as a suitable procedure for use in routine blood tests, its cost efficiency through freely optional lab values, as well as the availability of an electronic version with automatic statistical analysis from certain providers.

42.22 GGT-ALT Combination

Another combination of enzymes, GGT-ALT (alkaline phosphatase), can also be useful for clinical diagnostic validation of liver damage related to excessive and prolonged intake of alcohol. If the ratio of GGT-ALT exceeds the value 1.4, there is a probability of 78% that the liver impairment is due to alcoholism. This particular combination shown was not a biomarker when used for monitoring the treatment of alcoholics with disulfiram (Fig. 42.3).

Although the suspicion of alcohol abuse behind hepatotoxicity may be supported by several lines of clinical and biochemical data, the specific role of alcohol in many cases is difficult to distinguish in individuals who deny alcohol use. Clinical symptoms related to heavy drinking may originate from virtually any tissue. Unexpected abnormalities in liver enzymes or blood cell counts in health screening programs may also reveal alcohol abuse.

Subsequently, efforts should be focused on objective confirmation of alcohol use and to rule out other etiologies. Nonalcoholic fatty liver disease (NAFLD) is the most common nonalcoholic

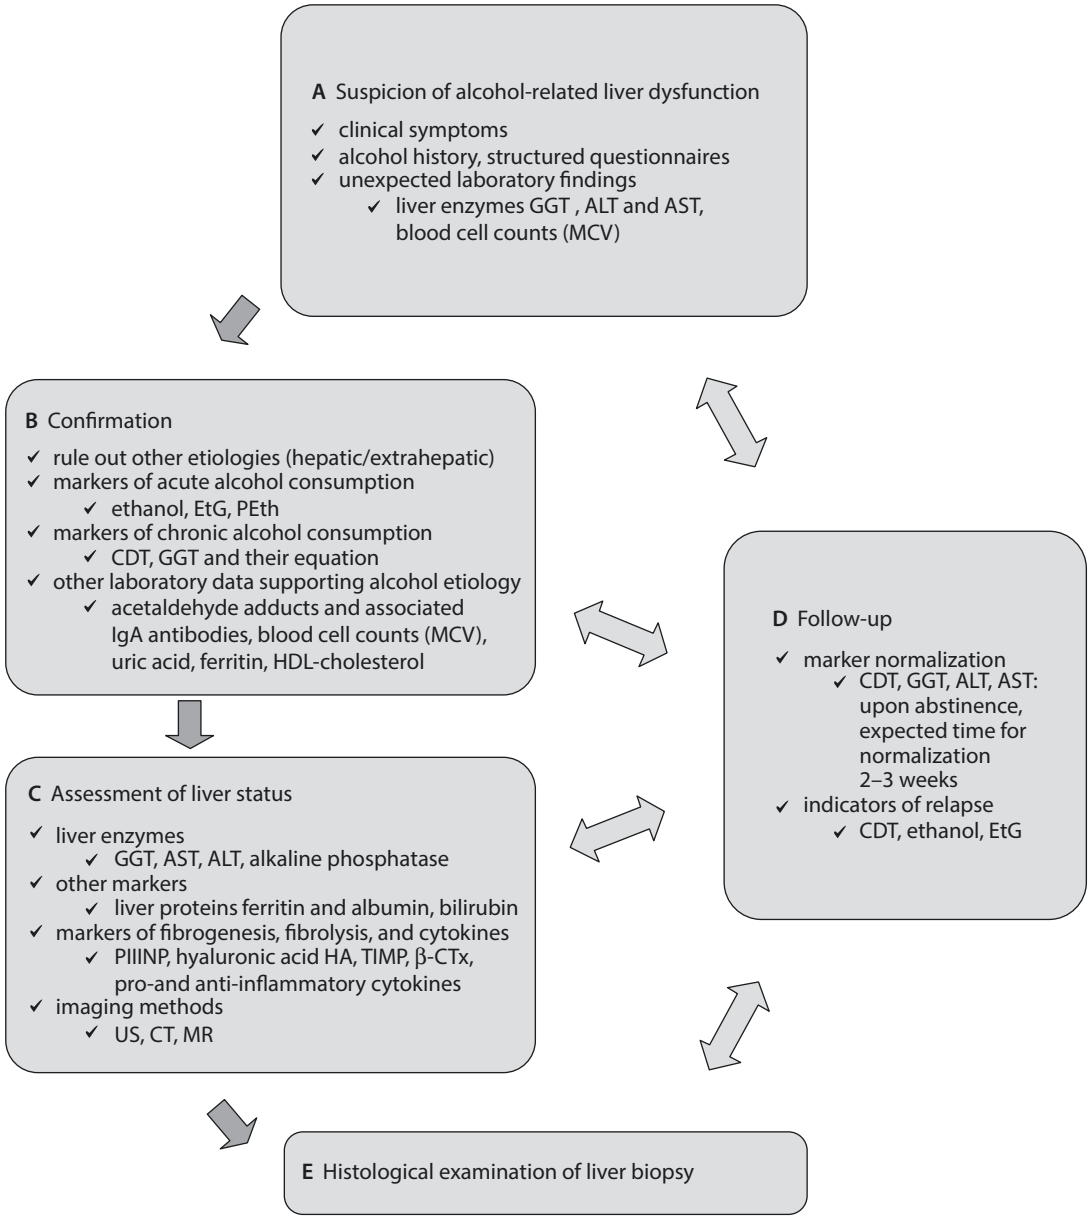

Fig. 42.3 Schematic representation of the clinical assessment of liver dysfunction in alcohol consumers. (Niemela and Alatalo [55])

etiology behind liver dysfunction, and the workup should consist of evaluating metabolic comorbidities with measurements of body mass index, waist circumference, and oral glucose tolerance. Specific tests are available to rule out viral hepatitis and several genetic diseases, such as hemochromatosis. In alcohol consumers, ethanol may be present even at the time of the clinic visit. Measurements of ethanol metabolites or other laboratory parameters sensitive to ethanol may provide confirmatory data. Liver enzymes give information on the nature of the liver pathology. An isolated abnormality in GGT is usually reversible and related to increased oxidative stress burden. Increased ALT is commonly a result of fat deposition in the liver and can be reversible.

Elevated ferritin and albumin may occur in early phases of liver disease, whereas in patients with advanced alcoholic liver disease (ALD), the rates of albumin synthesis decrease and correlate with poor prognosis. ALD status is also associated with both the collagen and cytokine markers. Markers of collagen synthesis and degradation as well as pro- and anti-inflammatory cytokines may follow inverse kinetics, which may help to differentiate alcoholics at risk for cirrhosis. US (ultrasonography), CT, computed tomography, MRI, and proton magnetic resonance spectroscopy are commonly suggested. Follow-up of laboratory values is an integral part of the comprehensive assessment and treatment of patients with signs of liver dysfunction. If excess alcohol consumption (or obesity) is suspected, normalization during abstinence (or weight loss) is confirmatory. If initial GGT levels return to normal after abstention, and the patient is likely to have recovered from liver disease. Liver enzyme activities repeatedly above twice the upper reference limit are used as decision-making point for liver biopsy to rule out severe liver diseases and to distinguish patients needing the closest monitoring. Follow-up by markers of ethanol consumption, such as CDT, can be used to assess the degree of alcohol dependence and to detect relapses, which increase the probability of subsequent severe liver problems. Current clinical gold standard for the diagnosis and grading of hepatic disease is liver biopsy. It is, however, an invasive procedure with sampling variability and therefore is not suitable for screening or repeated measurements.

42.23 Conclusion

Biomarkers, as additions to self-reports, are important in the diagnosis and therapy of alcohol-related disorders. The traditional biomarkers have varying other limitations besides practicability and cost efficiency.

In summary, especially regarding traditional biomarkers, a combination of various lab parameters (e.g., CDT and γ-GT) allows sufficient inference on regular and even longer-term (days, weeks) alcohol consumption The diagnostic sensitivity of individual parameters, such as ASAT or ALAT, is low, and the specificity is moderately high, with the exception of CDT which shows moderate sensitivity and high specificity to differentiate between alcohol-dependent individuals and control persons. The strengths of these traditional markers lie in their practicability and, except for CDT, cost efficiency in clinical routine. Normalization of this marker occurs only after weeks or months of abstinence so that inference of current or short-term recent alcohol consumption can be made.

In comparison, direct ethanol metabolites are highly sensitive and specific, covering the complimentary period between consumption and detection, and are routinely used. Thus, they open new perspectives in the prevention, interdisciplinary cooperation, diagnosis, and therapy of alcohol-related disorders.

Clinical Screening for Illegal Drug Use, Prescription Drug Misuse and Tobacco Use

43

Sawitri Assanangkornchai and J. Guy Edwards

Contents

Abstract

Screening aims at detecting substance use (ideally at an early stage) with a view of providing subsequent treatment if required. It is most productively employed in populations in whom there is a high prevalence of use, such as general and emergency medical patients and those attending clinics for pain or sexually transmitted disorders. It is of less value in well-staffed facilities that already routinely inquire about substance use during comprehensive clinical assessments. Screening may also be helpful in people who have come into conflict with the law.

Numerous screening instruments have been designed, but few have satisfactory psychometric properties, and none has been

shown to produce a better long-term outcome in the real world of clinical psychiatry than asking brief questions about substance use followed by referral for specialist treatment and rehabilitation when required.

Examples of the more widely used instruments are the Alcohol, Smoking and Substance Involvement Screening Test (ASSIST), CAGE-AID (mnemonic for items Cut down, Annoyed, Guilty, Eye-opener, -Adapted to Include Drugs), Drug Abuse Screening Test, and Fagerström Test for Nicotine Dependence. The choice of an instrument should depend on its psychometric properties, the population being screened, availability of staff to use it properly, and practicality of introducing it into the facility.

Ethical aspects of the use of the instruments are important. Outside purely clinical or sociological research screening is likely to have limited value unless follow-on treatment is available and offered to the substance misuser, and he/she is encouraged to accept it and adhere to it. The best test of the real value of screening will be a clear demonstration that it prevents longer-term medical and psychosocial consequences of substance misuse.

43.1 Introduction

Screening for substance misuse and use disorders aims at helping to identify people who have suffered the consequences of using one or more substances or are at risk of future harm if they continue to use the substance(s). Ideally this should be at an early stage and should be followed by treatment if indicated. Included among the WHO's recommended indications for screening in general are the seriousness of the effect the medical condition has on the health and well-being of the individual and the community and the availability of a suitable, reasonably priced screening test and effective treatment for patients screened positive. It is accepted that early recognition of the disorder followed by intervention leads to a more favorable outcome. Based on these indications, screening for misuse of psychoactive drugs is clearly indicated [5].

Screening instruments for drug misuse have been designed for use in the community and healthcare facilities and to help in medicolegal assessments. Cross-sectional and longitudinal screening for drug use is of value in research into medical treatment and academic sociological research.

43.2 Screening in Different Settings

43.2.1 Healthcare Facilities

Screening may be undertaken in primary care; general and emergency medical, psychiatric, and other specialized facilities (e.g., HIV/AIDS clinics or obstetric units); and community hostels. Some instruments are self-administered, whereas others are administered by staff of various disciplines. Studies have shown benefits of screening for drug use in healthcare settings using the Screening, Brief Interventions, Referral for Treatment (SBIRT). This is employed in an integrated, public health approach to the management of people at risk of adverse consequences of alcohol and other drug use and probable drug use disorders (DUD) [6]. Various factors militate against the implementation of SBIRT, the main ones being underfunding, understaffing, and competing priorities.

43.2.1.1 Primary Care

Primary care deals with a wide range of people and an equally wide range of lifestyles and disorders, including substance use disorders. Its workers are usually seen as trustworthy, and it provides an excellent opportunity for screening for drug misuse as a routine part of healthcare. Patients with problems related to drug misuse are likely to have frequent consultations. Screening in primary care may identify nondependent individuals who use drugs in a harmful way and respond well to intervention. Drug misuse may worsen concomitant health problems, so screening pro-

vides an opportunity to educate patients about this risk. We therefore endorse WHO recommendations on screening in general practice, with consideration given to the use of the Alcohol, Smoking, Substance Involvement Screening Test (ASSIST) or one of its modified versions [59].

However, the workload in primary care is usually stretched to capacity, so screening may only be carried out with great difficulty (or not at all) without extra resources. An example of this is seen in the UK where the current government underfunds the National Health Service (NHS) to such a degree that clinics typically have to ration time to only 10 minutes per symptom or problem per appointment. And that harsh rationing even applies to elderly patients with multiple pathologies.

If that is the situation in the fifth richest country in the world, it is not difficult to imagine the situation in the most deprived, poorest countries where even 10 minutes might be considered a luxury.

43.2.1.2 Secondary Care

General Medicine

There is a high prevalence of substance use among general medical patients. Hospitals are therefore important places in which to screen patients, hoping that any substance misusers identified will accept treatment. In hospitals there is more time for screening than in most other medical settings and also more time to educate the patient about the relationship between substances misused and his/her medical condition [41].

Emergency Medicine

Drug misusers often attend accident and emergency (A&E) departments with substance-related medical or surgical problems, notably toxic or withdrawal states, trauma due to accidents, deliberate self-injury, or injury caused by others. Thus, emergency departments too are appropriate facilities to screen, especially for the benefit of people who have less access to alternative healthcare. Screening instruments that rapidly identify patients who require further diagnostic evaluation and/or brief intervention are important. A systematic review identified 11 instruments that have been used in youngsters under 21 attending A&E and recommended asking just one question to detect cannabis use disorder – "In the past year, how often have you used cannabis?" – with the response categories, "Once or less" or "Two or more times" (sensitivity, 0.96; specificity, 0.86) [43].

To illustrate the problems faced by A&E departments, let us again consider the situation of the British NHS. Just as the government's gross underfunding has an adverse effect on patient care in other key services like general practice, so it affects overworked A&E departments. As a result, severely ill patients often have to wait for hours in ambulances and/or lay on trollies in corridors waiting to be assessed, and some patients needing admission may have a further wait for an inpatient bed to be found for them. So it is not difficult to understand why A&E staff, however much they would like to help in screening for drugs, may simply not have time to do so.

Services for Youngsters

Early to late adolescence is a critical risk period for starting to use substances, which peaks between the ages of 18 and 25 [58]. The American Academy of Pediatrics [1] therefore recommends screening of every pediatric patient aged 12 or over, whether or not they are reported as having used drugs.

The screening can be undertaken in healthcare facilities, schools, child welfare facilities, and the juvenile justice system. It should be carried out with a valid, sensitive instrument, and, when the results suggest there is cause for concern, youngster should be referred for a comprehensive clinical assessment. At all stages of the process, care should be taken to ensure that no vulnerable young person is unjustifiably labeled as a drug misuser.

The easy availability of cannabis, coupled with the erroneous idea that it rarely causes harm, makes this drug one of the most common substances initiated in adolescence [58]. So screening adolescents for its use is particularly important.

Validated screening tools available for substance use disorder (SUD) among adolescents aged 12–17 in primary care are the Brief Screener for Alcohol, Tobacco and other Drugs (BSTAD) and Screening to Brief Intervention (S2BI) [42].

Services for the Elderly

During recent years, there has been mounting concern over substance misuse in the elderly. There are many explanations for this. They include the 1946–1964 baby boom effect, with children born during this time reaching adolescence at a time of escalating substance use worldwide, and people then continuing to misuse substances throughout midlife until old age. During this period, there was also an increase in life expectancy. Increasing age was accompanied by multiple pathology, increased misuse of over-the-counter and illegal drugs, and increased prescription of drugs with addiction potential, notably benzodiazepines and opioids [58].

In addition to these trends, there has been a relaxation of enforcement of laws on cannabis possession (with some countries and states legalizing it) and latterly a relaxation of legislation of the use of cannabis for therapeutic purposes.

For these reasons, older adults should be sensitively but routinely screened for alcohol and other drug use, despite difficulties arising from similarities between the symptoms of drug misuse and those of some of the common illnesses of later life and lack of a specific screening instrument for the elderly.

Pain Clinics

Pain can be associated with drug misuse in several ways: there may be an underlying condition contributing to both the severity of the pain and the drug misuse (e.g., a depressive disorder); patients may become dependent on their prescribed analgesics (therapeutic dependence); and substance misusers with pain of organic origin, or with exaggerated or simulated pain, may try to manipulate their doctors into prescribing more addictive substances than are clinically needed – for themselves and/or to give or sell to other substance misusers. Whatever the relationship, screening patients attending pain clinics for the inappropriate use of prescribed or illegal drugs is important. During recent years, there has been a dramatic increase in the use of opioids for treating pain and a corresponding escalation in the number of deaths from overdoses of opioids at great human and economic cost [58].

Attempts to understand and tackle these increases are hampered by difficulty in diagnosing dependence in patients prescribed opioids [24]. If it is so difficult to make a valid diagnosis, it is not surprising that it is also difficult to create a valid screening instrument for opioid dependence, and we have to place much reliance on the clinical assessment.

The US National Institute of Drug Abuse (NIDA) recommends supplementing this by screening patients for opioid misuse on their initial clinic visit and prior to prescribing any opioids for pain**,** using the Opioid Risk Tool (ORT) [42, 60].

Psychiatric Units

There is evidence to suggest that the prevalence of tobacco and other substance misuse in patients with some disorders is higher than in others, but substance misuse and psychiatric comorbidity in general occurs so often that it is essential that a history of misuse is taken routinely in all psychiatric patients. In fact, failure to do so in some patients can be a serious omission, sometimes even bordering on negligence. Tiet et al. [56] in their review concluded that there are no currently available instruments that have particular advantages in psychiatric patients, while the lengthier, more complicated ones can be confusing for those with severe illnesses – particularly when administered in addition to a thorough psychiatric assessment.

Antenatal Care

Universal screening of pregnant women for substance misuse has been recommended [62]. It should be performed as early as possible in pregnancy and at every subsequent antenatal visit so that clinicians are aware of their patient's substance use, can make better informed decisions about drug treatment and prenatal care, and can minimize the time the fetus is exposed to the drug(s).

Screening during pregnancy is especially important in those with a previous history of drug misuse, prenatal and/or birth complications, delays in accessing prenatal care, or frequently missing prenatal appointments. Some screening instruments have been specifically designed for pregnant women, e.g., 4P's Plus [18], the Substance Use Risk Profile-Pregnancy (SURP-P) scale [63], and Wayne Indirect Drug Use Screener (WIDUS) [45].

43.2.2 Medicolegal Practice

43.2.2.1 Criminal Justice System

There is a high prevalence of substance misuse also in people who come into conflict with the law, especially those whose crimes have been carried out to acquire money for drugs. So here too there is fertile ground for screening – by personnel within the criminal justice system or by colleagues working in associated medical services, like prison medical officers or staff working in court diversion schemes. An aim of screening, in addition to providing treatment for those in immediate need, is to help interrupt the cycle of addiction and drug-related crime, with benefits to society as well as to the drug misuser.

Although drug-using offenders are mostly abstinent while in custody or prison, when released many resume their previous patterns of drug and alcohol use, placing them at risk of rearrest and increased health problems, including HIV. Thus, there is need for intervention to help reduce risky behaviors and encourage treatment.

During detention, people are at a "teachable moment" for screening and intervention. They have just been arrested and may want to avoid further conflict with the law. Initially, they may be distressed or simply just want "something to do" by way of distraction. That in itself does not mean the subject is well motivated for treatment, but in this teachable moment better motivation could follow [47].

Screening should begin with simple questions regarding substance misuse asked by the arresting police officer. Following this, there are several other opportunities for screening as the accused moves through the justice system: in the police station and prison and during pretrial investigations, meetings between prosecuting and defense council, and social assessments conducted by probation officers. The UNCOPE is a valid, brief six-item screen used for identifying substance use disorders among prisoners [48].

43.3 Some General Considerations

43.3.1 Ethics

There are many ethical as well as legal and social issues to be considered when deciding whether and how to screen patients. Screening is generally accepted as being harmless so long as the patient is fully informed of its purpose, permission is given, and any appropriate follow-up treatment required is provided.

Even when using a simple screening instrument, it is important that we remain aware of the concerns and sensitivities of our patients/clients, concerns such as embarrassment at succumbing to their "weakness" in taking drugs, believing there is no point in screening as there is no "cure" for their "addiction," or fear of the legal and social consequences of drug use, including stigmatization. As in all good medical practice, we should also ensure that honesty and transparency are central to our dealings with patients.

We can go some way toward allaying patient's anxieties by emphasizing that the decision to reveal information in response to questions asked by an instrument is theirs and theirs alone and assuring them that anything revealed will be treated in strict confidence and not disclosed to others without their permission. Doing this is particularly important in medicolegal work (whether in civil or criminal cases), especially when dealing with delinquent youngsters, to help gain their trust, confidence, and cooperation.

It should also be made clear to the patient that screening instruments do not possess "magical" properties; they simply comprise a set of questions that are asked regularly in a clinical assessment and contain no questions that attempt to

"catch them out" – which we have no right to ask. Any attempt to do so would be dishonest and, like failing to observe the fundamental principles of confidentiality, a breach of professional ethics.

43.3.2 Psychometric Properties

It is important to confirm that all instruments were properly constructed to begin with, properly evaluated subsequently, and then properly administered to the right person or population in the right way. Even when these principles have been conscientiously adhered to, there remains the glaring uncertainty as to whether the instrument measures what it sets out to measure. And, of course, what a person says he does is not necessarily the same as what he actually does.

43.3.3 Main Aims of Screening

While it is of interest academically to elicit data on all substance use, as clinicians we are less interested in people who occasionally take substances "recreationally," especially if conforming with the behavior of their peers or take them only in certain situations, like clubs or raves. Similarly, we are less interested in those who take substances for clearly defined, short periods, as during their university days, or for specific purposes like attempting to increase their sexual excitement.

We are prepared to advise all people of the dangers of such sporadic or short periods of drug-taking, but our main concern is for those who take drugs for longer periods. This is especially the case when they are dependent on one or more substance, have already experienced adverse medical or psychosocial consequences**,** or are exposed to the risk of these problems in the future.

Several familiar words and terms are used in the field of substance use, and there are debates on what is normal as opposed to abnormal use; differences between use, misuse, and abuse; when psychological and/or physical dependence begins; the difference between these conditions; and the question, "What is a disorder?" These are of theoretical and practical interest but matter less at the screening stage than later in assessment. The main aim at this stage is to identify people who have or are at risk of substance-related problems and may therefore benefit from advice and/or intervention regardless of what provisional labels are applied to them.

Having done the screening, the clinician, aided by the data elicited by the screening instrument, may then complete the assessment, sharpen up on the diagnosis, and provide the appropriate intervention.

43.4 Screening Instruments for Substance Use

There are available screening instruments for single or multiple substance use, problems caused by the substances, and comorbidity (Table 43.1). Some of these have been created for particular patient groups. We summarize below their main characteristics and uses of the most commonly used instruments.

43.4.1 Instruments Inquiring about the Use of One or More Drugs

ASSIST The ASSIST has high construct and concurrent validity [28] and is currently the most extensively studied and widely used instrument. It was developed by a group of WHO researchers to help detect substance use and related problems in primary and general medical care and assess the level of risk for each substance identified. It seeks information on the use of all types of psychoactive substances, including tobacco, alcohol, cannabis, cocaine, amphetamine-type stimulants, sedatives, hallucinogens, inhalants, and opioids. It asks if any of these have ever been used and, if so, the frequency of use during the past 3 months; if the respondents have had a strong desire or urge to use the substance; the frequency of any problems they have had; if the substance has interfered with their responsibilities; if anyone

Table 43.1 Screening instruments for drug use and drug use disorders

Instrument	Full name	Reference	Population studied	Time frame	No. of items	Administered by	Approx. time required	Responses/scores
(a) Instruments inquiring about one or more drugs								
ASSIST	Alcohol, smoking and substance involvement screening test	[61]	Adults	Lifetime Past 3 months	8 items	Clinician interviewed, computer administered, self-administered	10 min for administration, 5 min for scoring	0–3: low risk – no intervention (0–10 for alcohol) 4–26: moderate risk – brief intervention (11–26 for alcohol) 27+: high risk – more intensive intervention
DHQ PDHQ	Drug history questionnaire Psychoactive drug history questionnaire	[54]	Adults	Lifetime Past 6 months	5 items	Self-administered	5–10 min	No specific cutoff
S2BI	Screening to brief intervention	[36]	Adolescents 12–17 years	Past 12 months	8 items	Computerized self-administered	2 min	Answer “use” to each drug type
BSTAD	Brief screener for alcohol, tobacco, and other drugs	[31]	Adolescents 12–17 years	Past 12 months	3 + 2 items	Computerized self-administered	2 min	Answer “use” to individual drug and then continue to more drugs
SUBS	Substance use brief screen	[39]	Adult primary care patients	Past 12 months	4 items	Computerized self-administered	5–10 min	Answer “use 1–2 days in the past 12 months” to individual drug
TAPS	Tobacco, alcohol, prescription medication, and other substance use	[38, 40]	Adult primary care patients	Past 12 months and 3 months	4 + 25 items	Computerized self-administered and clinician interviewed	5–10 min	TAPS-1: Positive = use that substance and then continue to TABS-2 items specific to that substance class

(continued)

Table 43.1 (continued)

Instrument	Full name	Reference	Population studied	Time frame	No. of items	Administered by	Approx. time required	Responses/scores
CAGE-AID	Cut down, annoyed, guilty, eye-opener-adapted to include drugs	[13]	Adolescent; patients with comorbidity; adults	Lifetime	4 items	Self-administered	5 min	Range: 0–4 Cutoff score 1 or more for drug dependence
CRAFFT RAFFT	Car, relax, alone, forget, friends, trouble	[32]	Adolescents American Indian/native Alaskans	Lifetime past year	6 items	Clinician-interviewed, self-administered, computerized	5 min	Range: 0–6 Cutoff score of >2 for risky use
DAST	Drug abuse screening test. Adolescent version (DAST-A) available	[53]	Adults College students; pregnant women	Lifetime	10, 20, 28 items	Self-administered	5–10 min	Range: 0–10, 20, 28 DAST-28: Cutoff 6 DAST-20: Cutoff 6 DAST-10: Cutoff 2
DAP quick screen DAP-4	Drug and alcohol problem quick screen	[51]	Adolescents	Lifetime	30 items and 4 items	Self-administered	<10 minutes	Range: 0–30 Score of >6 considered high risk for "red flag" behaviors
DUDIT	Drug use disorder identification test	[10]	Adults	Lifetime past year	11 items	Self-administered	5–10 min	Range: 0–44 Cutoff score of 25 suggestive of substance dependence Cutoff score of 8 or less severe drug abuse
SACS	Substances and choice scale	[19]	Adolescents	Past month	10 items	Self-administered	5–10 min	Each item scores 0, 1, 2 for not true, somewhat true, certainly true Range:0–20 Cutoff: 2

SSI-SA	Simple screening instrument for substance abuse	[17]	Adults; law-enforced treatment programs for patients with comorbidity; adolescent medical patients	Lifetime	16 items	Clinician- interviewed, Self-administered	10 min	0–1: No/low risk 2–3: Minimal risk 4+: Moderate/high risk
TICS	Two item conjoint screen for alcohol and other drug problems	[12]	Adults	Past year	2 items	Self-administered	<5 min	Cutoff: 1
UNICOPE	Use, neglected, cut down, objection, preoccupied, emotional discomfort	[27]	Adults	Lifetime Past year	6 items	Interviewer administered	5–10 min	Cutoff: 2
(b) Instruments specific to one drug								
CAST	Cannabis abuse screening test	[35]	Adolescents	Lifetime	6 items	Self-administered	< 5 min	Range: 0–6 Score > 4: Problematic cannabis use
CUDIT CUDIT-R	Cannabis use disorders identification test	[2]	Adults; adolescents	Past 6 months Current	10 items 5-point Likert scale	Self-administered	5–10 min	Range: 0–40 Cutoff:8
CUPIT	Cannabis use problems identification test	[8]	Adolescents; adults	Lifetime Past 12 months	16 items	Self- administered	5 min	Range: 0–82 Cutoff:12
MSI	Marijuana screening inventory	[3]	Adults	Lifetime Past year	31 items	Self- administered	5–10 min	Range: 0–31 Cutoff:3

(continued)

Table 43.1 (continued)

Instrument	Full name	Reference	Population studied	Time frame	No. of items	Administered by	Approx. time required	Responses/scores
PUM	Problematic use of marijuana	[44]	General adult population	Lifetime	8 items	Self- administered		Range: 0–8 Cutoff:2
CDS-12 CDS-5	Cigarette dependence scale	[23]	Adults adolescents	Lifetime Current	12 & 5 items	Self- administered	10 min	Range: CDS-12: 12–60; CDS-5: 5–25
FTND FTQ m-FTND	Fagerstrom test for nicotine dependence	[26]	Adults adolescents college students	Lifetime	6 items	Clinician-interviewed; self-administered	<5 min	Range: 0–2 cutoff: 6
TDS	Tobacco dependence screener	[30]	Adults; smokers	Lifetime	10 items	Self- administered	5 min	Range: 0–10 Cutoff:
COMM	Current opioid misuse measure (for opioid medication misuse)	[15]	Adult patients with chronic non-cancer pain	Current past 30 days	17 items	Self- administered	5–10 min	Cutoff: 9
ORT	Opioid risk tool	[60]	Adult patients prescribed opioids for chronic pain	Lifetime	5 items	Patient-completed (PC-ORT) clinician-completed (CC-ORT)	5 min	Range: 0–16 Cutoff: 0–3 low risk, 4–7 moderate risk > 8 high risk
SOAPP	Screener and opioid assessment for patients with pain	[14]	Adult patients taking opioids for chronic pain	Lifetime	5, 14, or 24 items	Self-administered	5–10 min	Cutoff: >7

PDUQ	Prescription drug use questionnaire, -patient version	[21, 22]	Patients with chronic non-malignant pain and on opioid therapy	Current	42 & 31 items	Clinician-interviewed (PDUQ), self-administered (PDUQp)	20 min	Cutoff: 10
(c) Instruments inquiring about multiple problems, including dual diagnosis								
CODSI-MD CODSI-SMD	Co-occurring disorder screening instrument	[50]	Offenders	Past 12 months	6-item version (CODSI-MD) screens for any mental disorder 3-item version (CODSI-SMD) screens for severe mental disorder	Self-administered	5–10 min	CODSI-MD Range:0–6 Cutoff: >3 CODSI-SMD Range: 0–3 Cutoff: >2
DUSI[a]	Drug use screening inventory-revised	[55]	Adults; adolescents	Current status	159 items	Self-administered computer-based available	20–40 min	Range: 0–100% No cutoff specified in documents
PL	DrugCheck problem list	[29]	Adolescents, adults, co-occurring clients	Past 3 months	12 item	Clinician-interviewed	5–10 min	Range:0–12 Cutoff: >2
POSIT	Problem-oriented screening instrument for teenagers	[16]	Adolescents	Lifetime	139 items, 10 problem areas	Self-administered	20–30 min	Cutoff scores indicating low, medium, or high risk for each of the ten problem areas

[a]Fee required for use; other instruments free in public domain

has expressed concern about their substance use; if they have tried to decrease or discontinue use; and if they have ever used any substance by injection. Linked with brief intervention, the ASSIST can help a person explore options for addressing their substance use [59].

There are modified forms of the ASSIST – the NM-ASSIST (NIDA-modified ASSIST) [42]; ASSIST-Lite (ultrarapid ASSIST) [4]; ASSIST-Y for use in children and adolescents aged 10–17 years [59]; "ASSIST on ICE," which is the instructional video and manual of the ASSIST and brief intervention specific for methamphetamine use [25]; and the ASSIST Checkup, which is a free downloadable app for use on a mobile device and gives instant feedback and tips on how to cut back or stop substance use. It also provides information on where to seek help. Electronic versions of the ASSIST (eASSIST) and ASSIST-Lite (eASSIST-Lite) are also available. The ASSIST and its modified forms have been translated into several languages, including Arabic, Chinese, French, German, Spanish, and Thai [59].

In addition to the clinician interview version, self-report, paper-based [7], and computer-based (ASSISTc) [20] formats of the ASSIST were developed for use in university students and a self-administered audio computer-assisted, self-interview (ACASI-ASSIST) format for primary care [38, 40]. Both formats are comparable to the clinician interview format but have the apparent advantages of not requiring an interviewer, facilitating screening and assessment in college students and busy healthcare settings, and reducing costs.

Substance Use Brief Screen & Tobacco, Alcohol, Prescription medication and other Substance use (SUBS & TAPS) Based on the NM-ASSIST, the Substance Use Brief Screen (SUBS), a four-item computerized, self-administered screening instrument [39], and the Tobacco, Alcohol, Prescription medication, and other Substance use (TAPS) tool, a two-step screening and brief assessment instrument, were developed [38, 40]. They both seek information on the frequency of use of tobacco, four or more alcoholic drinks per day, illicit drugs including cannabis, and the inappropriate use of prescription drugs during the past 12 months. The TAPS consists of two parts: a four-item screen (TAPS-1) and a substance-specific assessment of risk tool (TAPS-2) for individuals who screen positive on TAPS-1. Both instruments performed well in primary care, and they have the advantages of being brief and self-administered**,** using a tablet computer or online tool [52].

Examples of instruments that inquire about any drug use and their adverse effects are CAGE-AID [13] and CRAFFT/RAFFT [32]. The CAGE Adapted to Include Drugs (*CAGE-AID*) is a modification of CAGE – a mnemonic based on Cut down, Annoyed, Guilty, Eye-opener – which has been used in screening for alcohol misuse since the mid-1970s [37].

CRAFFT is a mnemonic, based on its individual items: Car, Relax, Alone, Forget, Friends, Trouble [32]. It is the most well-studied instrument for screening for alcohol and drug use and related problems in adolescents and adults. Its six items are preceded by three preliminary questions that ask about the use of alcohol, cannabis, and other drugs. It asks about specific lifetime events and behaviors, irrespective of when they occurred.

The instrument was found to be suitable for distinguishing between alcohol and other substance use, problem use, abuse, and dependence. Although the CRAFFT was designed for clinical use, it is also suitable for large-scale surveys in other settings and provides a measure of severity but not frequency of use in adolescents [11].

Drug Abuse Screening Test (DAST) The DAST-28 is a research instrument used to screen and assess the effectiveness of treatment [53]. It provides a measure of the severity of drug-related and other problems experienced during the respondent's lifetime. It has been found most useful in people who do not seek treatment. The DAST cannot distinguish between active or inactive drug use or abstinence and low-risk use, abuse, or dependence.

Alternative versions of the DAST-28 have been developed – the DAST-20, DAST-10, and DAST-A (for adolescents). DAST has moderate to high reliability and validity, depending on the group studied [64]. Most recently, a two-item brief DAST (DAST-2) has been developed. The questions asked are "How many days in the past 12 months have you felt bad or guilty about your drug use?" and "How many days in the past 12 months have you used drugs other than those required for medical reasons?" A response of 1 or more days to each question was considered to meet the DAST criteria for drug use disorder (DUD) and negative consequences of drug use [57].

Screening questionnaires of this type are not only quick to administer, but they also have the advantage that people who use multiple substances may be more likely to respond positively to a question about drugs in general than to questions about specific drugs. However, they have some disadvantages. For example, they may not detect specific substances, and someone who uses only alcohol may not respond positively to a question that refers to "drugs."

43.4.2 Instruments that Ask about the Use of Single Drugs

Apart from instruments used to screen for alcohol, there are also instruments that screen for individual drugs.

43.4.2.1 Cannabis

Short instruments designed specifically for cannabis screening that have satisfactory psychometric properties and have been used in various populations include the Cannabis Abuse Screening Test (CAST) [35], Cannabis Use Disorders Identification Test (CUDIT) [2], and Problematic Use of Marijuana (PUM) [46].

43.4.2.2 Opioids

Because of the widespread increase in prescription of opioids, several instruments have been developed to detect prescription opioid misuse in various clinical settings, including A&E departments, pain clinics, and pharmacies. Examples of these include the Prescription Drug Use Questionnaire (PDUQ) [21], Opioid Risk Tool (ORT) [60], and Current Opioid Misuse Measure (COMM) [15].

The Opioid Risk Tool (ORT) is a brief, self-report, screening tool designed for use in adults in primary care to assess the risk of opioid abuse among individuals prescribed these drugs for chronic pain. It can be administered and scored in less than 1 minute and has been validated in men and women treated for pain [60].

Prescription Drug Use Questionnaire (PDUQ) The 42-item Prescription Drug Use Questionnaire (PDUQ), clinician interview version [21], and its 31-item self-report patient version (PDUQp) [22] have been validated to detect "problematic opioid medication use" in patients with chronic pain. It has domains of pain, opioid use patterns, social/family factors, and substance use history and can be self-administered in a busy clinical setting. The PDUQp has been shown to perform well in screening for prescription opioid misuse and use disorder among older adults in emergency setting [9].

43.4.2.3 Nicotine

The Fagerström Test for Nicotine (or Cigarette) Dependence (FTND) is a revision of the Fagerström Tolerance Questionnaire (FTQ) [26] and is the instrument most widely used to screen for nicotine use. The FTND was designed to provide an ordinal measure of nicotine dependence. It contains six items that seek information on the number of cigarettes smoked, compulsion to smoke, and dependence. It provides a rating of severity that can be used to help plan treatment and assess the prognosis. Its brevity and ease of scoring make it an efficient way of obtaining clinically meaningful information. It can be incorporated into general health and lifestyle screening questionnaires in clinical and nonclinical settings.

A modified version of the scale (modified Fagerström Tolerance Questionnaire, mFTQ) has been adapted for use in adolescents, which shows acceptable internal consistency and validity across countries [49].

Other available instruments are the Tobacco Dependence Screener (TDS) [30] and Cigarette Dependence Scale (CDS) [23].

43.4.3 Instruments that Inquire about Multiple Drug-Related Problems and Comorbidity

These instruments help identify drug-related problems in mental and physical health, relationships, and adjustment at school or work. They may locate areas in need of further assessment and suggest services required. Examples include the Drug Use Screening Inventory-Revised (DUSI-R) [55], Problem-Oriented Screening Instrument for Teenagers (POSIT) [16], Co-occurring Disorder Screening Instrument (CODSI) [50], and DrugCheck Problem List (PL) [29].

Problem-Oriented Screening Instrument for Teenagers (POSIT) The POSIT is a self-administered 139-item questionnaire, with fixed "yes/no" responses, designed for use in adolescents aged 12 to 19 [16]. It identifies problems in ten domains that require further assessment and might need intervention – substance use/abuse, mental and physical health, family and peer relations, vocation, and special education. The instrument can be used by school personnel, juvenile and family court personnel, medical and mental healthcare staff, and staff working in substance use disorder treatment programs. The POSIT has been found to have strong internal consistency in several of its subscales and good test-retest reliability and overall validity ([33], [34]).

43.5 Conclusion

Because of the high and increasing prevalence of substance use disorders and its consequences, screening for substance use is important in medical, psychiatric, and forensic services. There is a higher prevalence of use in some groups than others, such as those attending A&E departments and pain clinics and those who come into conflict with the law.

Numerous screening instruments have been designed and validated. Factors that determine the choice of an instrument are not only its psychometric properties but also the practicality of employing it. The enormous pressures of working in a busy clinical unit often preclude screening without special assistance.

Screening is only the first step on a very long journey toward providing a successful treatment and rehabilitation outcome. It is of limited value without the provision of treatment opportunities and encouraging substance users to accept and then adhere to any treatment offered. Finally, it is important to determine the success rate of screening in terms of discontinuation or at least decreased use of substances compared with standard practice and to assess what effect it has in reducing complications.

Abstract

Drug testing in addiction medicine is typically carried out via either immunoassay, such as in urine drug screens, or gas chromatography mass spectrometry (GCMS). Immunoassays are prone to false positives, and where there is conjecture, should be confirmed with GCMS. Guidelines, such as AS/NZS 4308:2008 in Australia, currently dictate the levels at which a test is considered positive in order to avoid false positives caused by such situations as passive cannabis inhalation or poppy seed ingestion. Most tests typically utilize urine, though other matrixes can be tested including saliva, blood, and hair. Amphetamine immunoassays in particular are prone to a high number of false positives due to their cross-reactivity with other medications. Cocaine, on the other hand, is typically fairly specific for its metabolite benzoylecgonine. Urine drug screens usually screen for non-synthetic opioids only: morphine, codeine, and heroin. While 6-monoacetylmorphine is pathognomonic for heroin use, this is often not present, and it can be challenging to determine the true source when opioids are detected in urine. Methadone metabolite EDDP can be tested via immunoassay; however, buprenorphine requires being sent to a laboratory that can perform GCMS. Chronic cannabis use can result in a positive immunoassay for weeks following cessation of use. Benzodiazepines have a complex metabolic pathway, and as such it is normal for patients on diazepam to test positive for temazepam or oxazepam. The increasing use of synthetic cannabis and cathinones presents a challenge for diagnostic testing, as there are vast numbers of new products entering the market regularly and diagnostics cannot maintain pace with production.

Keywords

Urine drug screen · Gas chromatography mass spectrometry (GCMS) · Illicit drugs · Immunoassay · Opioids · Benzodiazepines

Drug testing involves the analysis of urine or other bodily fluids for the presence of prescription drugs, illicit substances, and/or their metabolites. Drug testing is done in several contexts: clinical toxicology in emergency departments and clinics including addiction treatment, workplace drug testing, postmortem toxicology forensic toxicology including drug-facilitated sexual assault, and sports toxicology. Each setting adopts different approaches and technologies to detect the relevant drugs of abuse. This chapter primarily focuses on clinical issues relevant to addiction specialists. Testing for alcohol and its metabolites is considered in Chap. 10. Therapeutic drug monitoring is not considered here, with the exception of methadone blood levels to monitor agonist treatment.

44.1 Introduction

Self-report generally provides valid information concerning drug use, but valid and independent information about substance exposure is often very valuable. Laboratory methods may be employed to determine the substances used, the timing, and the amount of use. A range of bodily fluids or tissues can be assayed for the presence of drugs of abuse, including urine, blood, oral fluid, sweat, meconium, vitreous humor, and hair. Each has its own advantages and disadvantages. With some exceptions, the results are qualitative rather than quantitative and provide only limited specificity concerning time of use.

Urine is the most commonly used matrix as it tends to offer a longer detection window compared to blood and oral fluid and can be obtained

via relatively noninvasive means. The convenience of urine, however, is weighed against the risk of adulteration or substitution by the patient.

At this point, it is worth noting the medicolegal status of the tests done in addiction medicine. There are standards, such as AS/NZS 4308:2008 in Australia, that specify how samples need to be collected and tested in order to satisfy regulatory requirements for medicolegal testing (Table 44.1). Most hospital laboratories do not document chain of custody of sample nor adhere to the rigorous practice demanded for medicolegal testing. Thus, testing that is done for "clinical purposes" may not satisfy the regulatory requirements applied to medicolegal testing, depending on local policy. It is important to understand the testing procedures in the local setting and to discuss this with patients when doing drug testing.

Nonetheless, there are steps the addiction specialist can take to ensure a more reliable test. Collection should be done in an area without access to water and ideally where a dye has been added to cistern water. The temperature of the urine should be tested immediately after collection to determine that the sample has been freshly voided. The creatinine concentration, the pH, and the presence of oxidizing agents should also be tested to determine dilution or adulteration that can interfere with drug detection.

Table 44.1 Overview of standards for drug testing (Australian AS/NZS 4308:2008)

Collection site	Privacy Security and access Chain of custody
Integrity and identify of specimen	Precautions to prevent dilution Collection procedure Preparation for dispatch Transportation to laboratory
Laboratory requirements	Security Specimen reception Specimen integrity testing (measure creatinine) Specimen storage
Testing procedures	Use of immunoassay Personnel Quality control Cutoff levels (see Table 44.2) Confirmatory testing Reporting Record keeping

It is also worth noting that no single assay technology or assay strategy will detect all drugs of possible interest. Should a patient present appearing intoxicated, there is no specific test that will reliably identify the substance that has caused the reduction in consciousness. Comprehensive broad-spectrum analyses for all intoxicating drugs are labor intensive, and so most clinical laboratories that perform drug testing adopt a limited testing strategy to satisfy specific clinical situations and with varying degrees of success.

44.2 Drug Screening and Limitations of Testing

There are some important principles that apply to the use of drug testing in addiction medicine, namely, the concept of *screening tests*, *confirmatory tests*, *false positives*, and *false negatives*.

The most common test undertaken in addiction medicine, the urine drug screen, is an excellent example of a screening test, used to identify the most commonly abused substances. Most drug-screening tests use immunoassay technology, which use antibodies to detect the metabolites of drugs [1]. Because of cross-reactivity with other drugs, and because the cutoffs for screening tests are usually set very low in order to not miss positive results, there is a low specificity and high sensitivity. This will result in a higher number of false positives.

Most confirmatory testing for drugs, including those of dependence, is done via specific chromatography, typically gas chromatography mass spectrometry (GCMS) [2]. These tests are much more complicated and typically require being sent to a specific lab with specific conditions under which the tests are performed in accordance with relevant standards [3]. As these tests are more specific, they do not produce as many false positives. If there is discordance between the clinical situation and the result of a screening test, the sample should be sent for confirmatory testing with GCMS. The key practice point is that an aliquot from the *same sample* must be sent because drug(s) present in the first sample may no longer be present in a sample obtained days or

weeks later. Consequently, results must be reviewed and supplementary tests correctly ordered before the sample is discarded. This requires effective collaboration between clinical services and laboratories.

On top of this, it is important to appreciate that all laboratory testing, screening, or confirmatory, has cutoff values in order to avoid false positives. Part of the reason for this is that testing often occurs in the workplace, and a false-positive result can have significant consequences for an employee. A commonly used example is of poppy seeds causing positive opioid results [4, 5]. As such, the levels at which a test is deemed positive has been set for each illicit substance, be that opioid, amphetamine, or cannabis, by the particular standards of each country, such as AS/NZS 4308:2008 in Australia and New Zealand [3]. A negative result does not mean that the drug is absent, rather that the concentration in the matrix is less than the threshold concentration and, even if positive, considered unlikely to be of practical importance (a potential false negative). Cutoffs for immunoassay testing of common drugs of abuse according to AS/NZS 4308:2008 are shown below (Table 44.2).

As such we can see that all testing needs to serve the clinical context. A positive urinary drug screen should be sent for confirmation to ensure it is not a false positive particularly if significant action may follow from a positive result. On the other hand, when there is a high clinical suspicion for drug misuse, but a negative urinary drug screen, the sample should be sent for GCMS testing specific for the agent of concern.

This chapter will provide common false positives for each drug of abuse, but it is worth noting that circumstances can be highly variable. The strongest evidence of a legitimate false positive would be to have a patient produce a negative urine drug test, witness them take the suspected interfering drug, and send their urine for testing that shows positive immunoassay and negative GCMS. The weakest would be a case of a person denying use of an illicit substances and claiming use of an interfering substance [6].

Table 44.2 Cutoff levels for drug detection. (Reproduced from Australian Standard AS/NZS 4308:2008)

Class of drug	Cutoff level (ug/L)
Amphetamine type substances	300
Benzodiazepines	200
Cannabis metabolites	50
Cocaine metabolites	300
Opiates	300

There are other limitations on testing. Designer drugs, such as synthetic cannabis or cathinones ("bath salts"), are so new that specific assays are not available to test for these. Urinary drug screens are limited by time and as such cannot assess patterns of use and burden of dependence [7]. Furthermore, there are literature reports of passive inhalation of particular substances of abuse yielding a positive result [1].

44.3 Clinical Role of Drug Testing in Addiction Practice

The main role for drug testing is to detect the use of drugs not reported by the patient. Drug tests are no substitute for a good clinical history. There have been studies questioning the validity of self-reporting as a screening tool [8–10]. However it is worth noting that even within these studies, the sensitivity and negative predictive value of self-reporting remain quite high [8]. Furthermore, it appears that in patients seeking treatment – the very patients we work with in addiction medicine practice – the sensitivity and negative predictive value of self-reporting increase [11, 12]. Some papers also show that the bigger shortfall in self-reporting is *overstating* use, rather than understating [7, 13], and this may be because patients feel they need to overstate their dependence issue in order to receive treatment. Interestingly, Digiusto et al. looked at the urinary drug screens and self-reporting of 341 patients attempting to enter methadone treatment and found that while most drug use was overreported, especially in patients who had been treated before, the major drug underreported was methadone itself. This suggests patients are desperate for treatment, but may have already started medicating themselves illicitly, and fear the consequences of this being detected by the clinical team [13]. In short, uri-

nary drug screens should be an adjunct to clinical history but not a substitute. Typically, the patient will be more likely to report drug use if there is a strong therapeutic relationship and if there are no adverse consequences of reporting recent use. In this setting, self-report will provide details of quantity and frequency that laboratory testing is unable to match, such that self-reports are more useful than laboratory data. For the patient who does not appear intoxicated and who reports no recent drug use, periodic urine drug screening can be worthwhile. Indeed, the main clinical use of a positive urine drug test is to encourage more forthright and detailed self-reporting in this context.

In the addiction setting, there are a number of situations where drug testing can be useful, such as monitoring the use of prescribed benzodiazepines, ensuring that takeaway doses are being used by the patient and not diverted, and when there is concern around concomitant use of sedatives, in particular opioids and benzodiazepines. Even in these situations, an honest, nonjudgmental conversation about what substances the patient is using will supplant urine drug testing. For example, if a patient on a methadone program admits to using heroin, there is little benefit in testing for heroin on a urine drug screen particularly as most tests cannot detect heroin. Again, we emphasize the importance of clinical acumen and good rapport with a patient more than relying on regimented testing.

44.4 Dealing with a Positive Test Result

Discussing a positive test result with a patient can be confronting. It is therefore important to explain to patients in a clear and nonjudgmental manner prior to testing the reasons for performing drug screening. This will alleviate many of the anxieties around a positive result. Should a patient return an unexpected positive specimen, the clinician should undertake the following steps [14]:

- Review the patient's medications for possible false positives.
- Confirm the result with GCMS on the same sample if clinically indicated.
- Present the result to the patient in a clear and nonjudgmental manner.

Test results should only be interpreted by a suitably skilled clinician with knowledge of the patient and the testing process. The authors have experience of community workers removing children from their mothers because of false-positive urine tests as just one example.

44.5 Testing in the Emergency Department

The question of whether to use urine drug screens on patients in the emergency department is a vexed one. Some authors have suggested utilizing the UDS in order to diagnose substance abuse disorders and provide primary care [14]. However, there is no clear evidence to suggest this is useful. A literature review from Tenenbein of over 6000 patients presenting to the emergency department concluded that A UDS was unlikely to significantly impact upon management of the patient in the emergency department [15]. While this review focused primarily on immediate management outcomes, such as time in the emergency department, and procedures the patient received, others have suggested limited utility beyond this time frame. Riccoboni retrospectively reviewed over 200 psychiatric admissions, comparing those that had UDS to those who did not, and found it made little difference in management of their psychiatric illness [16]. This is supported by other studies in psychiatric patients that emphasize the urine drug screen should not trump good clinical history [17, 18]. The authors would suggest that urine drug testing in the emergency department should be performed in order to confirm a suspected diagnosis related to substance abuse when the patient's history does not corroborate. Furthermore, the information should only be presented to the patient when confirmed via GCMS and as a means of helping the patient seek appropriate treatment of a potential substance dependence.

44.6 Point-of-Care Testing

There are a variety of new point-of-care tests entering the market, including dipsticks, breath tests, cassettes, and urine drug cups, which integrate the testing strip with the collection cup [14, 19].

Point-of-care devices have the benefit of fast results and appear to have low rates of false positives and false negatives [14]. However, it is worth looking at devices that have been externally validated in studies and noting the cutoffs used by the particular test. Ultimately, they cannot replace GCMS for performance.

44.7 Saliva/Oral Fluid/Mobile Drug Testing

Mobile drug testing is now being utilized in the USA, Europe, and Australia for the detection of cannabis, cocaine, and MDMA in drivers [20–22]. These have many of the same advantages and disadvantages with other point-of-care tests listed above [2]. Saliva typically remains positive for 12–24 hours after drug use, though potentially longer in chronic users [22]. It is also worth noting a few idiosyncrasies to the testing of saliva. Cannabis has been shown to be more difficult to detect [22, 23], while drug deposits in the mouth can cause increased levels in quantitative testing when done in the immediate period after use [24].

Despite these shortcomings, saliva testing has the advantage of limited opportunity for adulteration [2, 22].

44.8 Detection Times

An often-asked question is how long a test will remain positive for, to which there is no hard and fast answer. One can expect a test to remain positive for around five half-lives of the drug, as this is the time taken to excrete around 97% of the drug. However, duration of positivity is determined by many pharmacological factors, including body weight and composition, half-life of the drug, dose, duration of use, volume of distribution, bioavailability of the drug, and the half-lives of metabolites [1, 2, 25]. Nonetheless, this chapter will attempt to provide a guide for each substance of abuse around how long a test will remain positive.

44.9 Drug Testing Technologies

44.9.1 Immunoassay

Most clinical laboratories use immunoassay on high-capacity automated analyzers as first-line screening. All immunoassays are based on an antibody directed against either the drug of interest or a metabolite of the drug of interest. An example would be the immunoassay screen for cocaine, which has an antibody against benzoylecgonine.

Cloned enzyme donor immunoassay is the most commonly used assay in Australasian laboratories. The process involves mixing the patient's sample with an assay kit. The kit will contain an antibody against the metabolite of the drug being tested for and also the antigen of the drug being tested for tagged with an enzyme, such as glucose-6-phosphate dehydrogenase [26]. This enzyme converts NAD to NADH. If there is no drug present in the patient's simple, then the antibody from the kit will bind the antigen from the kit, and no enzymatic reaction will occur. However, if there is drug present in the patient's sample, then these metabolites will bind the antibody of the kit, leaving the antigen from the kit free and thus able to complete its reaction. The product of the reaction, in this case NADH, can then be tested for.

Because of cross-reaction of different substances for the antibody in the assay kit, one can easily see how false positives and false negatives can occur frequently. This is a major limitation of immunoassays in drug testing.

44.9.2 Chromatography and Mass Spectrometry

Chromatography is a process whereby individual components of a complex mixture are physically separated and identified. There are three tech-

niques that can be used to separate and identify drugs in a body fluid such as urine: thin-layer chromatography (TLC), gas chromatography (GC), and liquid chromatography (LC). All these techniques involve a stationary phase and a mobile phase. For example, in GC the stationary phase is a polymer that coats the inner wall of a silica capillary tube. The mobile phase is an inert gas, such as helium. As in all forms of chromatography, the separation is achieved by allowing the drug to bind to the stationary phase and passing the mobile phase through so as to progressively remove the drug.

The identification of the drug eluted into the mobile phase uses a variety of techniques and requires comparison of the test sample with known pure standards. In TLC, drugs are detected by direct visualization, requiring the interpreter of the test to have knowledge of the various patterns that may be formed. GC and LC, however, use instrumental techniques of analysis, and while there are several different detectors that can be used to distinguish the presence of a drug, the preferred detectors in drug analysis are mass spectrometers.

Mass spectrometry involves the formation of charged ion(s) from the drug molecule. These charged ions can be sorted in the mass spectrometer and the mass of each ion determined. Different drugs give rise to a distinctive ion "fingerprint."

44.10 Detecting Specific Drug Classes

It is worth looking at each drug individually, focusing on the metabolism of the drug and the metabolites being test, the expected duration the test will remain positive, common cross-reactions, and, for certain drugs, whether passive inhalation can cause positive results.

44.10.1 Amphetamines

It is important to appreciate that the term "amphetamine" refers specifically to 1-phenylpropan-2-amine. There are, however, many other compounds structurally related to amphetamine that are often categorized under the broad umbrella of "amphetamines": methamphetamine ("crystal meth" or "ice"), methylenedioxyamphetamine (MDA), and methylenedioxymethylamphetamine (MDMA or "ecstasy"). The different assays used in urinary drug screens vary in reactivity for the various types of amphetamine.

Amphetamines are typically detectable in urine for around 48 hours after administration of the drug, though this can vary [27]. Amphetamines are typically basic, and consequently the rate of renal excretion of the unchanged drug is dependent on urine pH. Acidic urine gives amphetamine a charge that promotes excretion because the ionized form of amphetamine is poorly reabsorbed across the distal convoluted tubule of the kidney. Therefore by acidifying urine, such as with high doses of vitamin C, one can theoretically excrete amphetamine quicker. The half-life of amphetamines can be as short as 4 hours with acidic urine, as opposed to 12 hours with uncontrolled urinary pH, theoretically dropping the excretion time to less than 24 hours.

While there have been some concerns around immunoassay detection of amphetamines at low doses [28], GCMS is around 90% sensitive for detection even in doses as low as 10 mg [27]. It would not be unusual for a patient abusing amphetamines to be using far higher doses [25]. At the same time, patients that use medicinal amphetamines, particularly lisdexamfetamine for ADHD, would be expected to test positive as this is a prodrug converted in vivo to amphetamine.

As already mentioned, amphetamines have a vast number of cross-reactivities. This stems largely from the simplicity of the molecule, making it difficult to develop specific antibodies, and the high number of structurally similar sympathomimetics [6]. The most common source of a false-positive test is cold medicines such as pseudoephedrine. Promethazine [29], labetalol [30], ofloxacin [31], and bupropion [32] have all been shown to cause false-positive results for methamphetamines.

Furthermore methamphetamine is a chiral molecule. Typically, the illicit form is dextrorotary (d-form) or a racemic mixture of levorotary (l-form) and d-form. L-form methamphetamine

is also a metabolite of selegiline and Vicks VapoRub and thus these can cause false positives [33].

There is no evidence that passive inhalation of methamphetamines can cause false-positive urine drug tests [34].

Designer amphetamines and synthetic cathinones, such as mephedrone or methcathinone, present a new challenge for drug testing, due to the number of different chemical structures that exist among these drugs [35]. Furthermore, new designer drugs are being introduced into the market regularly, making it difficult to produce immunoassays for each drug. Nonetheless, there is at least one immunoassay on the market, validated for mephedrone, methcathinone, methylenedioxypyrovalerone (MDPV), and 3′,4′-methylenedioxy-α-pyrrolidinobutiophenone (MDPBP) [36]. Many other established cathinones can also be detected via GCMS [35].

44.10.2 Benzodiazepines

Benzodiazepines have a variety of metabolic pathways, which can complicate testing.

There is almost no excretion of unconjugated parent benzodiazepines, and only three are excreted following glucuronidation alone: oxazepam, temazepam, and lorazepam. However, these three drugs show the complexity of testing for benzodiazepines, as the immunoassays will not detect their glucuronide conjugates unless the urine was treated with β-glucuronidase before testing, a practice not commonly done.

The metabolism of diazepam also warrants specific discussion. Diazepam can be demethylated to form nordiazepam or hydroxylated to form temazepam. Both these metabolites can form oxazepam. When taken orally, temazepam itself is demethylated to oxazepam. As such, benzodiazepine assays typically look for oxazepam and nordiazepam, as they are common metabolites in benzodiazepine metabolism. However, they may miss other commonly abused benzodiazepines, such as alprazolam, whose main metabolites are α-hydroxyalprazolam and 4-hydroxyalprazolam [37]. Clonazepam is converted to 7-aminoclonazepam, and flunitrazepam, metabolized to 7-aminoflunitrazepam. Lorazepam is excreted as an inactive glucuronide (Fig. 44.1).

Given the above, if monitoring use of prescribed benzodiazepines in an addiction setting, a simple immunoassay will not suffice, and the urine should be sent for formal GCMS.

Interpretation of results is a key issue. A patient may be prescribed diazepam, and urine testing may reveal diazepam, nordiazepam, oxazepam, and temazepam. This result reflects normal drug metabolism and does not signify nonprescribed use of the latter two drugs.

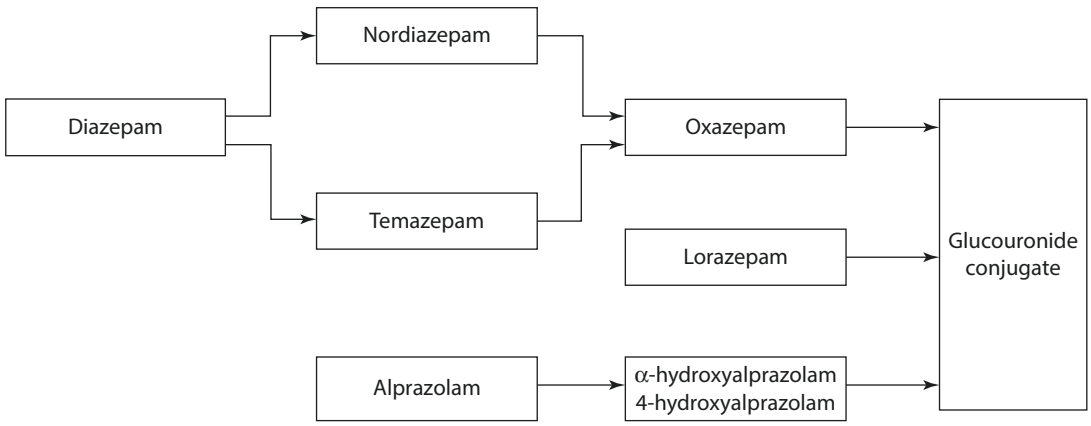

Fig. 44.1 Interconversion of commonly used benzodiazepines. (Adapted from Moeller 2016)

Detection times for benzodiazepines vary depending on duration of action. Diazepam, a long-acting benzodiazepine, can be detected for up to a week even after a single dose [26], while the metabolite nordiazepam can be detected for up to 3 weeks [38]. Short-acting benzodiazepines, such as alprazolam, temazepam, and oxazepam, may only be detectable for around 24 hours, while intermediate acting benzodiazepines, such as lorazepam, can be detected for up to 12 days [14]. Having said this, chronic use of benzodiazepines can result in a positive test for up to a month following cessation [14]. Flunitrazepam has received a lot of attention due to reports of it being used in cases of date-rape and is detectable after acute dosing for at least 48 hours using GCMS [39].

There is strong evidence that efavirenz [40], an antiviral used for HIV, and sertraline [41] both cause false positives in urine drug testing for benzodiazepines, while there has been a case report of oxaprozin, a nonsteroidal anti-inflammatory, causing a false positive [42].

44.10.3 Cannabis

Tetrahydrocannabinol (THC), the main psychoactive component of the hemp plant cannabis sativa, undergoes a complex metabolism to carboxy-THC. Carboxy-THC is not psychoactive and is extensively conjugated with glucuronic acid before excretion into urine.

The current cutoff concentration for immunoassay of cannabis metabolites has been set at 50 μg/L in the Australasian standard AS/NZS 4308:2008 because of concerns around passive smoking. There have been several studies that have looked at passive smoking, and the consensus is that passive smoking is unlikely to result in a urinary concentration of cannabis metabolites that exceeds 50 μg/L.

Carboxy-THC has an elimination half-life of around 6 days. However, THC is lipophilic and has a high volume of distribution, meaning chronic users of cannabis establish a significant reservoir of carboxy-THC in adipose tissue. The time taken for carboxy-THC to fall back to below the cutoff concentration in urine therefore depends on the amount of THC stored in tissue lipids, which in itself depends on duration and amount of exposure.

Following a single occasion of cannabis use, GCMS will typically be positive for 72 hours. Moderate users of cannabis, using four times per week, will typically have a negative test in 5–7 days after stopping the drug. Daily users will typically test positive for about 12 days post ceasing use, but chronic users may have a positive test for more than 30 days [43].

Given the extended duration of detection of carboxy-THC in the urine of long-term heavy users of the drug, it can make ongoing detection post cessation challenging. One approach is to determine a carboxy-THC: creatinine ratio for urine samples collected at different times. A comparison of these two ratios allows for assessment of continued use.

Detection of synthetic cannabinoids is difficult for many reasons. Typically, they are highly potent, so only a small dose is required, and metabolized quickly [44, 45]. Furthermore, there are over 800 different types of synthetic cannabinoids, making it difficult to produce immunoassays to detect all types and to keep up with the new drugs being introduced into the illicit market [44]. Despite the challenges, there are some immunoassay kits available for detection of synthetic cannabinoids, including DrugCheck K2/Spice Test, DrugSmart Cassette, and RapiCard InstaTest [45].

Clinicians should also be aware that dronabinol, a synthetic form of THC approved for use in spasticity in multiple sclerosis, will test positive on urine drug screens, though nabilone, approved in some countries for use in nausea during chemotherapy, will not [46, 47]. While both are synthetic cannabinoids, nabilone is a synthetic derivative [48] and has enough difference in structure to test negative.

Proton pump inhibitors have been shown to cause false positives both in case reports and formalized testing [49, 50]. The urinary metabolite of Efavirenz, 8-ether-glucoronide, cross-reacts

with cannabinoid immunoassays [51, 52]. Naproxen and ibuprofen also have a small possibility of false-positive results on immunoassay, and as such, confirmatory testing with GCMS is warranted should this occur [53]. Certain baby wash products can also produce a false positive on immunoassay, which is important in the setting of neonatal drug testing [54].

44.10.4 Opioids

An understanding of opioid metabolism is critical when interpreting urine drug tests. It is important to note that morphine, codeine, and heroin (diacetylmorphine) are the only fully natural opioids, and most immunoassays are directed at these three substances and their metabolites. Synthetic opioids, such as fentanyl, methadone, buprenorphine, pethidine, oxycodone, and oxymorphone, are structurally different enough to natural opioids that they will not be detected by these immunoassays and require either specific assays directed at their metabolites or GCMS [14]. Thus, a patient using illicit fentanyl or prescribed buprenorphine will typically have a negative urine drug screen, and further testing is required in order to show use of synthetic opioids.

44.10.5 Morphine, Codeine, and Heroin

Heroin is rapidly metabolized to both 3-monoacetylmorphine, which is inactive, and 6-monoacetylmorphine (6-MAM), which is rapidly deacetylated to morphine, and has a half-life of about 5 minutes. 6-Acetylcodeine is an impurity often found in illicit heroin, and this can be metabolized to codeine also [55, 56].

Morphine is mostly metabolized to 3-glucuronide and 6-glucuronide, though it has a number of minor metabolic pathways, including to form normorphine and hydromorphone [55, 57].

Codeine is O-demethylated to yield morphine via the actions of CYP2D6 in the liver. However, a large portion of codeine is excreted as codeine 6-glucouronide, while it may also be metabolized to norcodeine and hydrocodone [55, 57, 58] (Fig. 44.2).

Urine immunoassay will not distinguish between codeine, morphine, and heroin. If there is conjecture over which opioid the patient took, the sample needs to be sent for GCMS. Detection of 6-MAM is pathognomonic for heroin use; however, it is usually only detectable for a few hours because of its short half-life (20 minutes) [6–8]. This will often leave the clinician with a

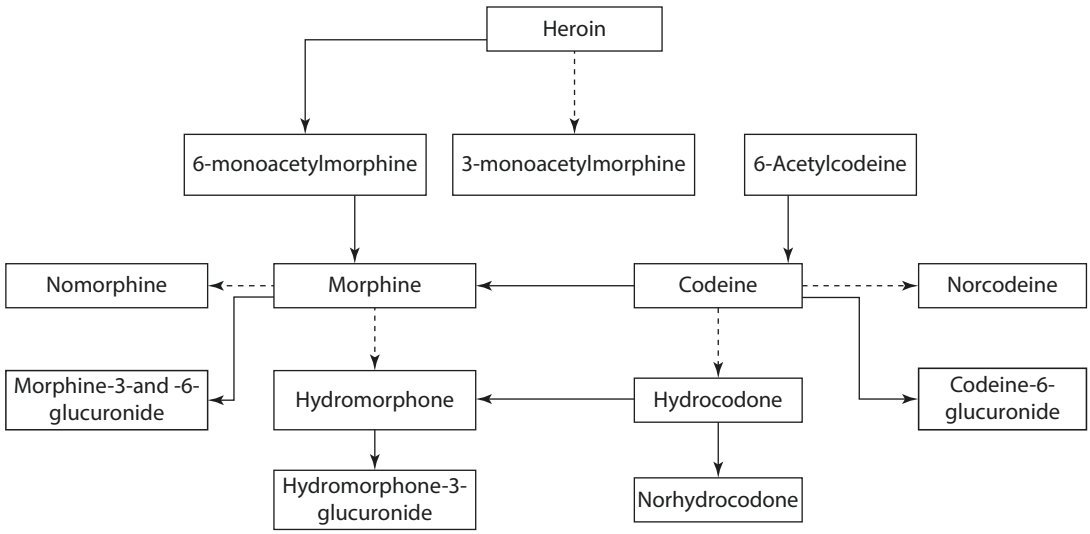

Fig. 44.2 Interconversion of commonly used opioids. (Adapted from French [55])

test that is positive for morphine, codeine, or both, which presents an interesting challenge. Codeine may arise from prescribed analgesics or, as mentioned above, from an impurity in heroin. Morphine may also be derived from codeine, from a prescription for the medication, or from heroin. Furthermore the patient may have used multiple opioids, further complicating the picture [59]. The codeine/morphine ratio may help in this situation. Several studies in both urine and blood have shown that when patients have used heroin, confirmed by the presence of 6-MAM, morphine levels will be greater than codeine [56, 59, 60]. Furthermore, when healthy volunteers take codeine alone, the level of morphine metabolites in urine will typically be lower than codeine, even though codeine is metabolized in part to morphine [59, 61, 62]. This has even been observed in the blood of rapid codeine metabolizers [63]. The following has therefore been suggested: A urine morphine/codeine ratio greater than 2 and total morphine >200 ng/ml suggests morphine or heroin use, while a morphine/codeine ratio less than 2 and total morphine <200 ng/ml suggests codeine use alone [60, 64] (Table 44.3).

Furthermore, current Australian guidelines dictated by AS/NZS 4308:2008 prescribes an opioid cutoff of 300 μg/L for immunoassay screening. This can still result in false positives caused by the ingestion of poppy seeds. In the USA, the Substance Abuse and Mental Health Services Administration (SAMHSA) changed this cutoff to >2000 μg/L in order to exclude poppy seeds as a potential cause of a positive opiate immunoassay. This cutoff, however, may miss true positives.

Several non-opiate drugs may cause false positive tests including the quinolone antibiotic gatifloxacin [65], ofloxacin [66], rifampin, and rifampicin [67, 68].

Table 44.3 Urine findings after use of morphine or codeine. (Adapted from Stefanidou [64])

Morphine/codeine ratio	Total morphine	Suggests
>2	>200 ng/ml	Morphine or heroin use
<2	<200 ng/ml	Codeine use

44.10.6 Methadone

Methadone immunoassays can test for either methadone itself or the inactive metabolite 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidene (EDDP) [1]. The latter is preferred for testing as patients can spike their urine with methadone in order to avoid detection of diversion of methadone doses. Methadone typically remains positive in urine for around 2–4 days, though it can be positive for up to 11 days [14, 69].

Quetiapine [70, 71] and verapamil [72] have both been demonstrated to cause false positives on methadone immunoassays.

The role of monitoring methadone serum levels during methadone treatment warrants some discussion. Currently, there is no recommendation to perform routine methadone levels in patients on methadone treatment. Currently, clinicians in NSW, Australia, only require a trough methadone level in order to apply to prescribe beyond 200 mg/day [73]. This is thought to identify patients that may be rapid metabolizers of methadone and thus require higher doses. At this stage, however, there is no clear plasma level at which methadone dosing is considered "effective." Trough levels tend to sit between 200 and 400 ng/ml [74, 75]. There have been a number of studies evaluating the relationship between methadone dose and plasma concentration, with some suggesting a strong relationship [76], some suggesting a poor relationship [77], while another has shown a strong relationship that only exists at doses less than 80 mg [78]. Further research is still required in this area. Specific stereoisomer testing for R- and S-methadone may improve the relevance of blood levels, but the assay is not widely available [79–81]. Serial measures of methadone levels may be helpful to detect rapid metabolizers but require patient attendance for many hours for multiple blood tests. This may be further complicated by often poor venous access, making this approach impractical for routine care.

44.10.7 Fentanyl

The main metabolite of fentanyl is norfentanyl [82, 83]. Because of its potency, estimated as

50–100 times that of morphine [84], only small concentrations are found in urine following prescribed or illicit use. Detection requires sophisticated techniques and sensitive analyzers that will not be available in many laboratories. Nonetheless, laboratories are improving their ability to detect fentanyl at smaller doses via GCMS and, with a smaller sample of matrix, even as low as 0.175 ml of serum [85]. Furthermore, new assays are now available for use in detecting fentanyl [86, 87], though these are not part of a standard urine drug screen.

Risperidone has been shown to cross-react with at least one fentanyl immunoassay [88]. Fentanyl metabolites are detectable via GCMS for at least 24 hours in urine following a single intravenous dose [84].

Street heroin has been found to be laced with fentanyl and its synthetic analogs, which can have potentially catastrophic consequences given its potency. The use of fentanyl testing in urine may therefore have a public health benefit as a warning to other users, though widespread use for this is not currently done [89].

44.10.8 Buprenorphine

Buprenorphine, widely used in opioid treatment programs, is not typically part of a standard urine drug screen panel, though it can be tested via immunoassay or GCMS [90, 91].

It is important to monitor the use of buprenorphine in patients on opioid treatment, especially those on takeaway dosing, as diversion of doses remains a risk [92]. Buprenorphine is dealkylated to form norbuprenorphine [90]. Both buprenorphine and norbuprenorphine can be glucuronidated, leaving four main metabolites in urine: buprenorphine, norbuprenorphine, buprenorphine-glucuronide, and norbuprenorphine-glucuronide [90, 93].

The laboratory may help with the detection of patients who spike their urines with their own supply of buprenorphine to give the impression that they are using the drug, when in fact they are diverting it [94]. The concentration of parent buprenorphine is typically lower than the other metabolites [95]. Therefore, norbuprenorphine/buprenorphine ratios are a good way to detect for spiked urines. In theory, all patients taking buprenorphine orally should have a norbuprenorphine/buprenorphine ratio greater than 1, and any ratio < 0.02 is considered to be spiked [90, 94]. One study has also suggested that norbuprenorphine levels may be able to estimate and guide the patient's dose of buprenorphine, though this is not validated or routine practice [96].

There are case reports that amisulpride [97], and high-dose morphine [98] can cause false-positive buprenorphine immunoassay results. The window of detection for buprenorphine is 4 days with a cutoff of 0.5 ng/ml [14].

44.10.9 Cocaine

The major metabolite of cocaine is benzoylecgonine, with around 45% of the dose excreted in the urine as such. Standard immunoassays show good reaction to benzoylecgonine, limited reaction to cocaine, and virtually no reaction to other metabolites. After use of 1.5 mg/kg intranasally, GCMS and immunoassay both appear to remain positive for around 2–3 days [99]. Interestingly, after administration of 20 mg of intravenous cocaine, immunoassays remain positive for only 2 days [100].

It is also worth noting that cocaine is still used as a vasoconstrictor and topical anesthetic for nasal surgery and that urines will test positive for similar timeframes as for illicit use [101]. Furthermore, passive inhalation of cocaine when smoked does not appear to cause false positives [34].

44.10.10 GHB

Gamma-hydroxybutyric acid (GHB) is particularly difficult to pick up on urine testing due to its short half-life and because it requires GCMS for detection, not immunoassay [14]. Furthermore, GHB is produced endogenously, and because of this, it has been suggested that 10 μg/ml is the cutoff for urine testing [25]. A 100 mg/kg dose of

GHB is undetectable in urine 12 hours later [102]. It is not routinely tested in the addiction medicine field.

44.10.11 Nitrous Oxide

The use of nitrous oxide among recreational drug users appears to be increasing, with around one quarter of ecstasy users admitting use in their lifetime [103, 104]. Subacute combined degeneration of the cord (SCID) has become a serious health issue in these patients [105]. While nitrous oxide is not tested in urine or other matrices, it is important for the addiction physician to be aware of the appropriate serum tests should a patient admit to using nitrous oxide recreationally. A normal B12 level is not reassuring because nitrous oxide inactivates B12, but it does not reduce serum levels, so serum B12 is often normal. Physicians should instead test for homocysteine levels. Vitamin B12 is important for the conversion of homocysteine to methionine, an important element for myelin production. An elevated homocysteine level suggests reduced levels of active B12, and potential risk of subacute combined degeneration of the cord [106, 107].

44.10.12 Ketamine and Phencyclidine

Ketamine has two major metabolites, norketamine and dehydronorketamine [108], which, along with ketamine itself, can all be tested via GCMS [109]. While not part of a typical urine drug screen, specific immunoassays are becoming increasingly available for ketamine as well [110, 111]. Ketamine is typically detectable for 3 days by GCMS when taken orally; however, dehydronorketamine can be detected for up to 10 days [112]. Quetiapine has been reported in two case reports to cause false positives on ketamine immunoassay [110].

Phencyclidine is now available on some urine drug screen panels, such as the Medtox Diagnostics EZ screen. Urine drug tests can detect PCP for up to 10 days post use. Ibuprofen, dextromethorphan, and metamizole have all been shown in both case reports and in spiked urine testing to cause false positives [113]. Venlafaxine has also caused false positives in both of these circumstances [114], while there has been a case report of desvenlafaxine doing likewise [115]. There have been cases reports of tramadol causing positive PCP result on immunoassay, though this appears to occur more readily at supratherapeutic doses [116, 117].

44.10.13 Lysergic Acid Diethylamide (LSD)

LSD is converted to a number of different metabolites, and only around 1% of the drug is excreted unchanged [118]. Despite this, most immunoassays are still directed at LSD itself [119], and these are typically positive for around 24 hours, though there has been a report of detection 80 hours post use [25].

Ritter et al. found 71 false-positive LSD results from immunoassay testing of almost 1900 positive samples [120]. Potential causative drugs included amitriptyline, bupropion, metoclopramide, labetalol, and calcium channel blockers; however, no confirmatory testing has been undertaken to prove which agents truly cross-react with the immunoassay. Ambroxol, however, has been seen in both case report and spiked urine testing to cause false-positive immunoassay results [121].

Contents

Abstract

Approximately 29.5 million people, or 0.6% of the global adult population, have a drug use disorder (United Nations Office on Drugs and Crime (UNODC), World Drug Report (ISBN: 978–92–1-148291-1, eISBN: 978–92–1-060623-3, United Nations publication, Sales No. E.17.XI.6), 2017). People who use illicit drugs often do not disclose their drug use due to the illegality and stigma associated with that use. The opportunistic nature of brief interventions for illicit drug use makes therapeutic engagement critical to effectiveness. In many settings time will be limited so that brief interventions also need to be efficient.

This chapter focuses on opportunistic brief interventions with people who use illicit drugs and are not engaged in treatment for their drug use. In this context the aim of the brief intervention is to reduce substance use and associated risk behavior as well as to prevent the development of dependence or to motivate the individual to obtain more struc-

tured treatment for their drug use. The objective is to reduce the overall burden of drug-related harms in the community or in particular target groups by identifying individuals who are experiencing, or are at risk of developing, drug use problems, to raise awareness of potential drug-related harms, and to intervene early before problems have developed or become severe. Brief interventions are part of a public health approach to drug use problems [3, 21].

This chapter provides practical information on the conduct of effective brief interventions covering the general approach to brief interventions, responding to the stage of change, and assessing risk.

45.1 Introduction

Substance use is one of the major preventable causes of disease and disability [31]. Alcohol and tobacco are by far the most prevalent substances used globally [26], but the prevalence of illicit drug use is still substantial. In 2015 an estimated quarter of a billion people, or around 5% of the global adult population, used illicit drugs at least once [31]. Cannabis was the most commonly used drug, with a reported 183 million users globally. Amphetamine and prescription stimulants were used by 37 million people, and 35 million people used illicit opioids [31].

The magnitude of harm caused by illicit drug use is substantial and has increased over the last decade. In 2015 an estimated 28 million years of "healthy" life (disability-adjusted life years (DALYs)) were lost worldwide as a result of premature death and disability caused by drug use. Of those years lost, 17 million were attributable solely to drug use disorders, across all drug types. Around 70% of the global burden of disease caused by drug use disorders is attributable to opioid use [31], reflecting the high risk of overdose associated with opioid use and the transmission of blood-borne viruses (HIV and hepatitis C) through use by injection [11].

Treatment is effective in reducing illicit drug use, reducing risk behaviors and improving physical and mental well-being, but fewer than one in six persons with drug use disorders are provided with treatment each year. In part this reflects limited availability of and access to appropriate treatments [31], but it is also likely to reflect the hidden nature of illicit drug use.

The stigma associated with illicit drug use, and possible legal implications, means that people who use illicit drugs may be reluctant to disclose their use. They may not be aware of the risks of harm associated with their substance use and not see the connection to negative consequences. For all these reasons, people who use illicit drugs rarely seek treatment unless pushed by a crisis of some sort – legal, financial, family pressure, or acute health effects.

This is where brief interventions come in. Brief interventions have been used in a variety of ways, including as adjuncts to structured treatment for alcohol and other drug problems and to reduce risk behaviors in specific populations such as people with HIV. Brief interventions have also been used to structure brief conversations about healthcare in general [6]. In this chapter we are focusing on opportunistic brief interventions with people who use illicit drugs and are not engaged in treatment for their drug use. In this context the aim of the brief intervention is to reduce substance use and associated risk behavior as well as to prevent the development of dependence or to motivate the individual to obtain more structured treatment for their drug use. The objective is to reduce the overall burden of drug-related harms in the community or in particular target groups by identifying individuals who are experiencing, or are at risk of developing, drug use problems, to raise awareness of potential drug-related harms and to intervene early before problems have developed or become severe. Brief interventions are part of a public health approach to drug use problems [4, 21].

Brief interventions can take place in various settings, such as primary healthcare, and can be implemented by a variety of trained healthcare providers. They are low in cost and time efficient and can be effective across many levels of hazardous and harmful drug use. This makes brief interventions ideally suited for use as a method of health promotion and disease prevention with primary care patients [16, 34].

The opportunistic nature of brief interventions for illicit drug use makes therapeutic engagement critical to effectiveness. In many settings time will be limited so that brief interventions also need to be efficient.

Brief interventions are most useful for those who are at low to moderate risk of drug-related harm. They are not intended as a stand-alone treatment for people with significant drug use disorders although a brief intervention can increase the proportion of patients identified as high risk or dependent who subsequently attend their first appointment at a specialist drug and alcohol treatment facility [3, 18]. Hence it is important to tailor the intervention to the individual by reflecting the risk of drug-related harm. Another important aspect of tailoring the intervention to the individual is taking account of the person's current stage of behavioral change.

There is moderately good evidence for the effectiveness of brief interventions in primary care settings for alcohol and tobacco [22, 30] and growing evidence for other drugs.

Brief interventions consist of feedback about personal risk, explicit advice on change, and emphasis on individual responsibility for change and provide a variety of ways to effect change. Brief interventions in primary care can range from five minutes of brief advice to 15–30 minutes of brief counselling [24]. Shorter duration interventions are typically the requirement in acute care settings where time may be particularly limited.

This chapter provides practical information on the conduct of effective brief interventions covering the general approach to brief interventions (Sect. 45.2), responding to the stage of change (Sect. 45.3), and assessing risk (Sect. 45.4).

45.2 General Approach to Brief Interventions

The aim of a brief intervention is to help the person understand that their substance use is putting them at risk and to encourage them to reduce or give up their substance use. Brief interventions should be personalized and offered in a supportive, nonjudgmental manner. Brief intervention techniques include an empathetic style and support for the person's perception of self-efficacy or optimism that they can change [32].

A number of brief intervention models have been developed, based on principles of motivational interviewing. These include the Brief Negotiated Interview (BNI) [8]; "FLO" – Feedback, Listen, Options [12]; and the 5 As (ask, assess, advise, assist, and arrange follow-up) that are widely implemented for smoking cessation [29].

Experience and research into brief interventions for substance use have found that effective brief interventions comprise a number of consistent and recurring features. These features have been summarized using the acronym FRAMES: feedback, responsibility, advice, menu of options, empathy, and self-efficacy [25]. The FRAMES model is considered in detail here as it is used extensively in brief interventions for alcohol and other drug use and is the approach we recommend for people who use illicit drugs.

Feedback of Personal Status Relative to Norms

Feedback is the provision of personally relevant information which is pertinent to the individual and is delivered in a non-judgemental and objective way in the Spirit of Motivational Interviewing [25]. The provision of personally relevant feedback (as opposed to general feedback) is a key component of a brief intervention. This includes information about the individual's substance use, the level of risk associated with their use, and the benefits of reducing or stopping use.

Information about personal risks associated with current drug use patterns (e.g., low mood,

anxiety, relationship problems, health problems) combined with general information about substance-related risks and harms comprises powerful feedback.

Responsibility for Personal Change

A key principle of an effective brief intervention is to acknowledge and accept that a person is responsible for their own behavior and will make choices about their substance use. Adopting phrases such as "*Are you interested in seeing how you scored on this questionnaire*?" and "*What you do with this information I'm giving you is up to you*" enables the person to retain control over their behavior and its consequences and the direction of the intervention. This sense of control has been found to be an important element in motivation for change [24]. Using language such as "*I think you should…*" may create resistance in the interaction and not be beneficial to behavior change.

Advice to Change

A central component of effective brief interventions is the provision of clear objective advice regarding how to reduce the harms associated with continued use. This needs to be delivered in a non-judgemental manner and in the Spirit of Motivational Interviewing. People may be unaware that their current pattern of substance use could lead to problems or make existing issues worse. Ask permission to give advice and then provide clear, objective information. Explain that cutting down or stopping substance use is the best way to reduce their risk of harms both now and in the future. This will increase their awareness of their personal risk and provide reasons to consider changing their behavior.

Advice can be summed up by delivering a simple statement such as "*the best way you can reduce your risk of* (e.g. depression, anxiety, injuries) *is to cut down or stop using*." This is best followed by an open-ended question to help explore the person's readiness to change. Once again, the language used to deliver this message is an important feature and comments such as "*I think you should stop using substances*" does not provide clear, objective advice nor promote further discussion.

Menu of Options from Which to Choose in Pursuing Change

Effective brief interventions provide the individual with a range or menu of options to cut down or stop their substance use in the pursuit of change. This allows the individual to choose the strategies which are most suitable for their situation and which they feel will be most helpful. Providing choices reinforces the sense of personal control and responsibility for making change and can help to strengthen the person's motivation for change.

Examples of options for clients to consider include

- Keeping a diary of substance use (where, when, how much used, how much spent, with whom, why)
- Identifying high-risk thoughts and beliefs and challenging them
- Identifying high-risk associates and situations and exploring alternate strategies
- Identifying other activities instead of drug use (constructive use of leisure)—education, volunteering, hobbies, sports, gym, etc.
- Identifying non-drug rewards and pleasurable activities
- Identifying people who could provide support and help for the changes they want to make
- Attending a self-help or peer support groups
- Putting aside the money they would normally spend on substances for something else
- Setting goals and working toward achieving them

You can also assist by

- Providing information about other self-help resources and written information
- Providing information about groups or programs that specialize in drug and alcohol issues

Empathic Counselor Style

Empathy is taking an active interest and effort to understand another's internal perspective, to see the world through their eyes. It does not mean sympathy, a feeling of pity, camaraderie, or identification with the person. Statements such as

"*I've been there and know what you are experiencing, let me tell you my story*" are not useful. The opposite of empathy is the imposition of one's own perspective, perhaps with the assumption that the other's views are irrelevant or misguided. Empathy is the ability to understand another's frame of reference and the conviction that it is worthwhile to do so [23].

In a brief intervention, empathy comprises an accepting, nonjudgmental approach that seeks to understand the individual's point of view. It is especially important to avoid confrontation and blaming or criticism of the individual. Adopting a position of *curious intrigue* is helpful. Skilful reflective listening which clarifies and amplifies the person's experience and meaning is a fundamental part of expressing empathy. The empathy and understanding of the professional are important contributors to how well the individual responds to the intervention [25].

Support for Self-Efficacy

The final component of effective brief interventions is to encourage the person's confidence that they are able to make changes in their substance use. Exploring other areas where the individual has made positive change is helpful. People who believe that they are likely to make positive changes are more likely to do so than those who feel powerless or helpless to change their behaviour. It is particularly helpful to elicit self-efficacy statements from individuals as they are likely to believe what they hear themselves say, and belief in the possibility of change is an important motivator.

45.3 Linking to Stage of Behavioral Change

Brief interventions are structured and personalized discussions which aim to motivate clients to undertake positive behavior change. The transtheoretical model of behavior change developed by Prochaska and DiClemente presents behavioral change as occurring in distinct stages [27]. The aim of intervention is to support people to move through the stages of change. While a person's stage of change may not be formally measured or assessed, interventions that are tailored to the likely stage of change may be more effective.

The transtheoretical model of behavior change proposes several stages (pre-contemplation, contemplation, preparation, action, and maintenance). The model identifies a number of stages which are commonly experienced during the process of adopting a new behavior. Progression is not necessarily linear, and the time spent in each stage is highly variable.

People in the *pre-contemplation* stage generally do not link their substance use to any problems. Commonly, they are unconcerned by their drug use or related consequences and are not yet considering a change or are unwilling to change. Motivational interviewing strategies are appropriate for this stage of change. Such strategies involve exploration of both the pros and cons of substance use and development of discrepancies between a client's current behaviors and future ambitions/goals.

In the *contemplation* stage, the person acknowledges concerns and is considering the possibility of change but is still ambivalent or uncertain about that change. Motivational interviewing is again appropriate, with the aim of normalizing feelings of ambivalence and helping the client to move toward change.

In the *preparation* stage, the balance has shifted. Change is seen as worthwhile, and the person is gaining confidence in their capacity to change. The person is preparing to take action by gathering information that will assist them. The negative consequences of drug use are now seen as outweighing the benefits. The focus should be on helping the person consider barriers to change and ways to overcome those barriers, exploring options, eliciting from the person what has worked in the past for them or others, and assisting the client to enlist social support.

In the *action* stage, the person is actively taking steps to change but has not yet reached a stable state. They are implementing strategies to change their drug use pattern. It is important to support their engagement in change, reinforce the importance of remaining committed, and help to find new reinforcers of positive change, including assessment of the strength of family and other social supports.

In the *maintenance* stage, the person has succeeded in stopping their harmful drug use and is concentrating on continuing that progress. The focus in this stage is on building resilience, self-monitoring, identifying high-risk situations, and developing appropriate coping skills. It is important to affirm the person's resolve and self-efficacy and review long-term goals. It is helpful to encourage them to articulate the positive reasons for maintaining change to reinforce their decisions and reaffirm relapse prevention approaches.

A *relapse* (or lapse – a one off or short period) is a return to the old behavior that was the focus of change. Most people who try to make changes in their substance use behavior may relapse to substance use, at least for a time. This should be viewed as a learning process rather than failure. Few people change on the first attempt, and relapse is an opportunity to help people review their action plan. A review should examine time frames, what strategies did actually work, and whether the strategies used were realistic. For many people, changing their substance use gets easier each time they try until they are eventually successful.

Most people identified opportunistically for brief interventions aimed at illicit drug use are likely to be mainly in the pre-contemplation stage, with some in contemplation. The aim of brief interventions for people engaged in the least amount of change is to help them understand that their drug use is putting them at risk and to develop ambivalence about their drug use that would then lead to them preparing to take action to change their drug use.

The principles outlined here can also be adapted for people preparing for change but who lack the confidence and knowledge and for clients who are in the action stage.

45.4 Assessing Level of Risk

A wide variety of standardized questionnaires and biological tests have been developed to detect psychoactive substance use [3]. Biological tests are generally not suitable for routine screening prior to brief intervention as they are costly, invasive, can only detect recent use, and results are not available immediately. A major shortcoming of biological screening is that biological tests fail to assess a person's pattern of use and level of risk of harm or dependence and so do not provide a foundation for brief intervention. Hence, assessing a person's level of risk to inform a brief intervention will generally involve use of a screening instrument.

Many of the available screening instruments are specific to alcohol (e.g., AUDIT) or tobacco (e.g., Fagerstrom). The Alcohol, Smoking and Substance Involvement Screening Test (ASSIST) was developed under the auspices of the World Health Organization (WHO) by an international group of specialist addiction researchers and clinicians in response to the overwhelming public health burden associated with psychoactive substance use worldwide [19] and offers the advantage of screening for alcohol, tobacco, illicit drugs, and the unsanctioned use of pharmaceutical drugs.

Other characteristics that should be considered when selecting a screening instrument to assess risk prior to a brief intervention include —

- Acceptability: The instrument should be acceptable to both health workers and those being screened in terms of safety, simplicity, and ease and time of administration.
- Reliability/repeatability: The instrument must give consistent results when repeated more than once on the same individual under the same conditions. It should also give consistent results when administered by different people (inter-rater reliability).
- Validity: The instrument must accurately measure what it purports to measure (construct validity) and accurately separate those who have the condition from those who do not (discriminant validity). Discriminant validity has two components, sensitivity and specificity.
  - Sensitivity is the ability of the instrument to identify correctly those who have the condition, that is, "true positives."
  - Specificity is the ability of the instrument to identify correctly those who do not have the condition, that is, "true negatives."

  - In the context of brief interventions for illicit drug use, sensitivity should be emphasized over specificity so as to minimize the possibility of not identifying people at risk of harm from their drug use.
- Cost which will depend on whether the instrument is self-administered or administered by a health worker or clinician, how long it takes, and what special training (if any) is required.
- Non-judgemental and non-confrontational: This is important so that people feel able to report their drug use.
- Culturally neutral: A culturally neutral screening test will have wider acceptability with different populations both nationally and internationally.

45.4.1 The Alcohol, Smoking and Substance Involvement Screening Test (ASSIST)

The ASSIST V3.1 (Appendix A) is an eight-item questionnaire designed to be either self-administered or by a health worker. For most people, the ASSIST can be completed in about five minutes and can be incorporated into routine consultation. The ASSIST is available as a web-based version which can be self-administered or administered by a health worker and as a smartphone/tablet application for self-administration (https://assistportal.com.au/).

The ASSIST has been through rigorous scientific testing to ensure that it is a reliable and valid instrument in international settings and able to link into a brief intervention [20]. The ASSIST has shown good cross-cultural neutrality, has been validated for use in adult populations (between 18 and 60 years of age), and is appropriate for use with adolescents.

The ASSIST obtains information about lifetime and recent use (last three months) of the following substances:

- Tobacco
- Alcohol
- Cannabis
- Cocaine
- Amphetamine-type stimulants (ATS)
- Inhalants
- Sedatives and sleeping pills (benzodiazepines)
- Hallucinogens
- Inhalants
- Opioids
- "Other drugs"

"Other" drugs are those that do not readily belong in any of the other drug categories. This could include Kava, Datura, Khat, Kratom, gamma hydroxybutyrate (GHB), and any other drugs of concern in the local population. There may be other substances native to some regions which don't easily fit into any of the other substance classes and need to be put into this "other drugs" category.

The ASSIST can identify a range of issues related to substance use including the risks associated with acute intoxication, regular use, dependent or "high risk," use and injecting behavior. Taken together, these questions provide an indication of the level of risk associated with the person's substance use and whether use is hazardous and likely to be causing harm (now or in the future) if use continues.

The score obtained for each substance falls into a "low," "moderate," or "high' risk category. Scores in the mid-range on the ASSIST are likely to indicate hazardous or harmful substance use ("moderate risk"), and higher scores are likely to indicate substance dependence ("high risk"). The level of risk determines the most appropriate intervention for that level of use ("no treatment," "brief intervention," or "referral to specialist assessment and treatment," respectively).

45.4.2 Linking Assessed Risk to a Brief Intervention

The ASSIST-linked Brief Intervention was specifically designed for people who are at *moderate risk* from their substance use, according to their ASSIST scores, to provide them with a structured appropriate brief intervention depending on their stage of change, that is, people who are *not* dependent, but are using substances in a risky, hazardous, or harmful way that may be creating health, social, legal, occupational, or financial

problems for the person or has the potential to create those problems should the substance use continue.

The ASSIST-linked Brief Intervention is based on the FRAMES model and motivational interviewing techniques. It follows ten main steps:

1. *Asking* if they are interested in seeing their questionnaire scores
2. Providing personalized *Feedback* to clients about their scores using the ASSIST Feedback Report Card
3. Giving *Advice* about how to reduce risk associated with substance use
4. Allowing people to take ultimate *Responsibility* for their choices
5. Asking how *Concerned* they are by their scores
6. Weighing up the *Good things* about using the substance against the
7. *Less good things* about using the substance
8. *Summarizing and Reflecting* on statements about their substance use with emphasis on the less good things
9. Asking how *Concerned* they are by the less good things
10. Giving clients *Take-home materials* to bolster the brief intervention

The suggested ten-step ASSIST-linked Brief Intervention is particularly appropriate for clients who are in the contemplation or pre-contemplation stage of change.

While the majority of people screened in primary care settings are likely to be at low to moderate risk of substance related harm, a proportion will be at high risk and may have a substance use disorder (including dependence). Brief interventions are not intended as a stand-alone intervention for people who are dependent or at "high risk" from their substance use. However, a brief intervention should be used to encourage such people to accept referral to specialized drug and alcohol assessment and treatment, either within a primary care setting or at a specialized alcohol and drug treatment agency.

45.4.3 The ASSIST-Lite

Translating the ASSIST into routine use in health services has proved problematic. Substance use disorders are not systematically screened, diagnosed, or treated in general medical settings, and time constraints on staff appear to be the main barrier [1]. In 2008, an American Preventive Service Task Force called for a research and development initiative to *provide questionnaires short enough to be potentially useful in the practice setting with acceptable accuracy and reliability*. The ASSIST-Lite was developed to address this need and is ideally suited for opportunistic and routine screening for substance use in primary, general medical, and welfare service settings [1].

The ASSIST-Lite is a short form of the ASSIST. The ASSIST-Lite screens for risk of harm from substance use, specifically, tobacco, alcohol, cannabis, stimulants including amphetamine-type stimulants, and cocaine, sedatives, and opioids including prescription opioids. There is also the opportunity to ask about any other psychoactive substance not listed. The ASSIST-Lite identifies which substances are of concern and gives an indication of the severity of substance-related risks and harms. Consequently, it can form a valuable part of a comprehensive health assessment.

The ASSIST-Lite risk score refers to risk of harm from current patterns of substance use. Harm is broadly defined and includes health, legal, social, financial, work, and family issues. The risk of harm score for each substance helps to initiate and frame a brief discussion with individuals about their substance use. Like the full ASSIST, the score obtained from the ASSIST-Lite for each substance falls into a "low," "moderate," or "high' risk category which determines the most appropriate linked brief intervention for that level of use.

A copy of the ASSIST-Lite is included in Appendix B. The ASSIST-Lite is available as a web-based platform and as a smartphone/tablet application for self-completion (available at https://assistportal.com.au/).

The ASSIST and ASSIST-Lite can be readministered after three months to monitor progress and changes over time. Interventions can be stepped up if the score has increased, and the Brief Intervention can be used to intervene early if it appears that other issues are developing.

45.5 Settings for Brief Intervention

Primary care settings such as general practice, community health centers, and other local health services are the first point of contact with the health system for most people. Primary care provides a wide range of services including health promotion, prevention and screening, early intervention, treatment, and management of a variety of chronic health conditions. This includes preventive activities such as immunization, as well as screening and early intervention for high blood pressure, obesity, high cholesterol, and other lifestyle risk factors. Screening and brief intervention for illicit drug use fit well with this role.

In the developed world, 85% of the population visit a primary healthcare clinician such as a general practitioner at least once a year [10], and there is evidence that people who have substance use-related problems have more frequent consultations [5, 17]. Widespread screening in primary care settings increases the likelihood of identifying and intervening with people who use illicit drugs. As a result of their position in the healthcare system, primary care clinicians are likely to see a wide cross-section of the community and hence are more likely to see people at an earlier stage in their drug use when risk and harm are lower. They have a unique opportunity to provide comprehensive, continuing, and person-centered healthcare as well as to link those in need to specialist services when required.

Primary care workers often have an ongoing relationship with clients of their service which enables them to develop rapport and demonstrate genuine concern for their welfare. People expect their primary care clinician to be involved in all aspects of their health and are likely to feel more comfortable about discussing sensitive issues such as drug use with someone they know and trust. The ongoing nature of the relationship means that such discussions can be spread out over time and form part of a number of consultations. Specialist drug and alcohol services may be associated with stigma which can deter some people from seeking assistance for substance use problems. Primary healthcare settings are not associated with this stigma making people more likely to attend a primary care service.

People who use alcohol and other drugs are also over represented in hospital emergency care presentations [14]. Australian research found that while alcohol is the most common substance used by intoxicated people who attend the emergency department, the contribution of other drugs is substantial [15].

Attendance at an emergency department is often a time of crisis when patients may be more willing to accept help and advice [8, 13, 33]. A brief intervention delivered in the context of presentation to a hospital emergency department can be used to help the patient gain insight into the consequences of their substance use and may be a motivating factor to encourage behavioral change [8] or engagement in structured treatment. Interventions in the emergency setting would have a public health aim [7], with those presenting in emergency department comprising a higher-risk population [28].

Providing brief interventions for substance use to people presenting to hospital emergency departments has the potential to facilitate management and discharge of some patients and may reduce the likelihood of repeat presentations [2, 9].

Screening and brief intervention can also be undertaken in specialist medical services such as mental health services and sexual health services where substance use is more prevalent than in the general population. A number of services worldwide have embedded the ASSIST and linked brief intervention into their routine practice demonstrating the feasibility of implementing brief interventions for illicit drug use in a wide range of contexts.

Appendix A: WHO - ASSIST V3.1

WHO - ASSIST V3.1

CLINICIAN NAME		**CLINIC**	
CLIENT ID OR NAME		**DATE**	

INTRODUCTION (Please read to client. Can be adapted for local circumstances)

The following questions ask about your experience of using alcohol, tobacco products and other drugs across your lifetime and in the past three months. These substances can be smoked, swallowed, snorted, inhaled or injected (show responsecard).

Some of the substances listed may be prescribed by a doctor (like amphetamines, sedatives, pain medications). For this interview, we will not record medications that are used as prescribed by your doctor. However, if you have taken such medications for reasons other than prescription, or taken them more frequently, at higher doses than prescribed or in ways in which it wasn't intended, please let me know.

While we are also interested in knowing about your use of various illicit drugs, please be assured that information on such use will be treated as strictly confidential.

NOTE: BEFORE ASKING QUESTIONS, GIVE ASSIST RESPONSE CARD TO CLIENT

Question 1 (please mark the response for each category of substance)

In your life, which of the following substances have you ever used? *(NON-MEDICAL USE ONLY)*	**No**	**Yes**
a. Tobacco products (cigarettes, chewing tobacco, cigars, etc.)	☐	☐
b. Alcoholic beverages (beer, wine, spirits, etc.)	☐	☐
c. Cannabis (marijuana, pot, grass, hash, etc.)	☐	☐
d. Cocaine (coke, crack, etc.)	☐	☐
e. Amphetamine type stimulants (speed, meth, ecstasy, etc.)	☐	☐
f. Inhalants (nitrous, glue, petrol, paint thinner, etc.)	☐	☐
g. Sedatives or Sleeping Pills (Diazepam, Alprazolam, Flunitrazepam, Midazolam etc.)	☐	☐
h. Hallucinogens (LSD, acid, mushrooms, trips, Ketamine, etc.)	☐	☐
i. Opioids (heroin, morphine, methadone, Buprenorphine, codeine, etc.)	☐	☐
j. Other - specify:	☐	☐

Probe if all answers are negative:
"Not even when you were in school?"

If "No" to all items, stop interview.

If "Yes" to any of these items, ask Question 2 for each substance ever used.

Question 2

In the past three months, how often have you used the substances you mentioned *(FIRST DRUG, SECOND DRUG, ETC)*?	**Never**	**Once or Twice**	**Monthly**	**Weekly**	**Daily or Almost Daily**
a. Tobacco products (cigarettes, chewing tobacco, cigars, etc.)	0	2	3	4	6
b. Alcoholic beverages (beer, wine, spirits, etc.)	0	2	3	4	6
c. Cannabis (marijuana, pot, grass, hash, etc.)	0	2	3	4	6
d. Cocaine (coke, crack, etc.)	0	2	3	4	6
e. Amphetamine type stimulants (speed, meth, ecstasy, etc.)	0	2	3	4	6
f. Inhalants (nitrous, glue, petrol, paint thinner, etc.)	0	2	3	4	6
g. Sedatives or Sleeping Pills (Diazepam, Alprazolam, Flunitrazepam, Midazolam etc.)	0	2	3	4	6
h. Hallucinogens (LSD, acid, mushrooms, trips, Ketamine, etc.)	0	2	3	4	6
i. Opioids (heroin, morphine, methadone, codeine, etc.)	0	2	3	4	6
j. Other - specify:	0	2	3	4	6

If "Never" to all items in Question 2, skip to Question 6.

If any substances in Question 2 were used in the previous three months, continue with Questions 3, 4 & 5 for each substance used.

Question 3

During the past three months, how often have you had a strong desire or urge to use *(FIRST DRUG, SECOND DRUG, ETC)*?	**Never**	**Once or Twice**	**Monthly**	**Weekly**	**Daily or Almost Daily**
a. Tobacco products (cigarettes, chewing tobacco, cigars, etc.)	0	3	4	5	6
b. Alcoholic beverages (beer, wine, spirits, etc.)	0	3	4	5	6
c. Cannabis (marijuana, pot, grass, hash, etc.)	0	3	4	5	6
d. Cocaine (coke, crack, etc.)	0	3	4	5	6
e. Amphetamine type stimulants (speed, meth, ecstasy, etc.)	0	3	4	5	6
f. Inhalants (nitrous, glue, petrol, paint thinner, etc.)	0	3	4	5	6
g. Sedatives or Sleeping Pills (Diazepam, Alprazolam, Flunitrazepam, Midazolam etc.)	0	3	4	5	6
h. Hallucinogens (LSD, acid, mushrooms, trips, Ketamine, etc.)	0	3	4	5	6
i. Opioids (heroin, morphine, methadone, codeine, etc.)	0	3	4	5	6
j. Other - specify:	0	3	4	5	6

Question 4

During the past three months, how often has your use of *(FIRST DRUG, SECOND DRUG, ETC)* led to health, social, legal or financial problems?	Never	Once or Twice	Monthly	Weekly	Daily or Almost Daily
a. Tobacco products (cigarettes, chewing tobacco, cigars, etc.)	0	4	5	6	7
b. Alcoholic beverages (beer, wine, spirits, etc.)	0	4	5	6	7
c. Cannabis (marijuana, pot, grass, hash, etc.)	0	4	5	6	7
d. Cocaine (coke, crack, etc.)	0	4	5	6	7
e. Amphetamine type stimulants (speed, meth, ecstasy, etc.)	0	4	5	6	7
f. Inhalants (nitrous, glue, petrol, paint thinner, etc.)	0	4	5	6	7
g. Sedatives or Sleeping Pills (Diazepam, Alprazolam, Flunitrazepam, Midazolam etc.)	0	4	5	6	7
h. Hallucinogens (LSD, acid, mushrooms, trips, Ketamine, etc.)	0	4	5	6	7
i. Opioids (heroin, morphine, methadone, codeine, etc.)	0	4	5	6	7
j. Other - specify:	0	4	5	6	7

Question 5

During the past three months, how often have you failed to do what was normally expected of you because of your use of *(FIRST DRUG, SECOND DRUG, ETC)*?	Never	Once or Twice	Monthly	Weekly	Daily or Almost Daily
a. Tobacco products					
b. Alcoholic beverages (beer, wine, spirits, etc.)	0	5	6	7	8
c. Cannabis (marijuana, pot, grass, hash, etc.)	0	5	6	7	8
d. Cocaine (coke, crack, etc.)	0	5	6	7	8
e. Amphetamine type stimulants (speed, meth, ecstasy, etc.)	0	5	6	7	8
f. Inhalants (nitrous, glue, petrol, paint thinner, etc.)	0	5	6	7	8
g. Sedatives or Sleeping Pills (Diazepam, Alprazolam, Flunitrazepam, Midazolam etc.)	0	5	6	7	8
h. Hallucinogens (LSD, acid, mushrooms, trips, Ketamine, etc.)	0	5	6	7	8
i. Opioids (heroin, morphine, methadone, codeine, etc.)	0	5	6	7	8
j. Other - specify:	0	5	6	7	8

Ask Questions 6 & 7 for all substances ever used (i.e. those endorsed in Question 1)

Question 6

Has a friend or relative or anyone else ever expressed concern about your use of *(FIRST DRUG, SECOND DRUG, ETC.)?*	**No, Never**	**Yes, in the past 3 months**	**Yes, but not in the past 3 months**
a. Tobacco products (cigarettes, chewing tobacco, cigars, etc.)	0	6	3
b. Alcoholic beverages (beer, wine, spirits, etc.)	0	6	3
c. Cannabis (marijuana, pot, grass, hash, etc.)	0	6	3
d. Cocaine (coke, crack, etc.)	0	6	3
e. Amphetamine type stimulants (speed, meth, ecstasy, etc.)	0	6	3
f. Inhalants (nitrous, glue, petrol, paint thinner, etc.)	0	6	3
g. Sedatives or Sleeping Pills (Diazepam, Alprazolam, Flunitrazepam, Midazolam etc.)	0	6	3
h. Hallucinogens (LSD, acid, mushrooms, trips, Ketamine, etc.)	0	6	3
i. Opioids (heroin, morphine, methadone, codeine, etc.)	0	6	3
j. Other – specify:	0	6	3

Question 7

Have you ever tried to cut down onusing *(FIRST DRUG, SECOND DRUG, ETC.)* but failed?	**No, Never**	**Yes, in the past 3 months**	**Yes, but not in the past 3 months**
a. Tobacco products (cigarettes, chewing tobacco, cigars, etc.)	0	6	3
b. Alcoholic beverages (beer, wine, spirits, etc.)	0	6	3
c. Cannabis (marijuana, pot, grass, hash, etc.)	0	6	3
d. Cocaine (coke, crack, etc.)	0	6	3
e. Amphetamine type stimulants (speed, meth, ecstasy, etc.)	0	6	3
f. Inhalants (nitrous, glue, petrol, paint thinner, etc.)	0	6	3
g. Sedatives or Sleeping Pills (Diazepam, Alprazolam, Flunitrazepam, Midazolam etc.)	0	6	3
h. Hallucinogens (LSD, acid, mushrooms, trips, Ketamine, etc.)	0	6	3
i. Opioids (heroin, morphine, methadone, codeine, etc.)	0	6	3
j. Other – specify:	0	6	3

Question 8 (please markthe response)

	No, Never	Yes, in the past 3 months	Yes, but not in the past 3 months
Have you ever used any drug by injection? ***(NON-MEDICAL USE ONLY)***	☐	☐	☐

IMPORTANT NOTE:

Clients who have injected drugs in the last 3 months should be asked about their pattern of injecting during this period, to determine their risk levels and the best course of intervention.

PATTERN OF INJECTING	INTERVENTION GUIDELINES
4 days per month, on average, over the last 3 months or less	**Brief Intervention including the "Risks of Injecting" card**
More than 4 days per month, on average, over the last 3 months	**Further assessment and more intensive treatment***

HOW TO CALCULATE A SPECIFIC SUBSTANCE INVOLVEMENT SCORE.

For each substance (labelled a. to j.) add up the scores received for questions 2 through 7 inclusive. Do not include the results from either Q1 or Q8 in this score. For example, a score for cannabis would be calculated r example, a score for cannabis would be calculated as: **Q2c + Q3c + Q4c + Q5c + Q6c + Q7c**

Note that Q5 for tobacco is not coded, and is calculated as: **Q2a + Q3a + Q4a + Q6a + Q7a**

THE TYPE OF INTERVENTION IS DETERMINED BYTHE PATIENT'S SPECIFIC SUBSTANCEINVOLVEMENT SCORE

	Record specific substance score	no intervention	receive brief intervention	more intensive treatment *
a. tobacco		0 - 3	4 - 26	27+
b. alcohol		0 - 10	11 - 26	27+
c. cannabis		0 - 3	4 - 26	27+
d. cocaine		0 - 3	4 - 26	27+
e. amphetamine		0 - 3	4 - 26	27+
f. inhalants		0 - 3	4 - 26	27+
g. sedatives		0 - 3	4 - 26	27+
h. hallucinogens		0 - 3	4 - 26	27+
i. opioids		0 - 3	4 - 26	27+
j. other drugs		0 - 3	4 - 26	27+

Now use ASSIST FEEDBACK REPORT CARD to give client brief intervention.

Appendix B: ASSIST-Lite

Alcohol, Smoking and Substance Involvement Screening Test
ASSIST-Lite

Instructions

The questions ask about psychoactive substance use in the PAST 3 MONTHS ONLY.

Ask about each substance in order and only proceed to the supplementary questions if the person has used that substance.

On completion of all the questions, count the number of "yes" responses to obtain a score for each substance, and mark the risk category.

Provide a brief intervention relevant to the risk category.

In the past 3 months	YES	NO
1. Did you smoke a cigarette containing tobacco?	☐	☐
1a. Did you usually smoke more than 10 cigarettes each day?	☐	☐
1b. Did you usually smoke within 30 minutes after waking?	☐	☐
Score for tobacco (count "yes" answers)	☐	
Risk category: ☐ Low (0) ☐ Moderate (1 or 2) ☐ High (3)		
2. Did you have a drink containing alcohol?	☐	☐
2a. On any occasion, did you drink more than 4 standard drinks of alcohol?	☐	☐
2b. Have you tried and failed to control, cut down or stop drinking?	☐	☐
2c. Has anyone expressed concern about your drinking?	☐	☐
Score for alcohol (count "yes" answers)	☐	
Risk category: ☐ Low (0 or 1) ☐ Moderate (2) ☐ High (3 or 4)		
3. Did you use cannabis?	☐	☐
3a. Have you had a strong desire or urge to use cannabis at least once a week or more often?	☐	☐
3b. Has anyone expressed concern about your use of cannabis?	☐	☐
Score for cannabis (count "yes" answers)	☐	
Risk category: ☐ Low (0) ☐ Moderate (1 or 2) ☐ High (3)		
4. Did you use an amphetamine-type stimulant, or cocaine, or a stimulant medication not as prescribed?	☐	☐
4a. Did you use a stimulant at least once each week or more often?	☐	☐
4b. Has anyone expressed concern about your use of a stimulant?	☐	☐
Score for stimulants (count "yes" answers)	☐	
Risk category: ☐ Low (0) ☐ Moderate (1 or 2) ☐ High (3)		
5. Did you use a sedative or sleeping medication not as prescribed?	☐	☐
5a. Have you had a strong desire or urge to use a sedative or sleeping medication at least once a week or more often?	☐	☐
5b. Has anyone expressed concern about your use of a sedative or sleeping medication?	☐	☐
Score for sedatives (count "yes" answers)	☐	
Risk category: ☐ Low (0) ☐ Moderate (1 or 2) ☐ High (3)		
6. Did you use a street opioid (e.g. heroin) or an opioid-containing medication not as prescribed?	☐	☐
6a. Have you tried and failed to control, cut down or stop using an opioid?	☐	☐
6b. Has anyone expressed concern about your use of an opioid?	☐	☐
Score for opioids (count "yes" answers)	☐	
Risk category: ☐ Low (0) ☐ Moderate (1 or 2) ☐ High (3)		
7. Did you use any other psychoactive substances?	☐	☐
If yes, what did you take?		
(Not scored, but prompts further assessment)		

Rapid guide to a Brief Intervention

Low risk: General health advice and encourage not to increase use.

Moderate risk: Provide a brief intervention using the FRAMES Model and offer take home information

High risk: Provide a brief intervention using the FRAMES Model and encourage further assessment by a specialist drug and alochol service. Facilitate referral and provide take home information.

Note: FRAMES - Feedback, Responsibility, Advice, Menu of options, Empathy, Self-efficacy.

46 Screening and Assessment for People with Substance Use Disorders: A Focus on Developed Countries

Brian Rush

Contents

Abstract

This chapter outlines the rationale for a more proactive concerted effort for screening and assessment of at-risk consumption, substance use disorders, and related comorbidity, with a special focus on a broad system approach that engages multiple services and sectors alongside specialist programs and providers. This aspect of clinical practice as well as treatment system development should be a priority given the strong evidence concerning under-detection in routine practice and the excellent performance of a host of screening and assessment tools and processes. When used for clinical decision making, best practice calls for a staged approach to maximize efficiency of the overall screening and assessment process and ensure a link to measurement-based care and subsequent outcome monitoring. Grounded in a conceptual framework that articulates this staged approach, several specific tools are highlighted. The essential principle for service and system planning is that these tools must be tailored to the setting and target population

for which they are being implemented. Whether working in generic settings such as primary care or specialized treatment settings, a collaborative approach, drawing upon multidisciplinary, multi-provider, and multi-sectoral expertise, is needed across the stages of screening and assessment. This approach also needs to be accompanied by a collaborative response protocol for level-of-care placement inclusive of adaptive treatment and support for smooth transitions. There are many challenges to implementing and evaluating the effectiveness of screening and assessment tools and processes, and more research is needed on the facilitators and barriers to implementation at both the level of the individual service provider and within collaborative, shared care arrangements.

Keywords

Screening · Assessment · Outcome monitoring
Collaboration · Systems approach

46.1 Introduction

The purpose of this chapter is to provide an overview of screening and assessment tools and processes in the context of middle- to high-income (i.e., "developed") countries. In this context, there are important similarities but also differences in the many other books and practice guidelines synthesizing this work from various disciplinary perspectives (e.g., psychiatric [26], psychotherapy [35], behavioral [86], psychosocial [85], or social work perspectives [42]). Like previous work, there is an acknowledgement of important principles and practices that may be seen as universal in nature, for example, the need for an evidence-based approach grounded on a comprehensive bio-psycho-social-spiritual model; sensitivity to individual differences in culture, diversity, and developmental age; the critical importance of empathy, listening skills, and therapeutic alliance; and the appropriate involvement of family and significant others. These aspects are critical elements of the interface between clinician and client. Such similarities notwithstanding, this chapter emphasizes more of a systems approach, recognizing that in so-called developed countries, the greater resource base offers an opportunity for a collaborative approach to engaging people in need, identifying and assessing their strengths and problem areas, offering a wide range of service options along a continuum of care, and adapting services based on measurement of outcomes. This collaborative approach may involve more than one professional, organization, and service delivery sector – a scenario that professionals working in low-income countries may only dream about in terms of collegial support for their work. Further, many screening and assessment tools that complement clinical skills and experience are not available and/or validated in many low-income countries. This is another advantage conferred on moderate- to high-income countries that have capacity for research and development.

In short, this chapter acknowledges screening and assessment as a core component of a broader "whole systems," public health approach to treatment and support for substance use, addictions, and co-occurring conditions [5, 76]. Given this foundation, this chapter is aimed at people working from a range of professional disciplines, for example, psychology, social work, nursing, family practice, psychiatry, and other medical and nonmedical specialists. Thus, some readers working from a particular disciplinary perspective may benefit from additional, reference texts such as those noted above.

Although there are many important intercountry differences in the capacity for screening and assessment, it is also important to recognize that many "developed" countries are far from homogenous in terms of community need and capacity to respond. Taking Canada as but one example, there is a tremendous range within the country in terms of rurality/urbanicity, multiculturalism, Indigenous versus non-Indigenous populations, and substance use patterns and related harms. These and many other factors all influence beliefs about substance use and addiction, the perceived value of treatment, help-seeking behavior, and no doubt cultural interpretation of concepts such as "assessment" or

"treatment." There is also wide variation in availability and accessibility of options for treatment and support, an obvious factor critical to screening and assessment considerations.

46.2 Rationale for Screening and Assessment

It is widely recognized that only a small minority of people with mental health and substance use-related concerns seek help from either community professionals or less formal services and that, among that do, the largest proportion will access a primary healthcare provider or other health and social service professional [87, 88]. Although many people with mental health and substance use- related problems, or who are at risk of such problems, are in contact with various service providers, these risks or problems are often not identified [62]. These contacts are missed opportunities for offering advice, more extended consultation, or referral for additional support. This highlights the importance of broadening the base of treatment through a system-wide, public health response [5] with generic community services, including primary care, hospitals, social services, educational, and justice-related services, being proactive in asking questions about mental health, substance use, and addiction-related issues. The aim is to identify concerns, increase opportunities for early identification, provide access to more in-depth assessment and other services and supports, and link the person to more specialized services when needed. For people with low- to moderate risk, or less severe mental health and substance use problems, engaging in proactive, opportunistic screening and on-site, brief intervention is intended to reduce risks and harms. For those with higher risk, or more severe and complex problems, opportunistic screening is intended to open a pathway to more comprehensive assessment, an appropriate treatment and support response, and improved health outcomes. Savings are also anticipated in future medical-, social-, and criminal justice-related costs.

Service providers differ in their attitudes and beliefs about the role of systematic screening and assessment to support their work with people seeking help: beliefs that reflect personal experience, training, and organizational context. Some professionals rely on their training and experience to guide problem identification and client-focused decisions. Some may have philosophical and ethical concerns related to asking about mental health and substance use issues, considering it to be intrusive or possibly harmful due to potential stigmatization and labeling (e.g., in educational settings). Some may doubt the increased efficacy and efficiency of these tools over their routine decision-making processes, while others may be reluctant to engage in consistent, structured screening due to concerns that they do not have the expertise or resources to respond appropriately. Research, however, suggests that critically important mental health and substance use concerns are missed when clinicians do not use structured tools and processes to prompt thorough questioning [93].

Given the high level of heterogeneity in demographic, cultural, psychosocial, and clinical characteristics of people needing treatment and support for substance use problems, it is axiomatic that no approach will meet everyone's needs. This calls for a thorough investigation of needs and strengths and a co-constructed matching of this profile to available service options across a continuum of care. The focus on screening and assessment is intended to increase the efficiency of client intake and engagement, improve individual treatment outcomes, and minimize service delivery costs across the system as a whole [40]. Best practices for treatment and support of people with co-occurring disorders who are already engaged with specialized services also call for more proactive screening of these co-occurring problem areas [71]. This includes screening for mental health problems among people seeking substance use treatment, as well as screening for high-risk/hazardous substance use and addiction-related problems among people seeking mental health treatment and support [70].

Research also shows that screening is most effective when combined with other staged investigations and matched therapeutic and motivation-based interventions [32]. Collaborative approaches can serve to mitigate the reluctance of profession-

als to use formal screening techniques by bringing together complementary services and resources, ultimately building capacity for improved service to individuals who come to them for assistance.

46.3 Collaborative Models for Screening and Assessment

Many service providers external to the specialized mental health and substance use treatment sector do not have the expertise and resources to identify mental health, substance use, and co-occurring concerns. Further, most specialist service providers do not have the resources to respond to the breadth of complex issues and problems that are identified through many screening tools. Collaborative care models provide the opportunity for various providers to bring together their collective strengths and capabilities to construct a system whereby individuals are screened and can receive required services in a seamless manner [2]. As such, screening processes must be connected to well-articulated response protocols in order to be useful and effective. These protocols should describe required actions among all partners based on positive results on screening tools, including recommendations for more in-depth screening and assessment, and follow-up consultation and referrals.

There are various models of collaboration that can incorporate screening, assessment, and referral protocols, and these include

- Single-site assessment process incorporating multidisciplinary teams – Single assessment processes reduce the number of assessments between mental health, addictions, and various health and social service professionals in order to enable a seamless care process [61].
- Integrated treatment and support for people with co-occurring disorders, whereby competencies and processes related to screening and assessment are key criteria for defining integrated programs as "concurrent disorder capable" [54].
- Centralized access point to care – This approach aims to reduce the number of points of entry of care for users, in some cases to a single-access point in order to reduce the number of professionals and organizations prospective to whom clients and their families have to tell their story [74].
- Network model with distributed common tools – Rather than a single point of access, this approach uses common screening and assessment tools across a network of providers and with electronic sharing of the information and joint treatment and support planning.
- Screening, brief intervention, and referral to treatment (SBIRT) – This approach requires health and social service professionals to use brief screening instruments to identify people at risk of, or experiencing, mental health and/or substance use problems and who then receive brief intervention on treatment on-site or who are proactively linked to specialist providers depending on severity [7].
- Co-located substance use specialists in generic settings – This involves either assigning/hiring a substance use worker to perform in-house screening and brief assessment or co-locating a worker from a specialized substance use service into the nonspecialized setting, for example, an emergency department [13]

46.4 Best Practices for Screening and Assessment

Through a treatment system lens, there are many disciplines and service delivery settings potentially involved in the screening and assessment process. An individual situation may require input from a medical, psychiatric, nursing, psychological, psychosocial rehabilitation, social work, and/or spiritual perspective. A collaborative approach to screening and assessment requires mutual interprofessional respect for the unique contributions that each has to offer to a client- and family-centered approach. The uniqueness of the various perspectives notwithstanding common principles include

- A "whole-person perspective" on strengths and needs
- Close engagement of family and other loved ones, while respecting client's preferences for privacy of information

– A sensitivity to diversity and related health equity issues
– A strong emphasis on creating a welcoming, motivation-based, therapeutic interface
– Adherence to an evidence-based approach

An evidence-based approach encompasses several factors including clinician expertise, exploration of person characteristics and contextual variables using psychometrically sound tools, critical thinking skills, personal and collateral input, and knowledge of evidence-informed interventions [42]. Screening and assessment must be seen as a process that continues over time as more information is shared and therapeutic relationships strengthen. A collaborative, longitudinal approach is particularly critical for the assessment of complex, co-occurring disorders given the need to disentangle etiological sequencing (e.g., depressive symptoms induced by heavy alcohol use). In a collaborative approach to screening and assessment, the sharing of information across service providers is also critical. If possible, this should be done through e-health technology but minimally through telephone, email, or written communication.

Best practice entails a staged approach that links screening, assessment, and outcome monitoring with a family of tools and related decision-making processes that are developmentally appropriate and delivered through a diversity-based approach to ensure equitable access and subsequent assessment and treatment. This approach is articulated in the conceptual framework for screening and assessment described below (see Fig. 46.1). The framework can assist in choosing the "right" tools and using them with the "right" people at the "right" time. It is recommended that in order to effectively apply the framework, it be considered in the context of a multi-sectoral continuum of care and the specific collaborative models and service delivery settings under consideration. Thus, application of the framework is very context-specific. For example,

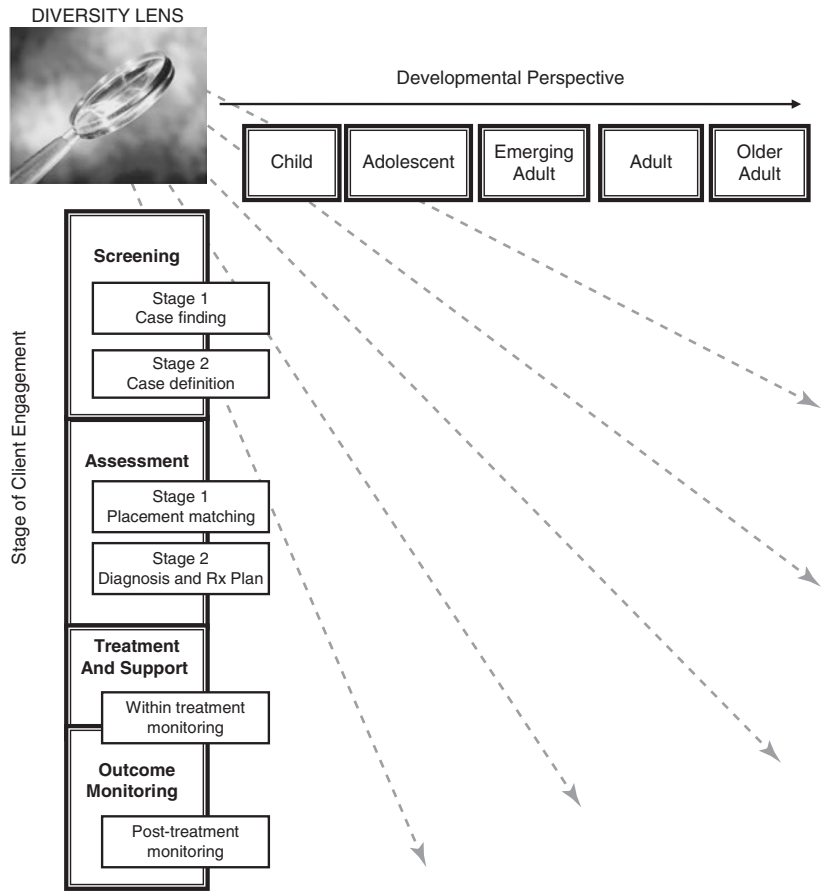

Fig. 46.1 Conceptual framework for screening and assessment. (Adapted from Rush and Castel [70])

the required level of treatment and support may not be readily available due to waiting time or the lack of service availability within the jurisdiction or via realistic distance/travel time. Collaborative arrangements with existing services may be required in order to offer the best service available at that point in time and to maintain client engagement. In the case of people with co-occurring disorders, provision of mental health services will often reduce substance use and ameliorate substance use-related problems [27]. Evidence reviewed by these same authors also suggests the reverse to be true for the provision of substance use treatment and consequent reduction of many mental health-related symptoms and improved functioning. Parikh [67] discusses several evidence-based mental health interventions that can be delivered in substance use services.

In short, it is important to work with local resources as best as possible while advocating for additional resources with a need-based planning model [75]. Alternative therapist-assisted and/or self-management tools delivered through the Internet or mobile-based technology are also increasingly available.

46.4.1 Diversity Lens

Every individual has a unique and complex set of strengths, circumstances, and challenges shaped in large part by the social determinants of health and including, for example, gender, sexual orientation, culture, ethnicity, social location, geography, political views, and religious/spiritual affiliation. As such, each component of this framework must be considered through a "diversity lens" when implementing tools, interpreting the results, and providing feedback to individuals in the context of day-to-day service delivery.

46.4.2 Developmental Perspective

The horizontal axis of the framework articulates the developmental trajectory across the life span as a frame of reference to also guide the choice of screening and assessment tools and processes. At each stage of this trajectory, there are specific developmental tasks and challenges that an individual must navigate, further complicated by the diversity lens noted above. Importantly, most tools are validated for use with groups of individuals defined by age rather than stage. For example, some emerging adults in the 18–24 range may be well-served by screening and assessment with adult measures and being treated in the adult sector, while others with adolescent measures and corresponding services in the youth sector. Therefore, tools and services that can be applied differentially to match developmental stage, rather than being bound by strict age boundaries, are preferred. The GAIN-Short Screener [21] is appropriate for use from age 10 to older adulthood and is, therefore, particularly helpful for collaborative, system-level application [52].

Developmental stage and consideration of service delivery settings that may be unique to specific stages are also important considerations for determining when during the engagement, treatment, and support process to ask different types of screening questions. For example, for young people being seen on an outreach basis in their school or street environment, it would not be appropriate to begin asking screening questions about sensitive topics such as high-risk sexual behavior, trauma experiences, or illegal behavior before a trusting relationship has been initiated. This will also be the case for many other settings and populations, especially those impacted by trauma. Interpretation and action in response to screening results also need to be developmentally informed. Considerable attention has been paid to this issue with respect to children, adolescents, and adults, but much attention has gone to further articulating the role of developmental stages in service transitions for transitional-aged youth and older adults.

46.4.3 Screening

In the context of substance use and addictions, and the broader field of mental health, screening is a relatively brief process designed to identify individuals who are at risk of having particular problems or diagnosable disorders that warrant

immediate attention, intervention, or more comprehensive review. The organizational context and population served will dictate whether screening will start at Stage 1 or 2, as further described below.

46.4.3.1 Stage 1 Screening: Risk Assessment/Case Finding

This stage of screening involves the use of psychometrically sound, typically self-report, questionnaires that cast a fairly wide net to determine the possibility of a particular problem area or mental/addictive disorder and which requires further investigation. In the substance use area, Stage 1 tools may also focus on the level of risk associated with alcohol and drug use per se, the AUDIT perhaps being the best known option for alcohol [6] and the ASSIST for other drugs, excluding tobacco [91]. Having a menu of Stage 1 tools to choose from, ranging from brief one- to three-item instruments to somewhat longer tools that focus on a small number of domains, can facilitate the implementation of systematic screening protocols in emergency rooms, primary care offices, and other service delivery settings where severe time constraints may otherwise preclude a more detailed, systematic screening approach.

Stage 1 tools are characterized by their brevity (typically between 1 and 20 items; completion time less than 5 min) and low-threshold training requirements and scoring algorithms. There have been recent developments toward very brief screeners (one to three items) for alcohol or other drugs in order to facilitate screening in busy settings such as primary care or emergency departments (e.g., [68, 82]) or with high-need populations that cannot tolerate completion of long questionnaires (e.g., people with psychosis: [50]). As noted, the AUDIT [6] is a Stage 1 tool focused on the level of risk of alcohol consumption. The NIDA-Quick Screen focuses on other drug use [66], as do short versions of the ASSIST also developed to facilitate use in high-volume clinical settings [4, 84]. Others are focused on consequences, including substance use/abuse or dependence (e.g., DUDIT, [39]; CAGE, [24]; BASIC, [12]; TWEAK, [77]; and CRAFFT, Knight et al. [46]).

The screening for mental health problems/disorders is also highly relevant for the assessment and treatment of people with identified substance use concerns. With respect to screening for mental health challenges, there is an important distinction between disorder-based tools and those based on a dimensional approach, such as measuring mental distress. Others that are longer such as the Beck Depression Inventory [8], the Beck Anxiety Inventory [9], or screeners for PTSD (SPAN, [15, 60]) and trauma [45] are best considered follow-up Stage 2 tools because of their length and diagnostic specificity. Disorder-based tools that are extremely short, such as those using one to three items for identifying depressive and/or anxiety disorder (e.g., the ADD, [57]), are considered Stage 1 screeners. However, Stage 1 mental health screeners also include brief dimensional measures such as the K6/K10 [44], the five-item mental health component of the SF-36 [11, 89]; the Psychological Screening Inventory (PSI: [48]); and either the Brief Symptom Inventory or the BSRS [23, 49], both being shorter versions of the Symptom Checklist 90-R [10, 22]. For children and adolescents, the Strengths and Difficulties Questionnaire serves as a useful Stage 1 mental health screener [33].

A small number of Stage 1 screening tools focus on *both* mental health and substance use, and these are highly valued because of their broader coverage and, therefore, their applicability in multiple settings involved in a collaborative care arrangement. The GAIN-SS [21] is one such tool rapidly growing in popularity across North America and elsewhere and available in multiple languages.

Biological tests for alcohol and drug use may also be helpful and have the advantage of ease of application in medical settings and their utility as a supplement to self-reported information. Limitations include cost, lack of specificity, and, in some instances, sensitivity to recent substance use. Biological testing includes alcohol breathalyzer testing, measures of tissue damage from chronic substance use such as reflected in the liver enzyme gamma-glutamyl transferase (GGT) or red blood cell mean corpuscular volume (MCV), and hair, saliva, and urine analysis (see [35, 86], for brief reviews).

Time and resources permitting, brief screening across other selected domains is also recommended. Screening for other health problems such as traumatic brain injury, cognitive impairment, fetal alcohol spectrum disorder (FASD), HIV/AIDS, and tobacco use is also of critical importance to treatment and support planning and may be called for in some healthcare settings using additional, brief screeners.

46.4.3.2 Stage 2 Screening: Case Definition

This second step in a staged approach to screening involves the use of psychometrically sound tools that are more specific and longer than those used in Stage 1 and which aim to tentatively identify one or more specific disorders or problem areas. This may include alcohol or other drug use disorders and other mental disorders such as psychotic disorders, major depressive disorder, a variety of anxiety disorders including PTSD, eating disorders, and ADHD. Although more specific and detailed than Stage 1 screeners, the information gathered through the tools in this category of the staged approach is still NOT sufficient on which to base a formal diagnosis, although some of the names of the tools can be misleading in this regard. The administration of a Stage 2 screening tool may involve the same or a different service provider than the one undertaking the Stage 1 screening. In any instances involving a transition to a new partner in a collaborative care process, a motivational approach and transition support to ensure ongoing engagement are critical, especially for people with complex co-occurring conditions.

Screening tools such as the Psychiatric Diagnostic Screening Questionnaire (PDSQ: [94]) and the Modified Mini Screen [3] are particularly helpful as diagnosis-based, Stage 2 screeners. Rush et al. [72] validated the PDSQ, as well as the psychiatric subscale of the widely used Addiction Severity Index for identifying mental disorders among people seeking substance use treatment. Magruder et al. [53] found both the PDSQ and the Conners' Adult ADHD Rating Scale which also performed well in adult substance use treatment settings. For adolescents, the POSIT [20] is more focused on specific problem areas rather than diagnosis (e.g., substance use, health, school, family) and is a well-validated option for Stage 2 screening in several settings. Others for children and youth are the Child Behavior Checklist (CBCL: [1]) and the DISC-R [51] and cover most mental disorders, including substance use disorders. For more discussion on specific screening tools and processes for children and youth, see the narrative review conducted by Rush et al. [69] and synthesized by the Centre for Addiction and Mental Health [17]. As noted earlier, tools such as the Beck Depression Inventory [8] and the Beck Anxiety Inventory [9] are considered to be Stage 2 tools due to their specificity in terms of diagnosis and length. This grouping also includes several mental health screening tools that are dimensional rather than diagnostic in nature such as the longer version of the GHQ-30 and the full SCL-90-R [22].

46.4.4 Assessment

In the staged framework, assessment is also conceptualized as involving two phases. Stage 1 assessment is focused primarily on further information gathering and placement/referral to the most appropriate service setting (i.e., level of care). Upon engagement in the appropriate setting, Stage 2 assessment goes further in examining strengths and needs across several bio-psycho-social-spiritual domains including health and mental health status, family/social situation, environmental risk factors, etc.

One helpful way to conceptualize the distinction between Stage 1 and Stage 2 assessment is that between "placement" and "modality" matching [31, 59]. Placement matching, the aim of Stage 1, refers to initial client assignment to a treatment setting with a certain resource intensity and, therefore, significant cost implications. Modality matching (the aim of Stage 2) refers to client assignment on the basis of the optimal clinical approach and intervention(s), including philosophical and goal orientation such as reduced substance use versus abstinence, based on the full profile of client strengths and needs. The overall assessment process needs to occur within a stepped-care, adaptive treatment strategy that

makes ongoing adjustments as new information arises, including the response to treatment, and supported transitions across the various levels of service [63, 64].

46.4.4.1 Stage 1 Assessment: Information Gathering and Service Placement

The essential feature of a Stage 1 assessment, especially in the context of collaborative care across multiple service settings, is the intention to gather enough information on both strengths and needs, including immediate needs for physical and psychosocial stabilization, to formulate an initial placement/referral in an appropriate level of care. This first step involves continued information gathering that is optimally done through the use of valid tools and structured interviews. For substance use services, this would include a determination of the need for withdrawal management which may be initiated in one of the three levels of care: home/mobile, community/medical, or, in the case of complex co-occurring mental and physical problems, a hospital-based service with adequate medical and psychiatric supports. The CWAW-Ar is an assessment tool that supports determination of the need for withdrawal management services [83]. A complementary assessment tool is available for measuring intensity of opiate withdrawal (COWS: [90]). Withdrawal management often needs to be accompanied by a period of stabilization prior to formal engagement in treatment and special care needs to be given to withdrawal management for opioid use disorder given the potential risk of overdose as a result of reduced tolerance and the risk of relapse.

Aside from withdrawal management, a Stage 1 substance use assessment should also determine the need for community or residential treatment at varying levels of duration and intensity. These levels of care are articulated in considerable detail in the ASAM criteria for placement/referral to substance use services [28, 29] and can be tailored for the purposes of need-based planning in specific jurisdictions [75].

It is critical to reemphasize that the initial placement/referral based on the Stage 1 assessment be undertaken in the context of a stepped care, potentially multiservice model – that is, stepping up to a higher level of care if required and stepping down on the basis of progress toward the individual's goals. At moderate-to-high levels of severity and case complexity, this typically requires transition support, including case management and shared e-health information. It also requires monitoring of outcomes, within and posttreatment (see below). The ASAM model specifies the dimensions across which a clinician must explore strengths and needs in order to make the appropriate placement match [29]. These dimensions include

- Acute intoxication and/or withdrawal potential
- Biomedical conditions and complications
- Emotional, behavioral, or cognitive conditions and complications
- Readiness to change
- Relapse, continued use of continued problem potential
- Recovery environment

It is highly recommended that these areas be examined with a semistructured or structured interview approach facilitated by validated instruments that support the initial placement/referral.

Assessment tools and processes for Stage 1 assessment include the GAIN-Q3 Standard MI or the GAIN-I-Lite – these tools being part of the GAIN "family" of substance abuse screening and assessment tools (www.chestnut.org). As with the GAIN-SS, these brief assessment tools are appropriate for use with individuals from age 10 and up. Another instrument for Stage 1 assessment is the Recovery Attitude and Treatment Evaluation (RAATE: [30, 58, 65]).

46.4.4.2 Stage 2 Assessment: Case Conceptualization and Comprehensive Treatment Plan

The next stage of the assessment process involves the creation of a case conceptualization, formulation, and/or diagnosis leading to an individualized and adaptable treatment plan. The language around this overall process changes depending on

the discipline and service delivery setting. The central idea, however, is to pull together all the information that has been gathered from validated screening tools, undertake additional information gathering as needed through assessment questionnaires, structured and semistructured interviews, collateral contacts, and case notes from previous service contacts (if available). The resulting case conceptualization or diagnosis informs the treatment plan, including responding to psychosocial and clinical needs and strengths, and facilitating linkage to services. The term "modality matching" summarizes the intention of a Stage 2 assessment, although this may also involve revision of the placement decision made at an earlier stage.

Stage 2 assessment is seen as being grounded in the present context of the person's life situation and problem-focused [42]. This approach, however, should not exclude consideration of critical underlying factors such as trauma, including intergenerational trauma, and neuropsychological mechanisms. A thorough health assessment including a full psychiatric assessment may also be required and is especially indicated for individuals presenting with more complex co-occurring conditions.

It is beyond the scope of this report to delve into all the critical issues involved in the person–clinician interface for purposes of comprehensive assessment and treatment and support planning. There are many excellent reference texts that approach this from various disciplinary perspectives and cited at the outset of this chapter. All such experts acknowledge the role of clinician experience and skills in conducting semistructured or structured interviews that operationalize core principles and practices such as sensitivity to individual differences in culture, diversity, and developmental age, the need for empathy and establishing therapeutic alliance, and the appropriate involvement of family and significant others. In the substance use field, there is a need for such interviews to cover several areas including, but not limited to, substance use history, including age of first use and onset of negative consequences, severity of substance use disorders, level of insight into past and current challenges, social supports and environment risk factors (e.g., for relapse), medical and psychiatric comorbidity, current phase of use (e.g., intoxicated or in withdrawal), and pressures to seek help and the person's readiness/motivation for change. For many of these areas, the approach is to explore these areas at a deeper level than investigated in Stage 1.

In the substance use field, there have been significant efforts to create integrated assessment packages to support individualized treatment plans and subsequent follow-up determination of outcome. Two well-known comprehensive substance use assessment packages are the Addiction Severity Index [55] and the GAIN-I (www.chestnut.org). The GAIN-I is now used extensively in North America and has the added advantage of being conceptually and instrumentally linked to the GAIN-SS (Stage 1 screener) and the GAIN-Q3 or GAIN-I-Lite (Stage 1 assessment). Another example, with a stronger focus on mental health, is the Psychiatric Research Interview for Substance and Mental Disorders (PRISM) which, although designed primarily as a research tool, provides systematic coverage of alcohol/drugs and mental health experiences and symptoms and functional impairment [37]. There is also the option to administer the full structured interview for DSM-IV disorders (DSM-IV) [25] although this would need to be supplemented with other substance use – specific tools assessing, for example, readiness to change.

46.4.5 Treatment and Support and Outcome Monitoring

Outcome monitoring is a critical component of the staged approach to screening and assessment because of the need to establish baseline status early in the treatment and support process and to inform service delivery on an ongoing basis via measurement-based care and/or engage the client in post-discharge follow-up processes. An important distinction is made between within-treatment and posttreatment outcome monitoring, both of which consider the contact for client and program assessment purposes, as an extension of the treatment and support process itself. This is conceptually quite different than a traditional "research" follow-up and much more likely to engage admin-

istrative and clinical staff, as well as clients themselves, in the outcome monitoring process.

46.4.5.1 Stage 1: Within-Treatment Monitoring

Within-treatment outcome monitoring tracks progress on an ongoing basis with very brief but highly relevant clinical tools applied at the front end of periodic therapist–client interactions. Variously referred to as measurement-based care [80], adaptive treatment sequencing [63, 64], routine outcome monitoring [16], or progress monitoring [34], this model evolved largely from the work of Lambert in the mental health area (e.g., [47]) and, in the substance use field [56]. Occurring at the clinical interface of therapist and client, it is critical that the assessment and outcome measures be brief, be implemented within the flow of the clinical encounter, and return feedback immediately in a useful format to further the therapeutic relationship and the client's progress toward goals. Appropriate within-treatment outcome monitoring can be accomplished with repeat application of some screening tools that are sensitive to change over time such as the GAIN-SS [21] and the Brief Addiction Monitor [14]. Others such as Lambert's [47] Outcome Questionnaire (OQ) have been designed specifically to assess psychological processes that cut across many types of mental health problems, including substance use and addictions.

46.4.5.2 Stage 2: Posttreatment Monitoring

Posttreatment outcome monitoring, sometimes referred to as "recovery monitoring" [18], involves the repetition of selected screening/assessment measures at some interval after program admission, such as 3, 6, 12, or 24 months, and determination of changes in these measures [73]. In addition, the follow-up contact is an opportunity to reengage the individual in treatment if indicated, using a guided, motivational return-to-treatment protocol [79]. Posttreatment monitoring is useful as an accountability and program evaluation tool and can also be helpful in identifying clients who may be struggling and need further assistance to recoup gains made in treatment.

Ideally, posttreatment follow-up also involves repeat application of one or more assessment tools or subscales by phone or face-to-face interview. The GAIN-I and GAIN-Q3-standards (www.chestnut.org) on the Addiction Severity Index [55] are useful measures for outcome monitoring. Other measures have been constructed directly from client's reported experience of "recovery" [19]. Locating clients and obtaining good follow-up rates (ideally over 80%) are the Achilles' heel of posttreatment follow-up for substance use programs. There are protocols for achieving substantially higher follow-up rates [78], and these can benefit from collaborative networks working together to locate and engage people in the follow-up process.

46.5 Implementation and Evaluation of Evidence-Based Screening and Assessment

The context in which screening takes place must be carefully considered in both implementation and evaluation of screening and assessment tools and processes. As already mentioned, the role and purpose of screening should be well understood and articulated in the context of the mandate and objectives of the service provider. Organizational policy must also support the implementation of screening and related protocols. Required staff competencies and program design should fit within clear service delivery protocols addressing where, when, and how screening will be administered and how the information gathered will be used. Personnel who are administering the tools must be trained to introduce, administer, score, discuss, and take appropriate action based on the screening results. All of this needs to be clearly conveyed to individuals engaging with the service so that they understand how screening can be helpful and provide fruitful ground for evaluative inquiry.

As noted above, implementing formal screening tools and processes is a logical fit in the specialized substance abuse treatment sector. In these settings, clients have already been

identified as needing further screening (e.g., for co-occurring conditions), assessment, or treatment. In other settings where routine screening and assessment of various health concerns are already taking place (i.e., emergency settings, primary care), the rationale for extending screening to identify at-risk substance use and substance-related problems is also clear. Screening in settings such as schools, employment counseling, and justice settings is also important given the evidence that rates of substance use and mental health problems are high and often not identified. While these settings provide important opportunities for early identification and early intervention, there are a number of potential risks that must be considered, including stigma resulting from identification and labeling, social exclusion, limitation of opportunities, and false-positives consuming scarce treatment resources. Risks associated with identification may be greater for some specific groups of people, for example, severe sanctions may be imposed on those identified as being involved in substance using activities by some schools, employment programs, shelter and housing providers, supported housing, long-term care facilities, families, and specific ethno-cultural groups and communities.

With respect to implementation of assessment tools and processes, the issue of staff competencies and qualification is more salient than with respect to screening tools, many of which can be undertaken with much less rigorous training. Importantly, the increasing level of integration of mental health and substance use services [70] is bringing the mental health perspective on "recovery" [81] closer to the substance use field with significant implications for screening and assessment. Among other things, the mental health recovery orientation to service delivery is contributing to the development of what is sometimes referred to as "single-session therapy by walk-in or appointment" that promises brief assessment of the most immediate needs to be addressed largely *from the perspective of the person presenting for assistance* [36]. The focus is very much on rapid linkage which, in many settings, contrasts with a more medical/psychiatric paradigm that requires thorough and, typically, diagnostic assessment.

Models of collaboration within which screening and assessment are core activities provide the field with rich evaluation opportunities, including outcome and process evaluation, and an opportunity to monitor trends and performance. Outcomes can be examined at the individual (i.e., client and clinician), organizational, and community level. For example, at the organizational level, outcome indicators could include changes in staff attitudes, skills, and behavioral engagement in screening and assessment practices and change in referral practices, as well as client perceptions of care. At the community level, indicators could include increased numbers of new clients referred to treatment and reduced number of emergency visits. It is also of interest to evaluate the extent to which the development of collaborative models of screening and assessment contributes to broaden collaborative processes across agencies/service providers – for example, building partnership capital to engage in other joint planning and service delivery. Using a consistent screening tool across a collaborative group of service providers provides an opportunity for decision-makers, funders, and researchers to look at presenting needs across settings and monitor trends over time within the collaborative as well as in comparison to the general population [38].

46.6 Conclusion

There is a very strong rationale for a more proactive concerted effort to screen for mental health problems and at-risk consumption of alcohol and other drugs and related addiction problems given the evidence concerning the level of underdetection in routine practice and the excellent performance of a host of screening tools and processes. Screening in multiple sectors, along with follow-up assessment and intervention, is one strategy to broaden the scope and reach of treatment and support beyond the traditional sector of specialized substance use services. There are many reasons to engage in more proactive screening, and both individual and collaborating part-

ners need to be clear about how the information will be used, including making improvements at the system level. When used for clinical decision making, best practice calls for a staged approach to maximize efficiency of the overall screening and assessment process. The specific tools and processes must be tailored to the setting and target population for which they are being implemented. For example, some tools will work best for screening in primary care and other generic health and social service settings, and others are more appropriate for screening in specialized mental health and substance use settings. That said, whether working in generic settings such as primary care or specialized settings, a collaborative approach, drawing upon multidisciplinary, and potentially multi-provider and multi-sectoral expertise, is needed across the stages of screening and assessment, along with a collaborative response protocol for level-of-care placement/referral for treatment and support.

The evidence is quite strong with respect to the ability of screening tools and processes to identify individuals needing brief intervention or other treatment and support. This evidence underlies the best practice guidelines that call for targeted screening in generic settings such as primary care and universal screening for all clients engaged with specialized mental health and substance use services. However, the effectiveness literature tells us that screening is only one part of the process of engagement and the results are more equivocal in terms of the impact of the screening per se on subsequent case management and health outcomes, the literature on SBIRT in the substance use field being an important exception. Collectively, the literature that cuts across the mental health and substance use area reminds us that screening alone may make little difference without a detailed response plan and follow-up intervention. Further, there is ample evidence that screening for different levels of risk for alcohol and drug use, accompanied by brief intervention or referral to treatment, is effective in engaging people in both these response options and subsequent outcomes [43]. That being said more work is needed on teasing out the most effective ingredients of the overall SBIRT protocol and addressing the challenges implementing SBIRT protocols in healthcare and other settings [41, 92].

Stepped Care Models in Addiction Treatment

47

Ambros Uchtenhagen

Contents

Abstract

Stepped care models aim at matching treatment intensity to defined patient characteristics in a systematic way, thereby avoiding misplacements and making best use of available treatment resources at the same time. In principle, treatment planning for new patients starts with the least intensive care, progressing to more intensive regimes for nonresponders. Such models have been introduced in psychiatry and in other medical fields.

Models of stepwise patient placement in addiction treatment are known from Northern America (Sobell model, model of the American Society of Addiction Medicine, ASAM) for adults and adolescents and special models for dual-diagnosis patients. Another model comes from Europe (the Dutch model for triage and evaluation in addiction treatment MATE; special model for judicial patients). The various elements and procedures of the ASAM and MATE models are described and compared.

An overview on evaluation studies and reviews is presented, concerning feasibility, validity, reliability, effectiveness, and cost-effectiveness of stepped care models. Outcomes are partly positive, but limitations are mentioned, and more research is asked for.

47.1 Introduction

47.1.1 A Concept for Patient Placement

It is normal practice to assign a new patient to an appropriate and readily available treatment and to switch a patient not responding to that treatment to another one, be it another intervention type, another medication, or another setting. The therapist makes his or her choice on the basis of guideline recommendations, scientific studies, or personal experience, eventually also on the basis of patient preference.

The concept of stepped care combines a systematized version of such practice with an attempt at matching treatment intensity to patient characteristics. Screening the new patient for specific characteristics provides the basis for treatment indication and placement, starting with the least intensive intervention and stepping up intensity for nonresponders.

Main principle: Patients should be offered the least intensive and intrusive care at first contact, except in case of emergencies and defined complications which ask for an intensive treatment. Otherwise, only nonresponders should receive care along a scale of increased intensity. This principle is aiming to protect patients from intrusive care they do not need and to make best use of available treatment resources by avoiding misplacements. "Stepped care models represent attempts to maximise the effectiveness and efficiency of decisions about allocation of resources in therapy" [11].

47.1.2 Models of Stepped Care

Approaches to stepped care in addiction treatment have been described repeatedly [16]. By now, stepped care models have been introduced in some fields of psychiatry. Guidelines of the National Institute for Clinical Excellence (NICE) provide stepped care models in the UK for the treatment of depression and anxiety [20]. In the USA, such resource allocation issues are mentioned for anxiety disorder, panic disorder, eating disorder, and alcohol dependence [11].

47.1.2.1 From First Line to Intensive Care

In the model proposed by the Sobells [4, 24], the recommended treatment should start with the least restrictive intervention in terms of cost and personal inconvenience for patients. The first step might even involve facilitating "natural recovery" outside of professional services. Stepping up requires a decision about patient progress and depends on the type of disorder and the effectiveness of available treatments. The decisions may be made on the basis of guidelines but should not disregard the risk of inappropriate stepping up and of missed stepping up and should include considerations about costs of treatments at different levels.

47.1.2.2 The ASAM Patient Placement Model

The American Society of Addiction Medicine (ASAM) started to develop the patient placement criteria PPC in 1991, and in 1994 the National Institute of Drug Abuse (NIDA) funded a validity study. Revised versions were published in 1996 (ASAM PPC-2) and in 2001 (ASAM PPC-2R). A further revision will be based on DSM-5 to come.

The follow-up version of the placement criteria is published under the name of ASAM criteria (available in a third edition, referenced under the American Society of Addiction Medicine [2]).

The basis of the model is a concept of individualized treatment: assessment at intake is made in a range of biopsychosocial dimensions (multiaxial DSM diagnoses); assessment dimensions include also readiness to change, continued problem potential, and recovery environment. This is followed by an identification of priority problems, leading to defining the appropriate model and level of service. Progress assessment is used as a basis for eventual reassignment [14, 16, 17].

Placement criteria have been set up for adults and for adolescents. Special attention is also paid to co-occurring mental and substance-related dis-

orders, in patient assessment, as well as in the specifications of services [15]. For dual-diagnosis patient, separate risk dimensions are set up: dangerousness/lethality, interference with addiction recovery efforts, social functioning, ability for self-care, and course of illness. The criteria also advocate for an adequate availability of treatment; by incorporating more use of outpatient care – especially for those in early stages of motivation for change – the criteria help to reduce waiting lists for residential treatment [17].

A supplement was published to delineate specific criteria for the use of pharmacotherapies for alcohol use disorders, for detoxification, and relapse [10].

47.1.2.3 MATE: A Model for Patient Assessment and Referral

The Dutch model for measurement in the addictions for triage and evaluation MATE [21, 22] is a national project, aiming at constructing and testing of a new instrument for the assessment at intake of all problems and needs in relevant domains in substance abuse treatment; the instrument should also be useful as a framework for the application of existing instruments in selected domains for matching, patient allocation, and treatment evaluation in the addictions. The instrument should help to make rational and transparent decisions about providing which and how much treatment to which patients. It was tested for feasibility, reliability, and validity in a population of heavy users, and in a subproject an instrument was developed and tested for judicial clients.

The assessment of substance use disorders at intake is made on the basis of the international classification systems ICD/DSM. Assessment of personal and social functioning is made in order to determine which type of services will be needed; this part of the new instrument is based on the WHO international classification system of functioning, disability, and health ICF. Existing instruments are used for the assessment of comorbidities, new modules for treatment history, motivation, and criminality. Overall, the MATE instrument is composed of ten modules. A manual and a protocol with detailed instructions were published in Dutch.

The MATE was adopted and further developed in Germany. A German version of the instrument was tested and implemented [6–8, 23].

47.1.3 The Main Elements of Stepped Care Models: A Comparative Overview

Stepped care models use three essential elements: patient indicators used for determining the appropriate level of care, treatment typology in regard to intensity of care, assessment, and referral procedures. The following figures summarize the relevant information on these elements in the ASAM and MATE models (Tables 47.1 and 47.2; Figs. 47.1 and 47.2).

MATE criteria were developed for Germany by the German Psychiatric Association and published by the German Ministry of Health.

Detailed criteria listed in the German evaluation protocol for treatment evaluation

Headings:	*A 1–12*	*Seriousness of condition*
	B 1–5	*Intensity of treatment*
	C 1–2	*Invasive interventions*
	D 1–6	*Comorbidities*

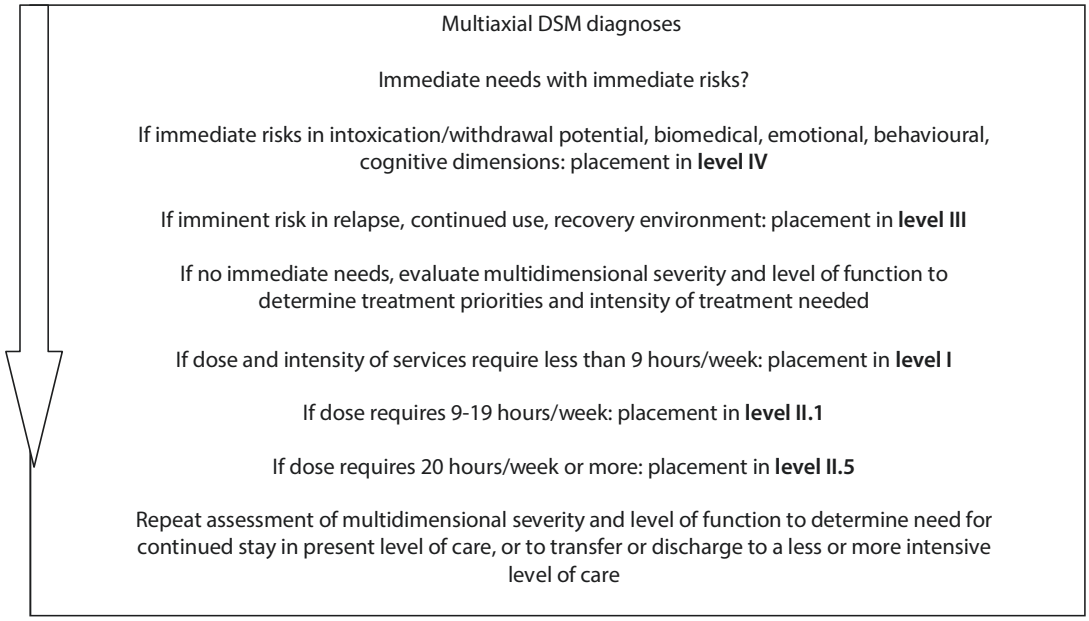

Fig. 47.1 Assessment and referral procedures in ASAM PPC-2r. (Source: [16], Fig. 6–1)

47.1.4 The NICE Model of Stepped Care

The National Institute for Health and Clinical Excellence (NICE) published recommendations for the psychological treatment of depressions and anxiety disorders in a framework of a stepped care system. The guiding principles are to deliver best possible outcomes while burdening patients as little as possible and to provide scheduled reviews how to step up or down to more or less intensive treatment if appropriate. The system includes three levels of intensity of care (starting with primary care, moving up to self-help interventions, and then to cognitive behavioral therapy) [19].

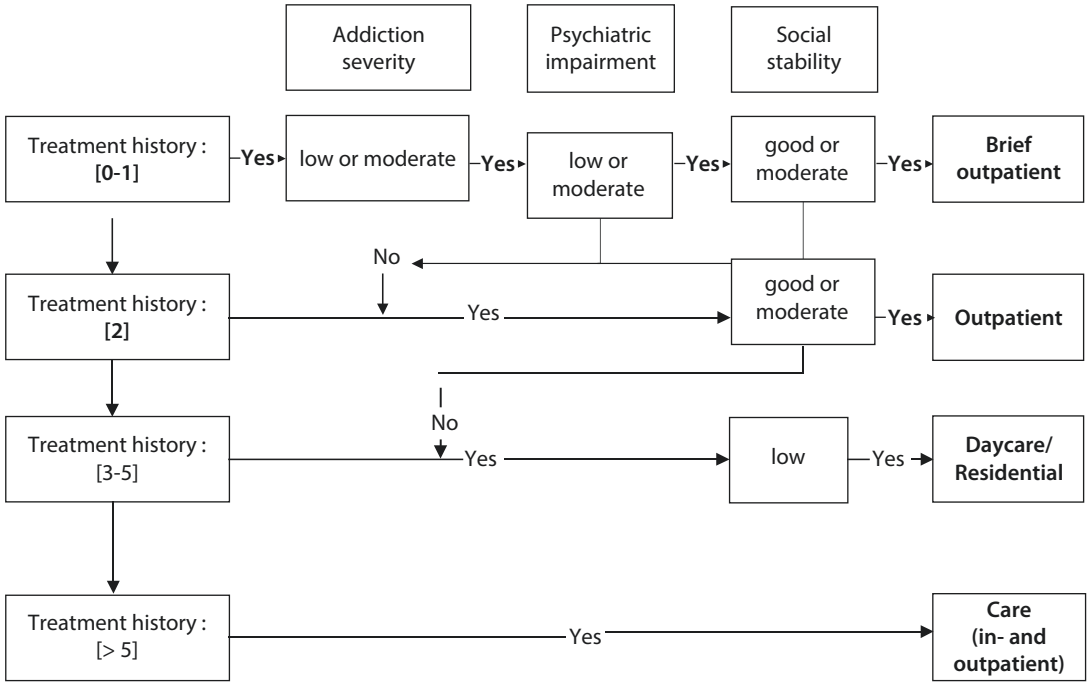

Fig. 47.2 MATE guidance for matching and referral. (Source: [18], Fig. 2)

47.1.5 Evaluation Results and Perspectives

A systematic review was made on the efficacy of stepped care models involving different levels of psychosocial treatment for alcohol use disorders and nicotine dependence, with or without medication [12]. Little evidence was found to suggest that stepping up nonresponders to more intensive therapy improved outcomes. In one study, the application of a stepped care approach was found to reduce treatment costs compared with usual care. There was some evidence that the greater differentiation between the intensity of the interventions offered at each step, the better the outcome. Further research is needed to evaluate the efficacy of stepped care approaches to providing psychosocial treatment.

A summary of research on the ASAM patient placement criteria is presented in the *Textbook of Substance Abuse Treatment*. The authors conclude as follows: "More than a decade of research of the ASAM PPC supports the predictive validity and the cost-effectiveness of the use of PPC. Based on this research, a variety of computer assisted assessment and placement tools are in development" [16, p. 88]. Another overview is presented in the *Principles of Addiction Medicine*. Nine evaluation studies were performed involving 3641 subjects; controlled studies found that "treatment based on the ASAM PPC are associated with less morbidity, better client functioning, and more efficient service utilization than mismatched treatment" [17, p. 398].

The ASAM placement criteria have been further developed in a guidebook on the treatment of substance abuse issues under the title of ASAM Essentials [1].

Feasibility and field testing of the MATE in a treatment-seeking population were performed in two large treatment settings. Construct validation with related instruments and evaluation of the dimensional structure of modules were performed. Among the results are a satisfactory inter-rater reliability and concurrent validity, indicating the usefulness of the instrument for allocating patients to substance abuse treatment, even in a heterogeneous population [22].

However, there were some problems with clinicians not complying with the guidelines, resulting in mismatched patients usually allocated to outpatient treatment instead of early interventions [18].

A recent manual provides guidance for implementation and comparative research [5]. This manual is now available in English, German, Dutch, Italian, Danish, French, Slovenian, and Portuguese (https://www.mateinfo.eu/german/index).

Another systematic review of stepped care in psychological interventions was made [3]. It identified the underlying assumptions on which the benefits of stepped care depend: equivalence in terms of clinical outcomes, efficiency in terms of resource use and costs, and acceptability of "minimal interventions" to patients and therapists. The review concludes that more research is needed in terms of rigorous evaluations of the underlying assumptions.

A comparison of minimal interventions with a stepped care model for patients with alcohol use disorders in the UK evidenced greater cost savings, greater motivation for change, and greater reduction of alcohol consumption for stepped care 6 months after randomization [9].

47.2 Further Developments

Stepped care models have a considerable potential to improve patient-service matching with improved outcomes and improved use of treatment resources. Stepped care is also considered to be an important element of individualized treatment [13]. A wider implementation of existing or new models however is slow and may meet problems if not politically supported.

Abstract

The therapeutic community (TC) is a major treatment modality serving a wide spectrum of substance abuse clients worldwide. The weight of the research evidence developed over some 40 years demonstrates that the TC is an effective and cost-effective treatment particularly for substance abusers with serious social and psychological problems in addition to their drug abuse. This chapter provides an overview of the essential elements of the TC approach: its perspective, method, program model, and adaptation for special populations, settings, and different cultures.

TCs have been successfully modified for special populations of substance users including those with co-occurring disorders, adolescents, women with children, criminal justice clients in prisons, and community-based settings. TC programs have been implemented in Europe, Asia, Africa, Latin America, and the Middle East. And, despite ethnic, social-political, and religious differences, TCs have retained their essential elements and effectiveness across a variety of cultures.

Its evolution over some 50 years has surfaced key issues that challenge the TC to maintain the integrity of its unique social psychological approach – community as method. Several of these are briefly highlighted including funding, workforce, research, treatment fidelity, and the diversity of TC programs. In the current context, the TC is compelled to reassert its place and mission in human services – that of promoting recovery and right living.

Therapeutic community · Cultural diversity · Treatment efficacy · International · Treatment perspectives · History

48.1 Introduction

Drug-free residential programs for substance abuse appeared a decade later than did therapeutic communities (TCs) in psychiatric hospitals pioneered by Maxwell Jones and others in the United Kingdom. The term therapeutic community evolved in these hospital settings, although the two models arose independently.

The TC for substance abuse emerged in the late 1950s as a self-help alternative to existing conventional treatments. The originators were recovering alcoholic and drug-addicted individuals [20, 21]. Although its modern antecedents can be traced to Alcoholics Anonymous and Synanon, contemporary TCs for addictions are sophisticated human services institutions. Today, the label therapeutic community is generic, describing a variety of short- and long-term residential and nonresidential programs that serve a wide spectrum of substance abuse clients. Although the TC approach has been adapted for different populations and settings, it is the perspective and method of the traditional long-term residential prototype for adult substance abusers that have documented effectiveness in rehabilitating substance-abusing individuals.

48.2 Essential Elements

48.2.1 The TC Perspective

The TC perspective or theory shapes its program model and its unique approach, community as method. The perspective consists of four interrelated views of the substance use disorder, the individual, recovery process, and healthy living.

48.2.1.1 View of Disorder

Drug abuse is viewed as a disorder of the whole person, affecting some or all areas of functioning. Cognitive and behavioral problems are often present, as are mood disturbances. Thinking may be unrealistic or disorganized; values may be confused, nonexistent, or antisocial. Frequently, the patient exhibits deficits in verbal, reading, writing, or marketable skills. Moral or even spiritual issues, whether expressed in existential or psychological terms, are apparent. Thus, the TC perspective considers the problem to be the individual, not the drug, and addiction is a symptom, not the essence of the disorder.

48.2.1.2 View of the Person

In TCs, individuals are distinguished along dimensions of psychological dysfunction and social deficits rather than according to drug use patterns. Regardless of differences in social background, drug preference, or psychological problems, most individuals admitted to TCs share clinical characteristics (Table 48.1). Whether they are antecedent or consequent to serious involvement with drugs, these characteristics are commonly observed to correlate with chemical dependency. More important, in TCs, a positive change in these characteristics is considered to be essential for stable recovery.

48.2.1.3 View of Recovery

In the TC perspective, recovery extends beyond drug freedom, involving a change in lifestyle and in personal identity. The primary psychological goal is to change the negative patterns of behavior, thinking, and feeling that predispose the individual to drug use; the main social goal is to develop the skills, attitudes, and values of a responsible drug-free lifestyle.

In many TC residents, vocational and educational problems are marked; middle- class, mainstream values are either missing or not sought. Usually these residents emerge from a socially disadvantaged sector. Their recovery in the TC is better termed *habilitation*, the development of a socially productive, conventional lifestyle for the first time. Among individuals from more advantaged backgrounds, the term *rehabilitation* is more suitable, which emphasizes a return to a lifestyle previously lived, known, and perhaps rejected.

Table 48.1 Typical behavioral, cognitive, and emotional characteristics of substance abusers in therapeutic communities

Low tolerance for all forms of discomfort and delay of gratification
Problems with authority
Inability to manage feelings (particularly hostility/anger, guilt, and anxiety)
Poor impulse control (particularly sexual or aggressive impulses)
Poor judgment and reality testing concerning consequences of actions
Unrealistic self-appraisal regarding discrepancies between personal resources and aspirations
Prominence of lying, manipulation, and deception as coping behaviors
Personal and social irresponsibility (e.g., inconsistency or failures in meeting obligations)
Marked deficits in learning and in marketable and communication skills

48.2.1.4 View of Right Living

TCs adhere to certain precepts and values that constitute a view of healthy personal and social living that guide and reinforce recovery. For example, community sanctions address antisocial behaviors and attitudes; the negative values of the street, jails, or negative peers; and irresponsible or exploitative sexual conduct. Positive values are emphasized as being essential to social learning and personal growth. These values include truth and honesty (in word and deed), a work ethic, self-reliance, earned rewards and achievement, personal accountability, responsible concern (being one's brother's or sister's keeper), social manners, and community involvement. The precepts of right living are constantly reinforced in various formal and informal ways (e.g., signs, seminars, in groups and community meetings).

48.2.2 The TC Approach: Community as Method

The TC approach can be summarized in the phrase "community as method" [2, 3]. A parallel concept – "community as doctor" – in the psychiatric or democratic TC was first coined by Rapoport [16]. Theoretical writings offer a definition of "community as method" as follows: the *purposive* use of the community to teach individuals to *use* the community to change themselves. The fundamental assumption underlying the TC approach is that individuals obtain maximum therapeutic and educational impact when they engage in and learn to use all of the activities, elements of the community as the tools for self-change. Thus, community as method means that the community itself provides a *context* of relationships and activities for social learning. Its

membership establishes the *expectations* or standards of participation in community activities; it continually *assesses* how individuals are meeting these expectations and *responds* to them with strategies that promote continued participation.

48.2.3 TC Program Model

The key components of the program model are its social organization (structure), peer and staff roles, groups and individual counseling, community enhancement meetings, community management elements, and program stages. Each component reflects an understanding of the TC perspective, and each is used to transmit community teachings, promote affiliation, and self-change.

48.2.3.1 Social Organization

The TC social organization is stratified with relatively few staff of the TC at the top complemented by resident peers at junior, intermediate, and senior levels. This peer level-to-community structure strengthens the patient's identification with a perceived ordered network of individuals. More important, it arranges relation- ships of mutual responsibility at various levels in the program.

The daily operation of the community itself is the task of the residents, who work together under staff supervision. The broad range of resident job assignments illustrates the extent of the self-help process. Residents perform all house services (e.g., cooking, cleaning, kitchen service, minor repair), serve as apprentices, run all departments, and conduct house meetings, certain seminars, and peer encounter groups.

The TC is managed by the staff, who monitor and evaluate patient status, supervise resident groups, assign and supervise resident jobs, and oversee house operations. The staff members conduct therapeutic groups (other than peer encounter groups), provide individual counseling, and organize social and recreational projects. They make decisions about resident status, e.g., discipline, promotion, transfers, discharges, furloughs, and treatment planning.

48.2.3.2 Peers as Role Models

Peers, serving as role models, and staff members, serving as role models and rational authorities, are the primary mediators of the recovery process. TC members who demonstrate the expected behaviors and reflect the values and teachings of the community are viewed as role models. TCs require multiple resident and staff role models in order to maintain the integrity of the community and ensure the spread of social learning effects.

48.2.3.3 Staff Members as Rational Authorities

Staff members foster the self-help learning process through performance of their managerial and clinical functions described above but also as role models and rational authorities. TC residents often have had difficulties with authorities who have not been trusted or who have been perceived as guides and teachers. There- fore, residents need a positive experience with an authority figure who is viewed as credible, supportive, corrective, and protective so that they may gain authority over themselves (personal autonomy). As rational authorities, staff members provide the reasons for their decisions and explain the meaning of consequences particularly in terms of recovery and personal growth.

48.2.3.4 Therapeutic Educational Activities (Groups and Individual Counseling)

Various forms of group process and individual counseling provide residents with opportunities to express feelings and resolve personal and social issues. They increase communication and interpersonal skills, bring about examination and confrontation of behavior and attitudes, and offer instruction in alternative modes of behavior. The main forms of group activity in the TC are peer-led encounter groups, staff-led therapy, and tutorial groups. Other groups that convene regularly or held as needed supplement the main groups. These vary in focus, format, and composition and include gender, ethnic, age-specific, or health theme groups. Additionally, cognitive-behavioral tutorials using manualized curricula are employed for targeted areas such

as relapse prevention, criminal thinking, trauma and PTSD, etc.

One-to-one counseling balances the needs of the individual with those of the community. Peer exchange is ongoing and is the most consistent form of informal counseling in TCs. Staff counseling sessions may be regularly scheduled or conducted as needed. The focus of staff counseling is to address issues that may impede progress and to facilitate the patient's adjustment to and constructive use of the peer community. Counseling is also employed for the purpose of developing an individualized treatment plan.

48.2.3.5 Community Enhancement Activities (Meetings)

Community enhancement activities are the facility-wide meetings that convene daily. These include the morning meeting, the seminar, the house (evening) meeting, and a general meeting. Some of these are held almost daily, while others are called when needed. These gatherings are necessary for building the spirit of community to which members are expected to participate actively. Though different in format, all meetings have the common objective of facilitating the individual's assimilation into the community. The purpose of the morning meeting is to instill a positive attitude in the community at the beginning of the day, motivate residents, create camaraderie, and strengthen unity. Seminars are community-wide teaching sessions led by peers or staff presenting topics that directly or indirectly relate to the TC perspective on recovery and right living. House meetings are coordinated by senior residents to transact community business. General meetings take place only when needed and are usually called so that negative behavior, attitudes, or incidents in the facility can be addressed. While these activities are often facilitated by senior residents, staff are available to oversee them. Community enhancement also occurs in a variety of nonscheduled, informal activities as well. These include activities related to rituals and traditions, celebrations (e.g., birthdays, graduations, phase changes, job changes), ceremonies (e.g., those relating to general and cultural holidays), and memorial observances for deceased residents, family members of residents, and staff members.

48.2.3.6 Community and Clinical Management Elements

Community and clinical management elements maintain the physical and psychological safety of the environment and ensure that resident life is orderly and productive. Thus, they strengthen community as a context for social learning. The main elements that are staff managed, although with some input from the senior resident social hierarchy, are privileges, disciplinary sanctions, surveillance, and urine testing. How- ever, peer confrontation in the form of verbal correctives, affirmations, and feedback (e.g., reactions, advice, information) are ongoing community management activities.

48.2.3.7 Program Stages and Phases

Recovery in the TC is a developmental process that can be understood as a passage through program stages of learning. The learning that occurs at each stage facilitates change at the next, and each change reflects movement toward the goal of recovery. Three major program stages characterize change in long-term residential TCs – *orientation-induction*, *primary treatment*, and *reentry* – and may include additional substages or phases. The original time frame for these stages was grounded in a planned duration of treatment ranging up to 24 months. Current stage and phase durations are shorter commensurate with decreased overall planned durations. Regardless of temporal changes completion of each stage is a celebrated event marking acknowledged programmatic and clinical progress.

Completion marks the end of active program involvement. Graduation itself, however, is an annual event conducted in the facility for individuals who have completed all program stages and have successfully spent some time outside the treatment facility. Thus, the TC experience facilitates a process of change that must continue throughout life; and what is gained in treatment are tools to guide the individual on a path of continued change. Completion, or graduation, therefore, is not an end but a beginning.

48.2.3.8 Aftercare

TCs have always acknowledged the patient's efforts to maintain sobriety and a positive lifestyle beyond graduation. Until recently, long-term TCs addressed key clinical and life adjustment issues of aftercare during the reentry stages of the 2-year program. As noted, funding pressures have resulted in shorter planned durations of residential treatment and the stages and phases therein. This has underscored the necessity for aftercare resources to address both primary treatment and reentry issues. Thus, many contemporary TCs offer post-residential aftercare treatment and social services within their systems, such as intensive day treatment and step-down outpatient ambulatory treatment or through linkages with outside agencies.

48.2.4 The Effectiveness of Therapeutic Communities

Over the past four decades, a considerable scientific knowledge base has developed with follow-up studies on thousands of individuals treated in TCs. The most extensive body of research bearing on the effectiveness of addiction TC programs has amassed from field outcome studies. These all employed similar longitudinal designs that follow admissions to TCs during treatment and 1–5 years (and in one study up to 12 years) after leaving the index treatment.

These studies show that TC admissions have poor profiles in terms of severity of substance use, social deviance, and psychological symptoms. The striking replications across studies leave little doubt as to the reliability of the main conclusion. Namely, there is a consistent relationship between retention in treatment and positive posttreatment outcomes in TCs. Replication studies overseas seem to follow the same trend. This conclusion is supported in the smaller number of controlled and comparative studies involving TC programs (for a recent review of the TC outcome literature in North America, see [4]). Overall, the weight of the research evidence from multiple sources (multi-program field effectiveness studies, single-program controlled studies, meta-analytic statistical surveys, and cost-benefit studies) is compelling in supporting the hypothesis that the TC is an effective and cost-effective treatment for certain subgroups of substance abusers, particularly those with serious social and psychological problems in addition to their drug abuse.

48.2.5 Adaptations and Modifications of the TC for Special Populations and Settings

The traditional TC model described in this chapter is actually the prototype of a variety of TC-oriented programs. Today, the TC modality consists of a wider range of programs serving a diversity of patients who use a variety of drugs and present with complex social and psychological problems in addition to their substance abuse. Client differences as well as clinical requirements and funding realities have encouraged the development of modified residential TC programs with shorter planned durations of stay (3, 6, and 12 months) as well as TC-oriented day treatment and outpatient ambulatory models. Having become overwhelmed with alcohol and drug abuse problems, correctional facilities, medical and mental hospitals, and community residences and shelters have implemented TC programs within their settings. Additionally, the TC approach has shown to be effective within these specialty settings [4].

Most community-based traditional TCs have expanded their social services or have incorporated new interventions to address the needs of their diverse residents. These changes and additions include family services, primary healthcare specifically geared toward HIV-positive patients and individuals with AIDS, aftercare services particularly for special populations such as substance-abusing inmates leaving prison treatment, relapse prevention training, components of 12-step groups, mental health services, and other evidence-based practices (e.g., cognitive-behavioral therapy, motivational interviewing). Mostly, these modifications and additions

enhance but do not substitute for the basic TC approach, community as method. Research literature documents the effectiveness and cost-effectiveness of modified TCs for special populations including homeless mentally ill chemical abusers, those in criminal justice settings, and adolescents (e.g., [2, 6, 9, 17, 19]).

48.2.6 TCs Worldwide

Over some five decades, TC programs have been implemented worldwide. In Europe, the establishment of drug-free therapeutic communities was the main treatment response to the emerging heroin problems in the 1960s and 1970s. The original American TC model was adapted to the European culture, and it integrated the long-standing local traditions and influences. Between 1968 and 1983, the TC approach spread rapidly across virtually all countries in Europe including the United Kingdom and subsequently to Asia, Africa, and Latin America. Globally, it is conservatively estimated that there are over 3000 TCs operating in hospital, prison, juvenile centers, outpatient, and community-based settings.

48.2.7 TC Outcome Research Worldwide

The North American research literature is the most extensive and has been briefly cited above. There is a modest but developing research literature on TCs worldwide particularly of European programs. The main conclusion from recent reviews of the European outcome studies may be briefly summarized.

"Length of stay in treatment and participation in subsequent aftercare were consistent predictors of recovery status. The authors conclude that TCs can promote change regarding various outcome categories. Since recovering addicts often cycle between abstinence and relapse, a continuing care approach is advisable, including assessment of multiple and subjective outcome indicators" [18]. Similar conclusions are obtained in outcome studies of TC programs in Peru and Thailand [10, 11] and Australia [15].

Although treatment process studies are few, emerging research has supported hypotheses concerning the generality of the perspective, model, and method of TC. Utilizing a common assessment instrument (the Survey of Essential Elements Questionnaire SEEQ; [12]), these studies emphasize that differences exist between standard and modified TCs in essential elements within cultures but that the similarities in elements outweigh the differences across cultures [7, 8, 10, 11].

48.2.8 Cultural Adaptations of the TC

Given the complexity of the TC as a social psychological approach, it is understandable that its implementation has been influenced by cultural context. Even within North America, for example, TC programs have adapted to ethnic diversity factors [5]. The adaptation of the TC to cultural diversity or context factors is still greater at the global level.

Beyond the above studies supporting the generality of the essential elements, there has been relatively little empirical research that focuses on cultural influences in the adaptation of the TC. However, a considerable descriptive literature of TCs in different cultures has unfolded over some four decades. Some reports can be found in scientific journals, but most are contained in the published conference proceedings of international and regional TC associations, e.g., the World Federation of Therapeutic Communities (WFTC), the European Federation of Therapeutic Communities (EFTC), the Australasian Therapeutic Communities Association (ATCA), the Latin-American Federation of Therapeutic Communities, and the Asian Federation of Therapeutic Communities.

These writings, along with the few empirical studies and the years of observations by trainers, consultants, and others, have identified various cultural context influences that are embedded in TC programs (see some examples in Table 48.2). It is beyond the purview of this chapter to discuss

Table 48.2 Some examples of cultural elements shaping the unique TC characteristics in different cultures

Gender. In cultures where there are strict norms regarding the mixing of the sexes, there are separate TCs for men and women. The segregation is not driven by clinical rationale intended to better meet the unique needs of a particular gender but more for moral and reasons of propriety.
Religion. In most Eastern TCs, religion and religious practices are integrated into the TC structure. Those who belong to minority religions are encouraged to practice their faith. Major religious holidays are observed, and program activities are tailored around celebrations of such holidays. Even dietary practices are observed.
Social organization. The traditional hierarchical structure of the TC is highly compatible with the formal and often rigid social structure in most conservative cultures. The TC hierarchical structure lends clarity which is consistent with the formal social structures of most of these societies. The delineation and lack of ambiguity of job positions and social status in the community promote social harmony. It also defines the social roles of and expectations from the community members.
Role of the recovering addict as therapist. In most Oriental or Eastern cultures, academic credentials are preferred over experiential training. The contributions of the "recovering" person as therapist are not greatly appreciated, unless the person has a college degree in addition to personal experience. It requires a paradigm shift to consider, for example, a recovering addict or a recovered mentally ill person who become therapists themselves.
Time orientation or temporal perception. Eastern culture has a fluid perception of time in contrast to Western society's highly structured time perception, "on-time" versus "in-time" orientation. Time orientation or how and when activities are implemented has implications in terms of operational efficiency and outcomes. The result-oriented and purpose-driven structure and schedule of the TC compel timeliness in order to comply with the demands and expectations of supporting and maintaining the community. Timeliness is observed across the board out of necessity, transcending cultural temporal perception.
The professional as TC staff. Many TCs outside the United States were founded by professionals who employed the services of TC-recovered ex-addicts as clinical staff along with professional staff. Working as a team, the combination creates a very progressive TC by exploiting the unique contributions of each.
Family. The importance of the family and their role in treatment in various cultures are evident in the popularity of family associations [14]. Some TCs, such as in the case of Indonesia, were conceived by parents who originally sent their children to a Malaysian TC for treatment. In due time, they initiated a TC movement in their own country. Malaysian and Chinese TCs consider family and religion (spirituality) to be central to treatment [1].

these in detail, but several working conclusions are offered concerning the TC's adaptation to cultural influences.

First, the TC perspective (i.e., views of the whole person disorder, recovery, and right living) and its approach (community as method) can be preserved and integrated within diverse cultures. Second, empirical research is needed to abstract a more complete list of cultural influences and to assess their impact on outcomes. Finally, across all cultures, maintaining *fidelity* of practice is necessary to assure the optimal effectiveness of the TC approach, a general issue which is briefly discussed in the last section of this chapter.

48.2.9 Issues and Challenges to the TC

The evolution of the contemporary therapeutic community (TC) for addictions over the past 45 years may be characterized as a movement from the marginal to the mainstream of substance abuse treatment and human services. Currently, TCs serve a wide diversity of clients and problems; they have reshaped staffing composition, reduced the planned duration of residential treatment, reset its treatment goals, and, to a considerable extent, modified the approach itself. These evolutionary changes have surfaced key issues that challenge the TC to maintain the integrity of its unique approach. Several of these are briefly highlighted: funding, workforce, research, treatment fidelity, and the diversity of TCs. Though interrelated, these issues are discussed separately.

Additionally, in the United States, many TC programs have "converted" or begun mergers with physical health clinics with the notion that TC integration with primary healthcare services will produce better outcomes [13]. However, it should be noted this integration may exacerbate the challenges of maintaining treatment fidelity.

48.2.10 Funding and Planned Duration of Treatment

Issue: The success of the TC approach has been demonstrated primarily for residential programs with planned durations of treatment of at least 9–12 months. In recent years, however, fiscal support has been steadily decreasing for long-term treatment in general and for residential treatment in particular. Thus, for the large majority of TCs that depend upon public funding, planned duration of treatment has been reduced often *below the threshold* of time needed to yield positive outcomes. This adjustment to funding pressures potentially undermines the viability of the TC as a cost-effective modality in the health-care system.

48.2.11 Workforce

Issue: The expansion of the TC to serve special populations in special settings has resulted in a number of problems in the recruitment, retention, and development of experienced staff. General problems include low salaries, limited career goals, and difficult working conditions. However, a specific workforce issue arises from the *diversity of staff* in TCs. The increased number of traditional professional staff from mental health and social services has posed a special challenge to the TC. Based on their education and training, traditional professional staff utilize concepts, vernacular, and methods that often counter or subvert the fundamental mutual self-help features of the TC. Moreover, most professionals and ex-addict paraprofessionals who work in TCs do not undergo rigorous and supervised training on the TC model and its practice.

48.2.12 Research

Issue: Despite decades of therapeutic community (TC) outcome research, some critics have questioned whether the TC is an evidence-based treatment for addictions. Given the relative lack of randomized, double-blind control trials, it is concluded that the effectiveness of the TC has not been "proven." Such conclusions contain serious implications for the acceptance and future development of the TC.

A new research agenda should build on the existing knowledge base that documents the contribution of the TC as a major health and human services modality. This agenda should include studies that demonstrate (a) *health and social benefits* (e.g., reduction in drug/alcohol use and social deviancy and increase in employment, education, and overall psychological well-being), (b) *cost-benefits* of both long-term TCs and shorter-term residential programs for specific subgroups of substance abusers, and (c) *collateral benefits* which refers to the *prevention* of trans-generational drug use, HIV, STDs, as well as family breakdown among treatment successes.

48.2.13 Treatment Fidelity

Issue: Understandably, TCs have pursued financial solvency by expanding to serve a wide variety of populations, e.g., mental health, homeless, corrections, juvenile justice, and childcare. Contracts have obligated TCs to meet regulations of community, state, and federal agencies and often to incorporate practices based upon different professional views of treatment.

This expansion outward of the TC, however, has been at the expense of *inward* refinement of the approach itself. It is one thing to modify and adapt the TC for special populations, settings, and shorter durations of treatment. It is quite another to ignore the development of the TC's unique approach, *community as method.* Thus, if the TC is to retain its unique identity within mainstream human services, it must address the complex issue of treatment *fidelity.*

TC effectiveness and fidelity of treatment are closely related. High-fidelity treatment produces better outcomes [7]. The key strategies needed to assure high-fidelity TCs are staff training based upon critical elements, teaching curricula grounded in a uniform definition of community as method, and appropriate training models that integrate didactic and experiential learning.

Table 48.3 Classification of TC programs

Standard TC programs. These are guided by the TC perspective, retain essential components of the program model, and utilize community as method as the primary approach. They are mainly housed in residential settings, with longer planned durations of treatments, serving the more severe substance abusers (primarily client driven).
Modified TC programs. These are guided by the TC perspective, incorporate essential components of the model, but adapt community as method for special populations (e.g., co-occurring disorders, criminal justice substance abusers, juveniles) and settings (hospitals, shelters, prisons). Key adaptations are more staff directed, greater emphasis on individual differences, moderated intensity of group process, and a more flexible program structure. Additionally, these programs incorporate strategies and services which have proven useful in addressing particular problems and special populations, including pharmacotherapy (e.g., methadone, buprenorphine, psychotropic medications) as well as varieties of counseling and family therapy (client and staff driven).
TC-oriented programs. These *are not* guided by the TC perspective and do not adhere to community as method. Typically, these serve less severe clients in short-term residential or day treatment settings and are eclectic in their approach. They select elements of the TC (e.g., community meetings, peer support group, etc.) but mainly utilize services and practices that are not specific to the TC (primarily staff driven).

48.2.14 Diversity of TC Programs

Issue: The TC approach and model have been successfully adapted and modified for various populations and settings. However, within the wide diversity of programs that represent themselves as TCs, many do not actually implement the TC approach that has proven successful. This often results in variable treatment outcomes and fosters misperceptions of the therapeutic community as an effective evidence-based approach. The credibility of the TC modality in health and human services will require classification of the diversity of programs as well as the development of standards of quality assurance.

48.2.15 Classification of TC Programs

The range of TC programs for substance abuse and related problems can be organized into three broad categories. These are based upon the extent to which a program is guided by the TC perspective (whole person, recovery, and right living), adheres to the approach (community as method), and retains essential components of the program model (see Table 48.3).

Thus, not all programs that label themselves as therapeutic communities are actually TCs. Clarification of differences in programs, the clients they serve, the goals of treatment, and the fidelity of the particular treatment strategies utilized, is necessary to preserve the integrity of the TC approach.

Finally, TCs worldwide are also undergoing many of the evolutionary changes described above, including modifications for special populations and particularly adapting to fiscal pressures to reduce time in residential treatment. A notable development is the rapprochement between the addiction TC and the psychiatric TC pioneered by Maxwell Jones that has been prominent in Europe. Both of these TC approaches share many of the common elements of community as method to treat populations with both substance use and personality disorder. Nevertheless, maintaining uniformity and fidelity of the TC approach in light of these changes remains a challenge.

48.3 Conclusion

Arguably, the therapeutic community for addictions (TC) is the first formal treatment approach that is explicitly *recovery oriented.* Surely, AA and similar mutual self-help approaches facilitate recovery, but these represent themselves as support, not treatment. Pharmacological approaches, notably, methadone maintenance, have as their treatment goal the reduction or elimination of illicit opiate use; and behavioral approaches, such as cognitive-behavioral therapy (CBT), contingency contracting, and motivational enhancement (MET), focus upon reduction, and not necessarily abstinence and recovery, in targeted drug use. In the TC perspective, however, the primary goal of treatment is *recovery* which is broadly defined as changes in lifestyles and identities.

Thus, in the current context of substance abuse policy and issues (e.g., various treatment options, harm reduction strategies, the economic pressures on health care), the overarching challenge of the TC is to reassert its unique place and mission – that of promoting recovery and right living.

Spiritual Aspects of the 12-Step Method in Addiction Treatment

Abstract

This chapter is directed at defining the nature of spirituality and its relationship to empirical research and clinical practice. An understanding of the spiritual experience can be achieved on the basis of diverse theoretical and empirically grounded sources. Furthermore, the impact of spirituality on addiction in different cultural and clinical settings is explicated by illustrations of its application with regard to Alcoholics Anonymous, Narcotics Anonymous, and Danshukai (Japan).

Keywords

Spirituality · Addiction · Alcoholics anonymous · Treatment · Recovery

49.1 Introduction

49.1.1 AA as a Spiritual Recovery Movement

How does spirituality relate to recovery from addiction? There is a parallel between the way attitudes are transformed in intensely zealous groups and the way the denial of illness and the self-defeating behaviors of people with alcohol and substance use disorders may be reversed through induction into 12-step groups like AA.

Members of the lay public may conclude that certain healthcare issues are inadequately

addressed by the medical community, particularly when doctors are not sufficiently attentive to the emotional burden that an illness produces. When mutually supportive groups of laymen coalesce to implement a response to this perceived deficit, they may form a spiritual recovery movement [15], one premised on achieving remission based on beliefs independent of evidence- based medicine. Such movements may ascribe their effectiveness to higher metaphysical or nonmaterial forces and claim to offer relief from illness.

AA can be considered as a highly successful example of a spiritual recovery movement, as such movements have three primary characteristics. They (a) claim to provide relief from disease, (b) operate outside the modalities of established empirical medicine, and (c) ascribe their effectiveness to higher metaphysical powers. The appeal of such movements in the contemporary period is due in part to the fact that physicians tend not to attend the spiritual or emotional concerns of their patients [16].

Clearly, the attitudes and behavioral norms that AA espouses are much more in conformity with the values of the larger culture than those of zealous religious sects. The expectation of avoiding drunkenness in AA, normative in our culture, illustrates this. People who are highly distressed over the consequences of their addiction are therefore candidates to respond to the strong ideologic orientation of AA toward recovery and are operantly reinforced by the relief produced by affiliation with the group's ideology and behavioral norms, all related to abstinence and a spiritually grounded lifestyle. Significantly, AA generates distress in its members by pressing them to give up their addictive behaviors, but the distress associated with this conflict is relieved if they sustain affiliation and cleave to the group [20, 21].

49.2 Spiritual Aspects

49.2.1 Spirituality as a Psychological Construct

Two empirically grounded perspectives have played a material role in framing how we conceptualize recovery. One is derived from a model of psychopathology modeled on the work of Emil Kraepelin [27]. He framed an approach that now characterizes the contemporary medical model for mental disorders, categorizing disease entities diagnosed on the basis of explicit and discrete symptoms. This approach is evident in the development of criteria for substance use disorders employed in recent editions of the symptom-based *Diagnostic and Statistical Manual of Mental Disorders* [2]. From this perspective, a state of remission, colloquially called recovery in rehabilitation circles, can take place with the resolution of the specific symptoms listed as diagnostic criteria. A second perspective on recovery derives from behavioral psychology, whose model of stimulus-response sequences has led to the ordering of experience around discrete phenomena that can be observed by a researcher or clinician. From this perspective, recovery can also be defined in terms of observable, measurable responses to substance use, lending credence to recovery as a process defined in behavioral terms.

Both perspectives are well suited to the study of psychopathology and have lent the addiction field approaches to studying addiction as a disorder, one that is compatible with research approaches employing experimental controls that are used in the physical and biological sciences. Both have therefore had heuristic value in promoting a research field that has yielded many advances in addiction treatment. There is a third perspective, however, that is defined on the basis of addicts' reports of their own subjective experience. These experiences are not directly observable by the clinician but are available only as reported through the prism of the person's own introspection and reflection. This model is more difficult to subject to measurement, but instruments are being developed that can be applied for its study, as will be discussed below. This approach is inherent in the spiritually oriented psychology of Carl Jung [25], who had a direct influence on Bill W's framing of the Alcoholics Anonymous ethos [5]. James [24], often described as the father of American psychology, also discussed mental phenomena in terms of subjectively experienced mystical or spiritual experience. (In fact, he wrote that "the drunken consciousness is one bit of the mystic conscious-

ness" [p. 378].) The need for spiritual redemption was vital in the writings of Viktor Frankl, who wrote *Man's Search for Meaning* [14], and has recently been espoused with regard to psychotherapy by William Miller [31].

This third perspective is related to the model of spiritually grounded recovery we will discuss here, insofar as it emphasizes the achievement of meaningful or positive experiences, rather than a focus on observable, dysfunctional behaviors. Research on this third approach would typically rely on self-report scales, such as those which can be facilitated by development of instruments like the Life Engagement Test [34], the General Well-Being Schedule, or our own Spiritual Self-Rating Scale [17]. We will consider its role in AA, models for how it takes place, and ways it can be measured. In this respect, recovery can be understood as a process whereby an abstinent addicted person is moving toward a positive adaptation in life. This movement can take place with varying degrees of success, depending on the person's own innate capacities and the circumstances in which they find themselves.

49.2.2 Spirituality and Religious Experience

The relative role of spiritual experience in the 12-step recovery process has been investigated from a variety of perspectives, generally in relation to patients' experience in AA. Kelly et al. [26] reviewed studies that applied mediational tests to ascertain how AA achieves beneficial outcomes and found little support for a role of AA's specific spiritual mechanisms. In fact, with regard to religiosity, Tonigan et al. [36] found that, although atheists were less likely to attend AA meetings, those who did join derived equal benefit as did spiritually focused individuals. On the other hand, in one study on persons recovering from cocaine dependence [13], respondents attributed their positive outcomes to religion and spirituality. Additionally, Zemore [39] followed-up a large sample of substance abusers 1 year after inpatient treatment and found that increases in spirituality contributed to the increment in total abstinence associated with 12-step involvement.

Our own experience, as well, is compatible with these findings, as we have found in multiple settings [19] that spirituality is integral to recovery in 12-step groups. This was particularly evident among long-term members.

49.2.3 Spiritually Grounded Recovery in AA

The AA "program of recovery" is mentioned in numerous places in the *Big Book*, Alcoholics Anonymous [1], and is associated there with terms such as "spiritual experience" and "spiritual awakening" and with working AA's 12 steps. Four of the steps include the word God, which is qualified "as we understood Him." Some clarity is lent to this latter phrase in the *Big Book* where it is pointed out that "with few exceptions, our members find that they have tapped an unsuspected inner resource which they presently identify with their own conception of a Power greater than themselves" (p. 569–570). Flexibility on the issue of theistic belief is also made clear in one chapter that addresses any alcoholic person "who feels he is an atheist or agnostic," encouraging their membership as well. The text points out for these members that even "We Agnostics…had to face the fact that we must find a spiritual basis for life" (p. 44) in order to achieve recovery, implying therein the fellowship's distinction between spirituality and theistic religion.

This issue of theistic connotation, however, is as yet resolved relative to the judicial system, where the application of AA is sometimes constrained because of potential church/state conflicts. It is open to question, however, whether the theistic connotations of AA can be modified without vitiating the program's effectiveness. In this relation, it should be noted that in a 5-year follow-up of recovering cocaine-dependent patients, the strength derived from religion and spirituality significantly distinguished between those who had a highly favorable outcome from those who did not [13]. Additionally, attendance at religious services distinguished significantly between criminal justice clients referred for substance abuse treatment who had a positive outcome and those who did not [3].

Spirituality among long-term members is likely instrumental in sustaining the integrity of the fellowship itself. The prominence of spiritually committed long-term members at meetings, and their availability to serve in the sponsorship role, creates readily available models for earnestly held sobriety. They serve as role models for believing commitment to the 12-step spiritual ethos to help newcomers achieve stabilization in membership. Nonetheless, some people attending NA meetings may find it hard to identify with the spiritual orientation of long-term members.

In the clinical context, recovery is based on a person's behavioral and physiologic status, which can be assessed by recourse to criteria employed in the DSM. Some of these criteria are also embodied in the Addiction Severity Index [30], which is employed widely in research to evaluate recovery. These items can be assessed relatively easily, as they are premised on observable behavior or delineated by symptomatology described by patient, family member, or clinician. A spiritually grounded definition of recovery, however, can be useful as well.

Such a concept relates to the importance of non-demographic subject factors, originally proposed as "quality-of-life" issues [4] – among which spirituality can be considered. In this context, a series of suitable criteria for "diagnosing" addiction (a more apt term than "substance dependence") could be developed. They could then be used to assess the spiritual aspect of recovery associated with the 12-step experience. Resolution of these issues could be considered as important to the spiritual aspect of recovery from addiction. A series of criteria could include items such as

- Loss of sense of purpose due to excessive substance use
- A feeling of inadequate social support because of one's addiction
- Continued use of a substance while experiencing moral qualms over its consumption
- Loss of the will to resist temptation when the substance is available

Another aspect of the DSM format can be considered as well. The manual stipulates "course specifiers" of remission such as "on agonist therapy" and "in a controlled environment." These are included because they are explanatory to the clinician. To them could be added "fully engaged in a program of 12-step recovery," which would be equally explanatory to many clinicians.

But are spiritually grounded criteria measurable? In recent years, methodologies have been developed and validated that could be used to assess outcome based on such subjectively experienced criteria. They employ a systematic approach to measurement and can be used to describe spiritually related states:

A. Affective state:
   (i) A sense of well-being, measured by the General Well-Being Schedule [11] (which we employed) or the Subjective Happiness Scale [28]
   (ii) Contentment with one's life circumstances, measured by the Satisfaction with Life Scale [10]
   (iii) Positive affect, assessed with the Positive and Negative Affect Schedule [37], dealing with both variables as separate dimensions, rather than bipolar ends of the same scale
   (iv) Feelings of support, employing a Scale for Perceived Social Support [6]
B. Existential variables: Meaningfulness in one's life: assessed by the Purpose in Life Test [8].
C. Flow: The experience associated with engaging one's highest strengths and talents to meet achievable challenges, as measured by Experience Sampling [9] or the Flow Scale [29].
D. Spirituality: The Spirituality Self-Rating Scale, which we developed and applied to both substance-abusing and non-substance-abusing populations [17], as well as other such scales. By means of our own scale, we were able to distinguish different populations of substance abusers' level of spiritual orientation from the of non-substance populations.

E. Personality assessment: The Classification of Strengths [33], a series of characteristics based on categories of moral excellence drawn from observations across different cultures.
F. AA involvement: Measures of the degree of affiliation and commitment to the AA fellowship [23].

A methodology for defining recovery based on measurements like these may not have the same appeal to biomedically oriented clinicians as does the conventional symptom-based approach, as these measurements are based on self-report of the person's subjective state. Furthermore, the enthusiasm of newfound recovery may yield a Hawthorne effect. The biomedical format currently applied in diagnosis derives from the school of Kraeplin and subsequent investigators like those who developed the Feighner criteria [12] in the 1970s and then in the ensuing DSM system. Spiritual variables, however, have a lineage as well, from William James, Carl Jung, and Bill W.

Spiritual awakening, a key aspect of 12-step recovery, is designated in the twelfth step of Alcoholics Anonymous (AA). Of long-term AA members who reported having had such an awakening, two-thirds reported no craving for alcohol or drugs at the time of the survey. Their responses reflected a major experiential transformation [18], which can be likened to religious conversion, because both involve a major transformation in personal disposition toward a spiritually oriented perspective on life. Pargament [32], who defined *religion* broadly as "the search for significance in ways related to the sacred" (p. 32), wrote of religious conversion as taking place only when a change comes about in both the destinations and pathways of a person's life in connection to the sacred.

49.2.4 Danshukai

The worldwide growth of secular but spiritual mutual aid organizations promoting addiction recovery has led to the option of people achieving addiction recovery outside of professional treatment. One example of the diverse approaches worldwide is Danshukai.

Japan has a history of recovery by mutual support in the Danshukai movement. Danshukai draws on Zen Buddhism and contains elements that parallel AA, such as undercutting denial, a process of amends, and service [38]. Danshukai meetings, however, typically include family members and offer prayers for those who have passed. The meetings are also much more structured than AA meetings, with decreased emphasis on anonymity. Attendees sign in on their entering the meeting, use their full names, and may wear Danshukai pins, indicating their membership.

49.2.5 AA in the Professional Context

The spiritually oriented 12-step approach has been integrated into professional treatment in some settings where it serves as the overriding philosophy of an entire program or, in others, where it is one aspect of a multimodal eclectic approach. The Minnesota Model for treatment, typically located in an isolated institutional setting, is characterized by an intensive inpatient stay during which a primary goal of treatment is to acculturate patients to acceptance of the philosophy of AA and to continue with AA attendance after discharge [7]. Although a variety of exercises are included during the stay, this approach has been criticized as dogmatic because of its sole reliance on the 12-step approach. The outcome of this model, however, has been shown to yield positive results in a survey of patients discharged from one such setting (Hazelden, in Center City, MN) [35], but randomization of patients treated in Minnesota Model facilities with those treated by means of an alternative approach is needed.

A more eclectic option is illustrated in the integration of 12-step groups into a general psychiatric facility for the treatment of patients dually diagnosed for major mental illness and substance abuse. The importance of spirituality in such a highly compromised population was

evidenced in our studies [17] in which such patients ranked spiritual issues like belief in God and inner peace higher than tangible benefits like social service support and outpatient treatment. One inherent advantage of this format is that it benefits from the introduction of an inspirational approach to patients who, as Goffman has pointed out [22], have become "degraded" by stigmatization due to their psychiatric disorders.

In summary, spirituality is a matter of personal meaning that is widely accepted. It is also central to the recovery process from addiction for many AA members. The fellowship of AA, in fact, can be considered a movement developed in relation to people's spiritual needs. Although spirituality is subjectively experienced, it can be assessed systematically in given individuals by employing currently available empirical techniques. By such means, an important aspect of addiction recovery can be defined and studied.

50 Addiction Recovery in Services and Policy: An International Overview

David Best and Rebecca Hamer

Contents

Abstract

This chapter provides an overview of the changes occurring in the recovery field in the United States and internationally, with special emphasis on the growing focus on recovery as the guiding vision for drug policy and as a framework for treatment. 'Recovery' goes beyond substance use to encompass improved functioning in all life areas and the realisation of individual aspirations. As substance use disorders are often chronic and relapsing, recovery is conceptualised as a process that unfolds

over time and requires a continuing care approach. We describe emerging service models, including recovery-oriented systems of care (ROSC) and the centrality of peer-driven recovery supports as part of a social and community emphasis on recovery sustainability. We conclude with some recommendations on strategies that professionals, peers and communities can be used to promote recovery amongst substance-using individuals.

50.1 Introduction

As healthcare evolves, healthcare professionals are grappling with new systems and care models whilst continuing to diagnose and treat human conditions such as substance misuse. However, the way society views addiction has changed over time – from moral failing or crime to chronic brain disease [77], with resulting changes in how addiction is addressed by healthcare services. In this chapter, we describe recent developments in a recovery orientation to substance problems. The chapter examines global research innovations, policy and practice responses and the integration of recovery-oriented approaches into healthcare and social care services.

50.2 Recovery as a Guiding Vision of Substance Use Services and Policy

There are two empirically based elements to the shift in policy and practice: the reconceptualisation of problem drug use as a chronic disorder requiring both treatment and ongoing recovery support and the broadening of what 'recovery' means. First, research in the past 20 years has concluded that addiction is best understood as a chronic disorder equivalent to diabetes, asthma or hypertension [77]. However, unlike these other conditions, treatment for problem drug use (PDU) has historically been delivered using an acute care model: intense episodes of care during which a person, often in crisis, is assessed, treated and discharged in a relatively short time [27, 56]. Growing evidence for long addiction and treatment 'careers' consisting of multiple cycles of treatment episodes [28, 45] followed by return to active addiction [94] has led to the conclusion that the acute care model is inadequate [44, 56, 78, 79, 87]. Kelly [56] contends that medical intervention alone is insufficient in achieving and maintaining recovery and that it is imperative for ongoing, long-term recovery support to be delivered following stabilisation and treatment phases. A continuum of care model consistent with chronic disease is also aligned with the experience of persons in recovery who overwhelmingly describe recovery as 'a process' versus 'an end point' [60].

The second element of the paradigmatic shift was summarised by McLellan and colleagues as'*the immediate goal of reducing alcohol and drug use is necessary but rarely sufficient for the achievement of the longer-term goals of improved personal health and social function and reduced threats to public health and safety – i.e., recovery*' ([79], p. 448). The emerging recovery-oriented model provides a continuum of support designed to promote and sustain improvements in substance use and psychosocial functioning. This reconciles a public health response with a strength- and community-based focus that places the individual at the heart of their own recovery journey and emphasises personal empowerment and individual ownership of recovery. Promoting recovery requires giving individuals the tools and strategies to develop 'capital', a strength-based approach that has gained prominence in both psychology [96] and criminology [92] and is embodied in the addiction field by the construct of 'recovery capital' [35].

Hennessy [40] asserts that the concept of recovery capital provides an exploratory framework with which to identify assets and obstacles to recovery to be built upon or ameliorated in order to support recovery journeys. Amongst the six recovery capital (RC) models included in Hennessy's [40] systematic review, recovery is characterised as ongoing and dynamic, is variable between and within individuals, consists of a broad range of resources from macro, meso- and individual levels, which can interact to further

build or deplete RC, and suggests that places, communities and resources can all intersect to generate and embed recovery capital. Finally, recovery is contagious through individuals, groups and society [40].

50.3 What Does 'Recovery' Mean?

The term 'recovery' has been widely used for decades but, until recently, had remained poorly defined. Researchers typically used the term in studies by measuring short-term abstinence (typically a year or less), some from a single substance (e.g., alcohol) and others from all substances (for a discussion, see [60]). In 2005, the Center for Substance Abuse Treatment (CSAT), convened a panel of experts representing a number of key stakeholder groups [20]. The following year, the Betty Ford Center convened a smaller panel of experts and stakeholders that published the first consensus definition of 'recovery' as 'voluntarily maintained lifestyle composed characterised by sobriety, personal health, and citizenship' ([10], p. 221).

The UK Drug Policy Commission [99] echoed these definitions whilst asserting that recovery can be achieved through a diverse range of strategies, including substitution therapy if desired, to provide a holistic continuum of care and support.

White [105] expands upon this, asserting that recovery consists of three elements: sobriety, improvements in global health (referring to the physical, emotional, ontological, life meaning and purpose) and citizenship. The Substance Abuse and Mental Health Services Administration [93] further elaborated a dual conception of recovery for both mental health and problem drug use, delineating ten guiding principles for recovery:

1. Hope: The power of hope is fundamental for individuals, families and communities to feel recovery is possible.
2. Relational: Recovery entails the formation of strong relationships with those who share hope and a vision for recovery, through which new positive identities and roles may be established, providing a sense of belonging, community and agency.
3. Person driven: Recovery is a personal journey, and it is fundamental that each recovery journey is navigated according to individual self-determination.
4. Culture: Recovery pathways are unique according to cultural values and beliefs.
5. Many pathways: The routes to recovery are diverse and comprise a broad spectrum of formal or informal support.
6. Holistic: Recovery is a multi-faceted process entailing improvements across all domains of quality of life and wellbeing.
7. Peer support: Peers are fundamental in providing mutual aid, modelling prosocial behaviour and possibilities to PDU and to communities. Furthermore, peer involvement provides those in recovery with new alternative identities to share their experience to help others and opportunities to reintegrate with and give back to their communities.
8. Strengths/responsibility: Individuals, families and communities all have assets that can be built upon to strengthen recovery.
9. Respect: Discrimination, stigma and ostracisation present significant obstacles to recovery, and so it is crucial that recovery systems recognise the bravery of those pursuing recovery and that their rights are respected.
10. Addresses trauma: Mental health problems and PDU are often preceded and exacerbated by experiences of trauma, whilst trauma similarly presents obstacles to recovery. Therefore, services and systems must be trauma aware and work to ameliorate the destructive effects of posttraumatic stress disorder (PTSD).

Correspondingly, Bassuk et al. [7] attest that *'as a broader definition of recovery gains traction, it is critical that future research expands to mirror the various domains of recovery by including outcomes related to housing, employment, educational status, quality of life, functioning, trauma exposure, mental health status and social support networks'*.

50.4 Recovery Prevalence

According to Huskamp and Iglegart [49], 82% of people with substance use disorders do not receive adequate treatment, whilst abstinence rates are complicated by very high mortality rates. Thus, whilst Grella and Lovinger [37] reported an abstinence rate of 80% in the surviving sample, the rate reduced to 30% if the individuals who had died were included in the study. In their review of remission rates, Hser et al. [45] contradicted the idea of 'maturing out' by suggesting that abstinence rates drop to around 30% after 10 years and then remain relatively stable, irrespective of age or chronicity of use. They concluded that opioid addiction is a chronic disorder characterised by frequent relapse, but that 'longer treatment retention is associated with a greater likelihood of cessation, whereas incarceration is negatively linked to subsequent abstinence' (p. 85).

In a review of 415 population and clinical studies between 1868 and 2011, around half of study participants reported remission from substance use disorders at the final study follow-up point. In Fleury et al.'s [31] systematic review and meta-analysis of 21 papers examining remission from substance use disorder, a standard remission rate of 54% and a conservative remission rate of 35% were reported after a mean of 17 years.

In a population-based representative US sample ($n = 39{,}809$), Kelly et al. [55] found that of respondents answering 'yes' to -'Did you use to have a problem with alcohol or drugs but no longer do?' 9.1% of the sample were in recovery, of whom 46% self-identifying as 'in recovery', whilst 53.9% reported 'assisted' pathway use. Assisted pathways were most common for opioid users and least common for cannabis users.

50.5 What Does Adopting a Recovery Orientation Mean for Addiction Treatment Services?

The paradigm shift discussed above mean that recovery supports need to be expanded in time, in philosophy and in scope. In terms of time, PDUs have thus far been addressed using intensive, short-term episodes of professionally delivered services. Whilst treatment is generally reported to be effective [101, 102, 103], return to active use following treatment, even amongst those who had achieved abstinence, is high [28, 45, 64, 78, 79]. Kelly [57] notes that in early recovery, people experience higher levels of stress-causing hormones such as cortisol and corticotropin, and thus their ability to learn new skills is hindered whilst their vulnerability to stress-triggered relapse is greater. Consequently, the ongoing recovery support favoured by Kelly [56] factors biological, neurobiological and psychosocial domains within ongoing support, monitoring and intervention to navigate potential or actual relapses along the recovery journey. Kelly [56] identifies four fundamental types of such ongoing recovery support:

- Emotional support
- Tangible support (e.g., links to housing)
- Informational support (advice/learning)
- Social support (sense of belonging)

Recovery support services are increasingly diverse and accessible, and Kelly [56] identifies six types of recovery support services (RSS) in the USA:

- Peer-based recovery support services
- Recovery community centres
- Recover support in education
- Mutual-aid organisations
- Recovery housing
- Clinical models

Most studies exploring the effectiveness of peer recovery support confirm the benefit to participants [7, 29, 98]. Although endorsement of the value of PBRSS is 'tentative', peer support can play a significant role in reducing relapse, building greater trust and relationships between service users and providers, forging prosocial networks and providing greater satisfaction and retention in treatment, so that there is support for integrated peer and professional support [29]. However, the specifics regarding the

impact of different levels of peer ability and experience, intervention intensity, duration, frequency and context in addition to the efficacy of peer support for specific populations remains to be explored [7].

Despite the supportive evidence, Greer et al. [36] have identified several barriers and disadvantages peer workers suffer. Stigma from non-peer workers can isolate peers in the workplace and diminishes their achievements. Peer work is also often subject to exploitation, low wages and the expectation of volunteering. As peers often go above and beyond as their motivation is to help their communities, this can be practically, emotionally and financially under-appreciated by employers who do not provide the necessary support, esteem and compensation given the dedication, expertise and passion of most peer workers. Peers may be at heightened risk from vicarious trauma and compassion fatigue which may endanger their own recovery. Further, the interference of peer work with welfare payments can result in individuals being disadvantaged. In Canada, peer work is separated entirely from welfare support and payments, ensuring that their contribution to their communities is suitably facilitated and valued. The BC Centre for Disease Control website features Peer Engagement Best Practice guidance as a result of their 3-year Peer Engagement and Evaluation Project (PEEP).

SAMHSA has begun to develop relevant guidelines ([7], p. 8). Awareness of discrimination, barriers and needs is fundamental if services and systems are to recognise the expertise, value and power that peers bring to recovery services and communities. In addition to asserting PBRSS as an 'evidence-based practice', additional research is required to implement peer support and to foster experiential experts whose knowledge, perspective and empathy inspire recovery [7, 29].

A recovery orientation requires the provision of comprehensive services to address needs in all life areas impaired during active addiction and where improvements are considered an inherent part of recovery, for example, physical and mental health, employment, economic, family and social life. Services addressing these issues have thus far often been referred to as 'ancillary' in status or 'aftercare' in the timing of delivery in spite of their importance to clients and their role in the transition to stable recovery [65]. Laudet and White [62] examined challenges and life priorities in a sample of 356 community-based persons in abstinent recovery and found that working on one's recovery (e.g., staying sober and 'making recovery a priority') was consistently cited as the top priority (cited by 34–49% across stages). Employment was the second most frequently mentioned priority, cited by the same percentage of persons abstinent over 3 years as working on one's recovery (34.1% each).

As both approaches originate from different models, Galanter [33] contends that treatment and recovery support must be defined as separate but related stages. The implication is that the partnership and streamlining of relationships and referrals between professional treatment and ongoing recovery support services hold great potential for improving service users' recovery chances.

50.6 Recovery-Oriented Systems of Care (ROSC)

In the United States, the shift to a recovery orientation in treatment has been primarily spearheaded by the Substance Abuse and Mental Health Services Administration (SAMHSA), whilst in the United Kingdom, impetus to formalise recovery orientation has come from the English and Scottish Government, as discussed below. The need for this new model was perhaps stated most explicitly by a SAMHSA lead: 'Recovery is more than abstinence from alcohol and drugs; it's about building a full, meaningful, and productive life in the community. Our treatment systems must reflect and help people achieve this broader understanding of recovery' ([23], p. 2). ROSC's goals are to intervene early with individuals, to support sustained recovery and to improve the health and wellness of individuals and families. The ROSC model proposes a multisystem, person-centred continuum of care in which a comprehensive menu of coordinated

services and supports is tailored to individuals' recovery stage, needs and chosen pathways [22, 23]. Services and supports are provided in a comprehensive array of domains, including education and job training, housing, childcare, transportation to treatment and work, case management, spiritual support as well as prevention services, for example, relapse prevention, recovery support, education for family members, peer-to-peer services and coaching, self-help and support groups [53, 97].

Services are intended to address the multitude of life areas adversely affected by active substance use and to respond to clients' changing needs across their lifespan. ROSC is responsive to calls for a shift from the acute care model to one more akin to the model used in other chronic conditions [48, 50, 77, 106]. From a systems perspective, this means that the care coordination function of services is conferred a more prominent role in treatment design and delivery. Key principles guiding the recovery orientation include primacy of participation; promoting access and engagement; ensuring continuity of care; employing strength-based assessment; offering individualised recovery planning; functioning as a recovery guide; community mapping, development and inclusion and identifying and addressing barriers to recovery [58, 59].

Implementing ROSC internationally will require transformative changes in agencies and systems, which has implications for the training and evaluation of peer and professional staff and service managers and those responsible for commissioning services.

50.7 What Do Recovery-Oriented Addiction Services Systems Look Like?

In supporting the transition to continuing care approaches, the most common form of aftercare consists of a stepped down course of services typically following intensive inpatient or residential treatment [73, 74, 76]; in spite of its established existence and intuitive appeal, few clients access these resources, and the evidence for effectiveness remains limited [34, 73]. In the past decade, clinicians have also started to capitalise on health technology such as telephone-based continuing care [75], and several large treatment agencies are developing proprietary web-based online recovery maintenance and support programmes for clients to use after they leave service. Ashford et al. [5] explored digital recovery support services (DRSS), observing that these can take the form of websites, online forums, social networking, smartphone apps and text messaging services. The authors reported that DRSS has not been demonstrated to facilitate and support recovery journeys, due largely to the anecdotal and qualitative nature of accounts. However, its popularity and proliferation support these testimonials. In the USA, 11% of adults in recovery have used one or more DRSS and their digital format can provide more available and accessible recovery support, particularly for especially stigmatised populations [5].

50.8 Individual Recovery Support Services Elements

A range of recovery support services (RSS) have been described in recent articles and monographs that also review the emerging science [53, 61, 97, 104, 105]. Unlike professionally delivered aftercare, peer-based RSS are not only delivered after treatment but can also be provided alongside professional services. This is important as there are often barriers to treatment that include wait lists, finances, stigma and ambivalence about seeking professional help [3, 26, 65, 109]. RSS are often delivered by peers, individuals who have experiential knowledge [17] and work as volunteers or as paid service workers [53] to assist others in initiating and maintaining recovery and enhancing their quality of life [105]. Many individuals in recovery report that being in the company of peers is helpful [35, 63, 71, 86]. In Glasgow, Scotland, one study found that the two strongest predictors of positive quality of life in recovery were spending time with other people in recovery and engagement in meaningful activities, including working, training, volunteering and involve-

ment in community groups [12]. A series of systematic and scoping reviews have surmised the overall promise of peer and self-help group supports in alcohol and drug recovery, albeit this endorsement is tentative due to the lack of methodological rigor and depth of exploration within research [7, 8].

One key aspect of peer involvement is around assertive linkage to prosocial groups. Manning et al. [70] showed significantly greater engagement in mutual aid groups during and after residential treatment when supported by peer assertive linkage (compared to doctor referral or written information). Following up on this, O'Connell et al. [88] used a similar design with patients with co-occurring disorders but added ongoing peer support and found that this condition was associated with lower psychotic symptoms at 9 months and better ongoing treatment engagement.

Andreas et al. [1] reviewed the Peers Reach Out Supporting Peers to Embrace Recovery (PROSPER), a programme involving peer-run groups, coaching, workshops and seminars and extensive training and supervision for peers. Engagement in the programme resulted in increases in self-efficacy, perceived social support, and quality of life. In a Native American context, Kelly et al. [55] found that participation in a peer recovery support service that was community based resulted in reduced recent alcohol and drug use and better rates of employment and stable housing.

Parkman et al. [90] found three factors to determine the efficacy of self-help groups (in this case, for alcohol treatment): attendance, involvement (as a measure of active engagement) and location (proximity to the meeting place and the home of a key worker). Some of the benefits of peer groups are their impact on social networks and sense of identity, as it is the active participation and inclusion in a prosocial group that correlates with positive recovery outcomes.

Perhaps the most well-known and widely available peer self-help model is 12-step mutual aid [54]. In a review article of 12-step facilitation, Kelly [55] reported that eight of the fifteen studies found that the 12-step facilitation produced superior outcomes on at least one of the outcome indicators. In the same review, Kelly [55] concluded *that 'the evidence in this regard is strong. TSF interventions and AA participation is associated with improved substance use outcomes, particularly prolonged abstinence and remission, and is likely to be highly cost-effective'* (p. 18). In a 16-year follow-up study of alcohol treatment, [83] reported that, following the initial 6 months of treatment, 12-step involvement was associated with better outcomes than further professional treatment. Humphreys and Moos [47] have argued that whilst an initial episode of specialist treatment may be beneficial, long-term 12-step engagement may be a better predictor of outcomes over time.

There are other models of peer-based recovery support, including the sober residence, a home that offers mutual help-oriented, financially self-sustaining, self-governed, democratic communal-living environments where individuals in recovery can reside for as long as they choose after inpatient treatment or incarceration, during outpatient treatment or as an alternative to treatment [91]. Recovery residences or sober living houses provide stable housing and a structured, prosocial living environment, and such housing comprises a critical component on the continuum of recovery-oriented systems of care [81].

Recovery housing is derived from mutual aid traditions, the most prevalent of which in the States is Oxford Houses Inc., who have established 2287 houses across 44 states [85]. The benefits of the model in terms of substance use and related domains (e.g., employment, criminal involvement) have been documented in peer-reviewed studies across subpopulations [2, 51, 52, 68, 69, 82], as has been its cost-effectiveness [67, 89]. Chavarria et al. [21] conducted a 2-year followup comparing Oxford Houses Inc. and a standard continuing care model and reported that at 2 years, the clients of Oxford Houses Inc. were more than twice as likely to be abstinent, had higher monthly incomes and were less likely to be incarcerated.

There are now national standards governing recovery houses, although there is a lack of empirical findings correlating recovery resi-

dences with improved outcomes. Mericle et al. [80] found that the type of recovery house resulted in varying results – houses that were part of a group or a wing of a larger organisation led to increased chances of abstinence, whilst those affiliated with a treatment programme improved employment outcome.

50.9 Therapeutic Communities

Therapeutic Communities (TCs), such as San Patrignano in Italy and River Garden Auchincruive in Scotland, also provide residential, peer designed and led environments in which recovery is facilitated and maintained by the mutually supportive recovery community. Therapeutic Communities (TCs) were developed in the 1960s in the USA in response to the lack of capacity in healthcare and social care services to respond to the treatment needs of problem drug users. These were often privately funded and centred around self-help. Although they filled a certain gap in provision, there were issues of professionalism, the ability to upscale consistently and with leadership powers creating unmoderated, abusive and punitive cultures within communities [100]. Synanon, founded by Charles Dederich, was implicated in intolerance of relapse and aggressive shaming measures such as head shaving, verbal abuse and making residents who failed to adhere to house rules wear signs featuring stigmatising and debasing labels in public [108]. Whilst some such practices persisted until the late 1970s, radicalised communities were increasingly replaced as recognition of variation in recovery, addiction experiences and populations; professional standardisation and progressive policies and procedures permeated the TC field [19].

In a significant departure from the dictatorial early days of Synanon, TCs in various countries across Europe have since developed to meet the needs of specific populations with complex needs such as women and children and individuals with dual (concurrent mental health) diagnoses [100]. TCs are also being established in prisons, and transitioning programmes also assist in reintroducing those who have achieved recovery into the community [100]. Therapeutic Communities have thus evolved to encompass the current broader vision of recovery, recognising the breadth of need and experience amongst PDU populations and the importance of community reintegration and cohesion. Whilst TCs in Europe were initially inspired by the revised American equivalents, European theories and techniques plus staff comprising of trained professionals and a focus on the family unit marked these communities apart [100].

Vanderplasschen et al. (2014) conducted a literature review of 28 articles set in the USA and 21 undertaken in Europe exploring the efficacy of TCs. The authors note that '*There is some evidence for the effectiveness of TC treatment in terms of reduced substance use and criminal activity, at least in the USA. A small number of studies also showed positive effects on employment, social functioning and general mental health'*. This implies that TCs have been at least tentatively evidenced to provide the multi-faceted improvements in quality of life and social integration now associated with recovery. However, Vanderplasschen et al. [100] also attest that TCs are less effective than other treatments; although, as with other interventions, positive outcomes are strongly correlated with retention and completion. The European evidence base is also methodologically limited; although this similarly suggests TCs offer reductions in problem drug use and criminal justice experiences alongside holistic improvements in quality of life and well-being. With regards to prison-based TCs, evidence provides a strong endorsement with regards to recidivism when compared to other interventions [100].

Recommendations to ensure the future of TCs include demonstrating efficacy and value for money as emphasis on cost-efficacy continues to permeate addiction and recovery landscapes, a focus which holds implications for the training and payment of employees in TCs [100]. Within a social model of recovery, the TC movement has evidenced the importance of peer-based interventions and suggested a recovery pathway independent of 12-step mutual aid, with a fundamentally different conceptualisation of addiction

and recovery. The TC approach is entirely consistent with four core tenets of recovery-oriented services: a care coordination across a range of service sectors requiring case management skills and 'outward-looking' specialist treatment services, an increased role for peers, a recognition of the validity of 'expertise by experience' and a continuity of care model that acknowledges the need for integrating acute services with those targeting longer-term changes in wellbeing and social integration.

50.10 What Can Professionals, Peers and Communities Do to Promote Recovery Amongst Problem Drug Users?

For professionals to adapt and embrace the shift to recovery-focused practice, Best et al. [16] emphasise the need for clinicians to transition from 'doing to' to 'working with' service users in order to help them move on. Correspondingly, Humphreys [46] refers to the 'gatekeeper myth' that 'holds that the path to recovery can only be walked with the aid of highly educated specialists in addiction treatment'. The gatekeeper myth and dominance of the professional is, however, being eroded by recovery strategy and practice that places the individual, those with lived and living experience, and communities at the heart of recovery. The individual nature of recovery also means policy; practice and research must pay particular attention to marginalised populations whose cultural and individual needs must be considered.

Whilst women's drug-using careers are shorter and women begin their recovery at an earlier stage than men (Best et al. 2015), they also face a host of issues which complicate and exacerbate their experiences of addiction and recovery.

Women with histories of substance use problems commonly have lifelong experiences of stigmatisation, deprivation, violence and abuse [25, 107]. The symptoms of trauma include dissociation, numbing and avoidance and often aggression/defensiveness which are often both attempted to be managed by survivors through drug and alcohol abuse and which have often been misinterpreted in services as unwillingness, disobligingness and disinterest in recovery [39].

Herman's [41] pioneering three-stage recovery model advocates for stabilisation in order to provide PTSD survivors with the sense of safety and control essential from which to begin their recovery. The need for all services and systems working with women to be trauma informed continues to gain increasing traction in research findings, strategy and practice recommendations [6, 24, 25, 39, 41].

50.11 The Recovery Landscape in Europe

The final section of the chapter will focus on the gradual emergence of a recovery movement in Europe and the policy and research innovations that have underpinned this transition, starting with the UK, where recovery policies have dominated addiction services since 2008. The origins of a recovery orientation in addiction policy are different in Scotland from England, with Scotland's Road to Recovery [95] building on the success of the Scottish Recovery Network for mental health. In England, the UK Drug Strategy [42] had its origins in the mounting critique of a treatment system predicated on low-intensity treatments [11] and a dissatisfaction with the prevailing treatment system and philosophy [4]. The 2017 English Drug Strategy comprised a continuation of 2010's strategy which marked a discursive and practical shift away from a focus on crime prevention (which relied on maintenance and harm reduction) to a focal inclusion of 'promoting recovery' as one of the main objectives. The English strategy also built upon its predecessor by proposing to:

1. *'Provide stronger governance for delivering the strategy, including a Home Secretary-chaired board and the introduction of a National Recovery Champion.'*
2. *'Expand the data we collect on levels of drug misuse and recovery from dependence and*

develop a set of jointly owned outcome measures to drive action across a broader range of local services.'

3. *Expand on the two overarching aims of the 2010 strategy: to reduce illicit drug use and increase the rate of individuals recovering from their dependence'*

Recent drug strategy in England makes consultation with peers a requirement in treatment providers' decision-making processes and explicitly references the important role peers can have in designing, implementing and reviewing drug and alcohol treatment systems [43]. The UK strategy describes peer support as 'an essential component of successful recovery', emphasising its importance throughout the recovery journey in enhancing treatment engagement and outcomes in addition to reducing stigma. An aspect of PHE's avowed recognition of PBRSS is their intention to explore digital support services in the form of online forums and mandate that community services must develop in line with peer involvement.

Similar to the English endorsement of recovery policy, Scotland's 2008 Road to Recovery and its refresh 'Rights, Respect and Recovery' [95] represented a shift in treatment monitoring in which services were to focus on producing measurable recovery outcomes. In Scotland, the Road to Recovery strategy established the Scottish Recovery Consortium to coordinate services, individuals and communities under a common aim whilst ensuring experiential expertise remains focal in-service design, implementation and in policy and public advocacy and representation. The SRC has an explicit strength-based focus on the benefits recovery brings to society as opposed to the previously dominant narrative of the destructive effects of addiction. Scotland's 2018 Rights, Respect and Recovery was developed in consultation with peers, and acknowledges the nation's flourishing peer recovery groups and communities. Furthermore, the strategy devotes a chapter to 'developing recovery-oriented systems of care', which presents peer involvement as a human rights-based approach to be implemented through advocacy services promoting participation, equality, empowerment and accountability via peer champions and navigators.

There has been a more recent transition towards recovery-informed policy in Belgium and the Netherlands. In the Netherlands, recovery policies have historically been formulated locally and from the grass roots movements in the absence of national or state policy. Recovery was not explicitly mentioned in national policy until 2010 when a charter was formulated in agreement with 15 professional specialist treatment organisations, wherein it was agreed that quality of life and societal reintegration ought to be the focal principle of recovery interventions [72].

Belgium's recovery strategy comprises a 2016 concept paper which delineates recovery to entail *'strengths-based support, client participation and input, quality of life, social recovery, and attention to different life domains'* [9].

Bellaert et al. [9] contend that this communitarisation is impeding the implementation of parallel mental health and addiction recovery strategies in Belgium due to the division of funding sources, commissioning and implementation bodies, an obstacle the authors suggest may be resolved through bridging between authorities and systems.

The impact of national and policy variations on recovery pathways is currently subject to research investigation in the Recovery Pathways (RECPATH) study in England, Scotland, the Netherlands and Belgium and is an exploration of recovery pathways by gender [14]. The study has a focus on gender differences in recovery pathways and has used the Life in Recovery method ([30]; Best et al. 2015) to screen for recovery stages and to identify candidate mechanisms for recovery. This builds on work by Kelly [55] on mechanisms for behaviour change in Alcoholics Anonymous (AA). Kelly argues that social-network change (along with cognitive transformations) is critical in male recovery, but that increases in abstinence self-

efficacy was the primary mechanism of behaviour change brought about by attendance at the 12-step mutual aid groups for women.

This is crucial in developing a plausible science of recovery in which mechanisms of change can be linked to predictors to increase our understanding of life-course changes. The developing evidence base around recovery capital (summarised by [40]) UK–US research collaborations have been central in developing two key measurement instruments – the Assessment of Recovery Capital [38] and, more recently, the REC-CAP [18]. In both of the underpinning studies, there is evidence supporting a strength-based approach to building resources that are predicated on engaging in prosocial networks and the resulting engagement in meaningful activities.

The UK recovery research model has, consequently, focused on social catalysts for recovery, including the Social Identity Model of Recovery [13] and the Social Identity Model of Cessation Management [32]. In each of these approaches, recovery is seen as resulting from changes in social networks (from using to recovery focused), resulting in shifts in belonging and connected changes in attitudes, values and beliefs.

Much of this work links to a mental health approach to recovery-oriented interventions that is based on a review of the evidence by Leamy et al. [66] that concluded that effective recovery interventions required five change mechanisms – they had to generate positive Connections; they had to inspire Hope; they had to offer positive changes in Identity; they had to support linking people into Meaningful activities; and they had to create Empowerment, summarised in the acronym CHIME. This model has been adapted for the addiction recovery space by Best et al. [15], who has argued that assertive linkage into prosocial groups has the potential to generate the sense of hope that recovery is possible. In this model, hope is seen as the key driver of a dynamic engine in which a virtuous circle of meaningful activity generates a positive sense of identify and growing self-esteem that further perpetuates the cycle of change and recovery growth.

50.12 Conclusion

Whilst there is a growing evidence base around personal recovery pathways and journeys and an increasingly credible evidence base, driven largely by US research, two other key themes are emerging. The first is that recovery models and methods are increasingly influencing policy and practice not only outside of the United States but in the non-English speaking parts of Europe. Secondly, there is a growing awareness that recovery is not a solipsistic activity and that effective recovery models (including policies) require a social and community framing and an improved evidence base around what constitutes an effective and integrated recovery-oriented model of care.

51 Strategies of Drug Prevention in the Workplace: An International Perspective of Drug Testing and Employee Assistance Programs

David E. Smith, Lisa Marzilli, and Leigh Dickerson Davidson

Contents

Abstract

Drug testing in the workplace is not universal and is regulated by various governmental agencies at the federal, state, and municipal levels, as well as by select industries. Safety-sensitive occupations are typically targeted and various industries and agencies have specific drug testing protocols. In the United States, drug testing is highly structured and much of it falls under the purview of a Presidential Executive Order issued in 1986, with subsequent legislation calling for a drug-free workplace. An assigned Medical Review Officer (MRO) resolves any questionable results, be it a false-negative or false-positive drug test report.

In the European Union and other countries, drug testing is much less uniform, as attitudes to workplace alcohol and drug use are quite variable with no "standard approach." While the use of illicit drugs spurred widespread drug testing in the United States, prescribed medications that may impact workplace safety

have become a controversial issue and have not been fully addressed. Many companies establish Employee Assistance Programs (EAPs) that are designed to help employees deal with life issues, including work–life stressors, family issues, financial concerns, relationship challenges, productivity issues, and concerns of substance use and abuse. Various services are provided to the employee, largely free of charge, relating to substance misuse and its effect on job performance. While the effectiveness of US programs is easier to assess due to consistency in approach, the variability of European programs makes them more difficult to evaluate.

Addiction · Drug testing · Employee Assistance Programs · Medical Review Officer · Substance abuse · Workplace safety

51.1 Introduction

The majority of people using alcohol and other drugs, both legal, such as prescription medications, and illicit, are employed.

Substance misuse in the workplace is a major public health and economic issue, as the majority of substance misusers are employed. Substance use disorder (SUD), including alcohol use, is associated with increased accidents, absenteeism, and health costs. Therefore, modern concepts of drug use prevention, including drug testing, apply to the workplace and, when effected, produce benefits for both the employee and the employer.

As defined by DuPont [10], drug use prevention can be divided into three levels:

1. The primary strategy is aimed at preventing any illegal drug use. Drug use laws vary from country to country, so a broader concept relates to preventing use that produces impairment and threatens safety. Experts such as DuPont stress that any drug use by youth when the brain is still developing can be problematic, and a drug-free workplace can be a motivating factor for youth to avoid drug use.
2. Secondary prevention focuses on reducing the consequences of illicit drug use, such as workplace accidents and health costs for chronic diseases, for example, hepatitis and heart disease.
3. Tertiary prevention focuses on the individual who has a defined addictive disorder that requires treatment. With the passage of the Affordable Care Act in the United States, substance abuse is viewed as a medical issue that requires treatment before the individual can return to duty. If cleared, these individuals are protected by the Americans with Disabilities Act of 1990 (ADA) as long as they maintain their recovery in an appropriate monitoring system.

The secondary and tertiary levels of prevention are applicable to the workplace to reduce injury, accidents, and medical complications; all of which are costly to the employer and damaging to the worker. Different reduction strategies are used for each level, with drug testing and Employee Assistance Programs considered essential.

Most substance misuse in the workplace falls into one of the following areas: desired improvement in performance/productivity, relief of boredom, alleviation of physical and/or psychological pain/discomfort, addiction, or self-medication to relieve the side effects (e.g., hangovers, anxiety, etc.) of alcohol and other drugs. Substances ranging from opioids to stimulants may be used, depending on the user's objectives and preferences [25].

Drug-facilitated work impairment may not be noticeable or significant in ordinary situations. Emergencies, however, or unexpected demands on the worker, may precipitate unfortunate consequences. In addition, preoccupation with issues resulting from the worker's substance misuse, such as family arguments or contemplation of procuring more drugs, may reduce the worker's attentiveness to the requirements of

the job. The employer may also be impacted by the worker's theft or misuse of company resources to obtain additional drugs, absenteeism, turnover, violation of governmental guidelines for a drug-free workplace, or adverse publicity [25].

Cannabis use, particularly its principal psychoactive ingredient delta-9-tetrahydrocannabinol (THC), has been associated with negative health outcomes, including cannabinoid-induced hyperemesis and cannabis-induced psychosis. Cannabis use is associated with drugged driving and increased risk of accidents. This is relevant to the workplace as a majority of workers drive as part of their employment [14].

Cognitive risks have also been associated with chronic cannabis use, including impaired learning and executive function. High potency THC compounds have been associated with greater psychiatric and neurological risks, including diminution of gray matter, particularly in adolescent early onset users whose brains are still maturing.

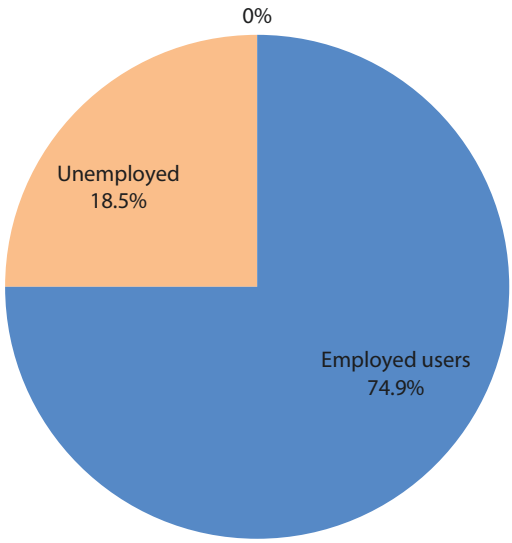
51.2 Drug Prevention in the Workplace

In the United States, drug testing to promote workplace safety and deter drug use is regulated by various governmental agencies at the federal, state, and municipal levels. And some employers' insurance carriers require specific drug testing programs. Different protocols exist for various industries and agencies; however, certain elements are consistent. Some companies require testing of every employee, others require preemployment testing only, and still others require periodic testing for employees holding safety-sensitive positions. Particularly after an accident, most employers require testing for potential drug or alcohol use. With the legalization of medical and recreational marijuana in many states, this has created another layer of complexity. The consequences of verifiable illicit drug/alcohol use in the workplace range from disciplinary action, referral to treatment, suspension, or employment termination.

The era of drug use prevention (other than alcohol) in the workplace began in the United States in the 1980s with the establishment of the Drug-Free Workplace Program**,** Executive Order #12564 [12]. This paralleled the drug epidemic permeating industrial settings and contributed to several highly publicized fatal accidents in which several employees tested positive for marijuana. As a result, in 1986 the US Federal Government issued Executive Order #12564:

> The Federal Government, as the largest employer in the nation, can and should show the way towards achieving drug-free workplaces through a program designed to offer drug users a helping hand and, at the same time, demonstrating to drug users and potential drug users that drugs will not be tolerated in the Federal workplace….

The Executive Order mandated that most Federal agencies, under the purview of the Executive Department, required the following: employees must refrain from illicit drug use, agencies implement and develop Employee Assistance Programs (EAPs), and they establish standard drug testing policies and procedures. The focus of the drug-free workplace was to eliminate illicit drug use of heroin, cocaine, amphetamines, marijuana, and 1, 1-phenylcyclohexyl (PCP). This panel became known as the National Institute on Drug Abuse-5 (NIDA-5). However, because alcohol was and is the primary drug problem in the industrial setting, both in the United States and worldwide, the Omnibus Transportation Employee Testing Act of 1991 included alcohol. According to the Division of Workplace Programs of the Substance Abuse and Mental Health Services Administration (SAMHSA) in the United States, the majority of active illicit drug/alcohol users are employed full-time and constitute two-thirds or more of the adult population [15]. The 2013 SAMHSA National Survey on Drug Use and Health reported that 68.9% of the estimated 22.4 million illicit drug users, age 18 or older, were employed full or part-time, while upward of 75% of adult binge and heavy alcohol drinkers were employed [24]. And in 2018, the number of users that were employed full-time rose to nearly 75% [7, 14].



The majority of current drug users are employed (current users of illicit drugs, ages 18 and over). (Source: National Survey on Drug Use and Health: National Findings)

While illicit drugs were the main impetus for establishing the drug-free workplace regulation in the 1980s in the United States, prescribed medications, especially opioids, became a growing issue, ravaging all regions of the United States. The resulting restrictions on prescribed opioids beginning in 2016 and becoming even more stringent in 2018 have created a shift to the utilization of heroin, illicit fentanyl, and other synthetic opioids (Centers for Disease Control). In 2017, the Centers for Disease Control (CDC) reported that over 70,200 drug overdose deaths involved opioids, and the primary driver was attributed to synthetic opioids (illicit fentanyl and analogues). Unintentional overdoses in the US workplace due to nonmedical use of drugs and alcohol increased over 25% each year from 2012 to 2017. The challenges employers face in this climate have resulted in far-reaching consequences beyond the scope of this chapter. It is worth noting that on January 1, 2018, the Federal Department of Transportation (DOT) added four additional drugs for screening: hydrocodone, hydromorphone, oxycodone, and oxymorphone.

US legislation established the designation of "Medical Review Officer" (MRO) [3, 20] in the 1980s specifically for the evaluation of "questionable" drug test results. A limited number of professional organizations offer courses to provide clinical training in the review and analysis of drug test results and a formal certification of MRO. The Medical Review Officer Certification Council (MROCC) promotes and preserves the highest quality of standards among MROs and their team members by setting standards, defining MRO competencies, promoting a Code of Ethics, offering certification examinations, and providing publications and educational activities. The role of the MRO in assessing safety in the workplace with prescribed medications, specifically opioids, continues to be extremely challenging.

Many companies that operate internationally have established EAPs designed to help them address safety and productivity issues by providing various services to behaviorally effected employees in order to alleviate and resolve issues interfering with their job performance. The Employee Assistance Professionals Association lists several national and regional EAP associations and organizations at www.EAPASSN.org.

51.3 Drug Testing in the United States Workplace

Workplace drug testing in the United States is highly structured and is intended to foster workplace safety standards and creates a healthy work environment [2, 6]. Tests are generally administered in a nonmedical setting, where body fluids, most commonly urine, are collected and analyzed. The sample passes through a rigorous and well-documented "chain of custody" process. The frequency, type, and drugs tested for typically depend on the industry and various government regulatory agencies involved. Companies

and organizations with US government contracts must be compliant with regulations regarding drug use in the workplace.

Drug testing is most common in settings where employees perform hazardous or safety-related tasks: such as operation of heavy equipment; transportation of passengers, medical, and surgical procedures; operation of nuclear power plants, public safety, and law enforcement. Every branch of the military has a specific program for drug testing of its service members.

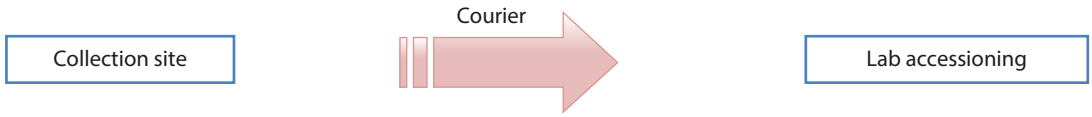
There are several instances that will initiate an order for a drug test. Some of these include preemployment, after an accident/incident, impaired performance on the job, observed use of drugs or alcohol, random assignment, voluntary, follow-up to treatment, and return to work. Continued monitoring and random drug testing may be instituted as part of an employee's recovery plan and often in conjunction with a medical professional.

Interpreting drug test results is more nuanced than a simple "positive" or "negative" if a valid result is to be obtained. Individuals may test positive if they are prescribed an opioid pain medication, for example. If a specimen is compromised or adulterated, either intentionally or inadvertently, an erroneous result report is likely to occur. For this reason, it is advisable that a qualified MRO be available to certify the results obtained. It must be noted that while MRO protocols are quite rigorous to assess sample adulteration, Internet search engines and individual initiative offer an ever-growing abundance of information on specimen tampering. Laboratories provide testing for validity markers (i.e., temperature, pH, and specific gravity) in order to assess for adulteration.

Medically prescribed drugs do not necessarily result in impairment or risk of accident on the job. Therefore, the focus in the United States as it relates to drug testing has been on substance use prevention and education. New synthetic drugs (e.g., synthetic cannabinoids, synthetic stimulants, etc.) that are continually emerging are not included on a standard drug test and pose a challenge to employers.

Random drug testing is mandated by many regulatory agencies in order to accurately assess whether or not an employee is using alcohol or illicit drugs. Employee identifications are typically generated in a random fashion, and the employee must report for a drug test within 24–48 hours at a location determined by the employer. After the specimen is collected, it may be analyzed on site immediately or may be shipped via overnight express to a centralized laboratory. Samples are usually "split" in the event there is a need to repeat and further analyze the specimen. For example, an employee may dispute the result at which time the MRO would intervene and review the results report or potentially request a retest in order to validate the findings.

Though specimen testing is largely via urine sample, other testing matrices may be utilized, such as blood, saliva, and hair. Regardless of the specimen collected, all must follow a rigorous protocol in order to balance the following: the employee's right to privacy, monitoring for specimen tampering, adherence to the process in the "chain of custody," and ensuring a valid and secure results report.

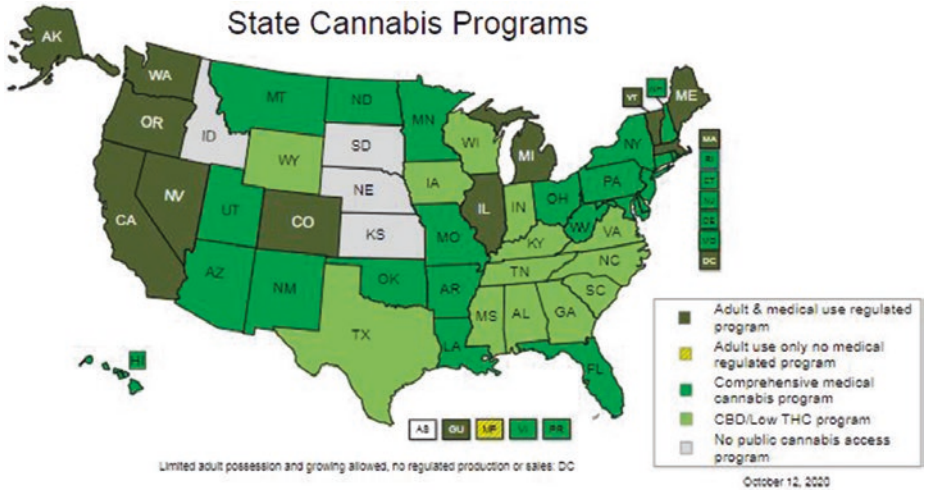


Components of specimen collection

- Employee's right to privacy
- Chain of custody
- Federal custody and control form (CCF)
- Integrity, security, and identification
- Temperature recording
- Tamper-evident bottle seal

Employees testing "positive" with an unexpected result are sometimes suspended from work until the results are reviewed and verified by the MRO. The specimen integrity, chain of command, potential shipping delay, or ambiguous result may require further investigation. Assessing the employee's use of over-the-counter (OTC) medications is also critical, as some of these products interfere with the laboratory testing, causing a false-positive result. In this case, the MRO must carefully review, assess, and interpret the results report for further clarification. Depending on the sensitivity and specificity of the drug testing methodology, foodstuffs like poppy seeds may also generate a false-positive result for opiates. For this reason, workplace testing in the United States has established cutoff levels for opiates above the levels generally triggered by poppy seed ingestion.

Similarly, a policy to raise the marijuana cutoff level has been instituted to address the issue of second-hand smoke or "passive inhalation" when in the presence of an individual smoking marijuana. However, with the legalization of medical and recreational marijuana in many states across the United States, many challenges continue to manifest. State laws and employer policies are highly variable, and the issue of impairment on the job must be addressed. That said, the DOT has not waivered or modified their drug testing program, even though the Department of Justice (DOJ) has issued guidelines for prosecutors in states that have enacted laws authorizing the use of medical or recreational marijuana. Currently, MROs are prohibited from verifying a DOT drug test as "negative" based upon a physician recommending an employee use of "medical marijuana." For more detailed information on this topic, visit the US Department of Transportation website for the full manuscript and current ruling posted 2019 (USDOT/documents/medical-marijuana.pdf).



Current state. Approved Marijuana status, August 2018. (Source: DEA)

While federal mandates for safety-sensitive jobs are clearly defined, the decision-making for private employers is extremely challenging as it relates to marijuana use. And according to the National Safety Council Report (February 2019 [19]), roughly 15 million employed individuals are struggling with some degree of substance misuse disorder. The top two substances are alcohol and cannabis, followed by opioid pain medications, benzodiazepines, and many other illicit drugs.

With the October 2018 legalization of cannabis in Canada, the Occupational and Environmental Medical Association of Canada (OEMAC) issued a position statement in September 2018 stating that "current evidence indicates cannabis is the most commonly encountered agent in workplace drug testing in Canada and, second to alcohol, the most prevalent substance implicated in driving under the influence." The document concludes that use of cannabis can lead to impairment, that motor vehicle or equipment operation is not advisable, that workplace drug and alcohol policies be updated, and that additional research and education are needed [21].

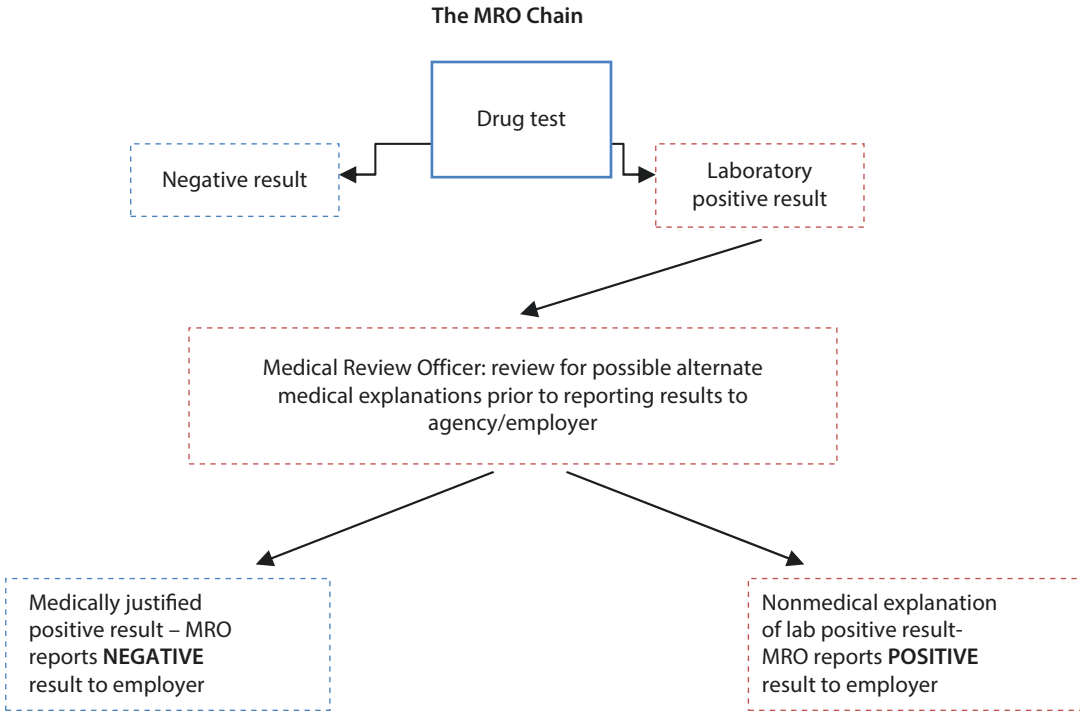
Some US states, including California, Massachusetts, and Nevada, have seen double-digit increases in the number of employees who test positive for marijuana. The complexity of this changing landscape has forced several private companies (in several states that have legalized medical and recreational cannabis use) to drop marijuana from their drug testing profile [13, 23].

Another significant challenge that is not captured by the NIDA-5 testing panel is the ever-growing issue of "designer drugs," now globally referred to as novel psychoactive substances (NPS). In 2008, synthetic cannabinoids (e.g., K2, spice, etc.) and synthetic stimulants were just emerging in the United States. Continued modification of these substances and creations of new products (e.g., illicit fentanyl and other synthetic opioids) have made it nearly impossible for a basic drug test to detect use [18]. Impairment on the job without the objective evidence from a drug test has created yet another dilemma for MRO recommendations and employer risks.

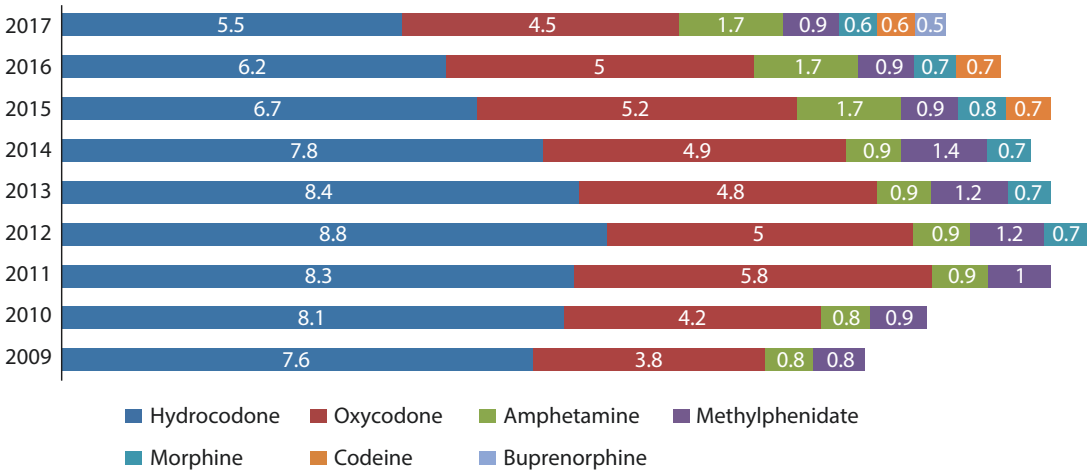
Over the last 5 years beginning in 2014, illicit fentanyl and fentanyl analogues have created severe risks in health-hazard exposure. The National Institute for Occupational Safety and Health's (NIOSH) 2018 guidance is available for reference, providing an in-depth review on preventing occupational exposure to these potentially lethal products [13].

Nonetheless, drug testing remains crucial for effective identification, intervention, and monitoring in the workplace. This medical test produces a results report that provides objective data that may be used for nullification purposes and also provides a platform to monitor effectiveness of treatment after an SUD has been diagnosed in the individual. The MRO designation was partly established so employees would not be denied necessary prescribed medications in overzealous attempts to extinguish illicit drug use.

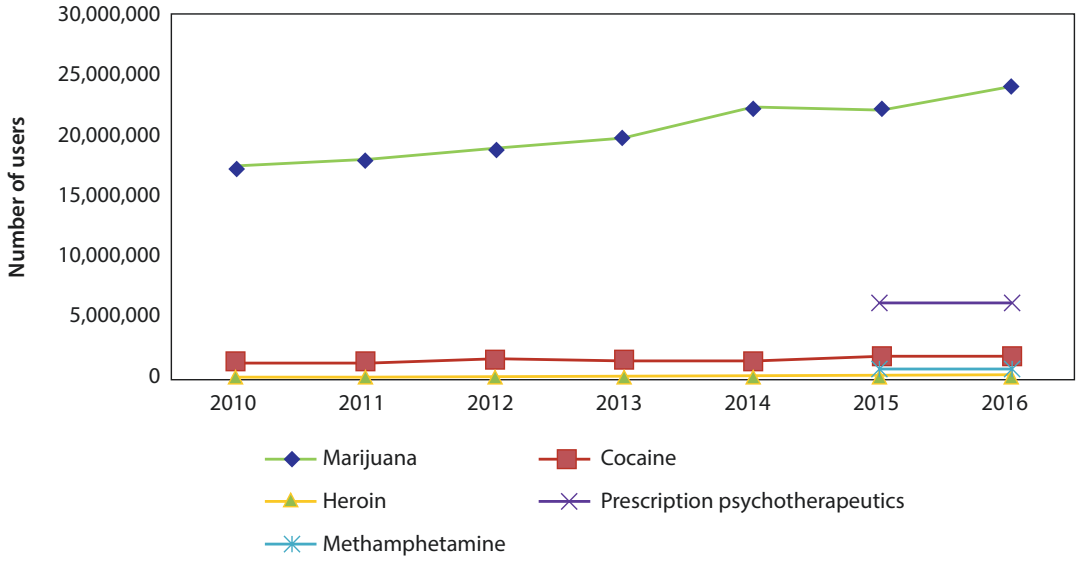
The following graphic illustrates the MRO decision tree and laboratory analysis:



The MRO chain



Top controlled prescription drugs sold to domestic retail level purchasers in billions of dosage units, 2009–2017. (Source: Automation of Reports and Consolidated Orders Systems, DEA)



Number of past month, nonmedical users of psychotherapeutic drugs compared to other select drugs of abuse, 2010–2016. (Source: Substance Abuse and Mental Health Services Administration, National Survey on Drug Use and Health)

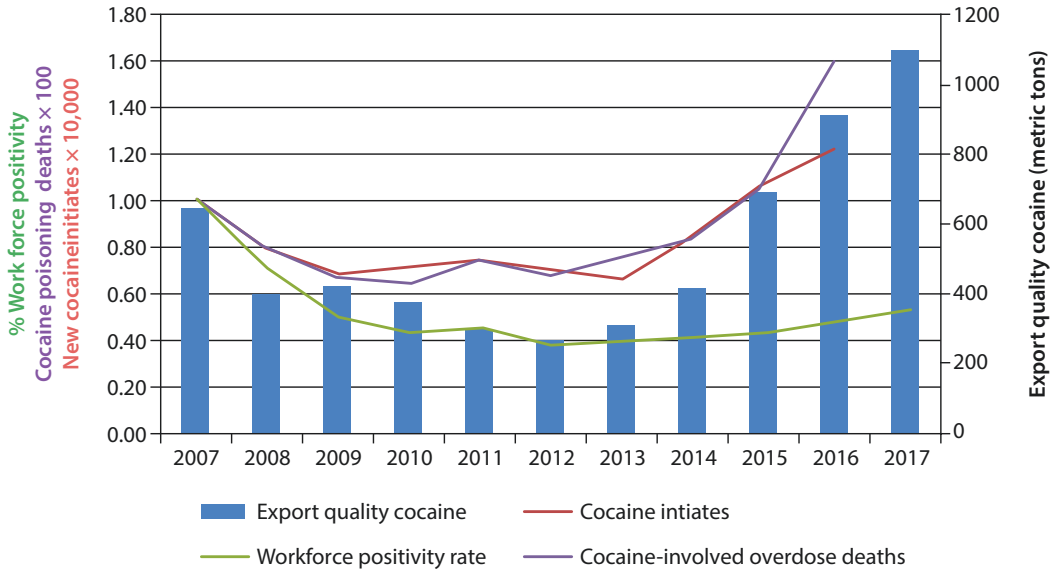
Though opioid-prescribing regulations and restrictions continue to tighten in the United States, they remain an issue for employees that use pain medications appropriately (with a valid physician prescription). Differentiating between appropriate use, misuse, abuse, addiction, and drug diversion in the workplace is crucial so that legitimate pain management is not confused with inappropriate use that results in negative health consequences and/or safety risks in the workplace. In these circumstances, when an employee's drug test indicates a "positive" opioid detection, the MRO must notify the employee and request a copy of the physician's prescription, to include a clinical diagnosis for treatment. Typically, the MRO will instruct the employee to cease work and immediately report to the supervisor. If the employee supplies the information to support medication use, the MRO will review the documents and notify the employer that the individual is medically cleared to return to work as long as no documented issues with performance or behavior have been observed.

Opioids, even when used for appropriate pain management, may potentially lead to workplace accidents, performance problems, and other medical, psychological, and behavioral problems. Side effects associated with opioid treatment include drowsiness, inattentiveness, impaired judgment, poor hand/eye coordination, tolerance and dose escalation, physical dependence, loss of function, perception of emotional pain as physical pain, and hyperalgesia (continual increases in dosage resulting in escalation of pain and the perception of pain).

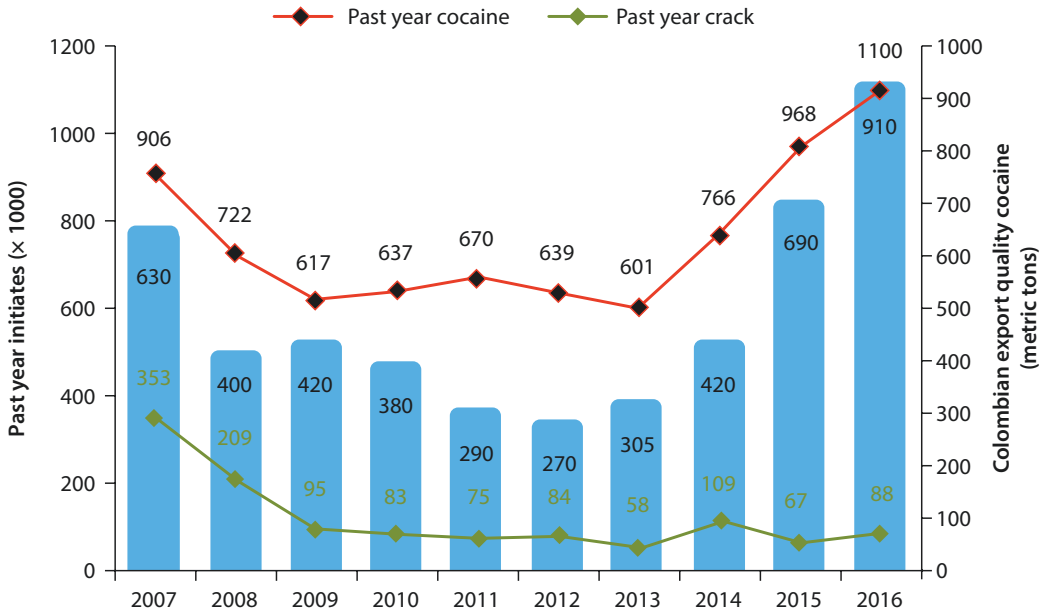
To date, there continues to be an issue of establishing set protocols for appropriate use of prescription medications as it relates to proper assessment of workplace performance. An individual's right to privacy is a significant factor. In the United States, the Americans with Disabilities Act (ADA) became law in 1990 to prohibit discrimination against individuals suffering from a disability in the workplace, schools, transportation, and all public and private areas that are open to the general public [17]. Several amendments to the civil rights law have been made over the years to guarantee civil rights protection for both public and private employers (more than 15 employees). Two recent settlements serve as a reminder that employers must be prudent when assessing cases that involve employees prescribed medication use and their ability to perform job duties.

MRO courses such as those presented by the Medical Review Officer Certification Council

(MROCC) provide clinical training on opioid medications and the potential of negative consequences such as intoxication, addiction, and overdose, as well as information on several other medications and substances of abuse, including stimulants like amphetamine, methamphetamine, and cocaine that are widely used and misused in the workplace. The latest Federal DEA data published in 2018 reports a significant escalation of coca production, cocaine trafficking, and imports have reached an all-time high in the United States [26]. As supply rises and prices fall, access and use increase [18].

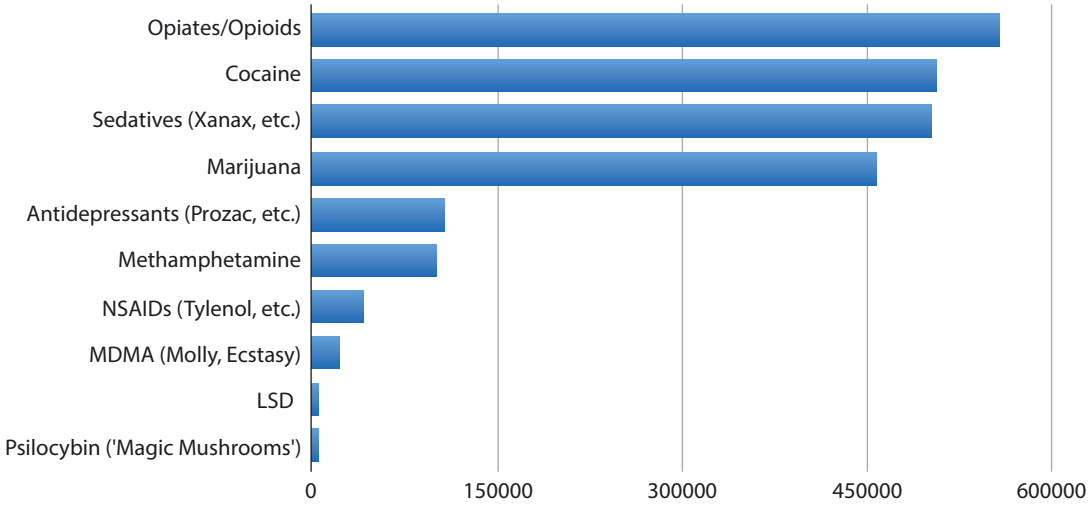


U.S. cocaine indicators and Colombia export quality cocaine production, based on 2007 value, 2007–2017. (Source: DEA National Forensic Laboratory Information System, August 2017)



Past year cocaine initiates and export quality cocaine production. (Source: National Survey on Drug Use and Health and United States Government)

By definition in the Diagnostic and Statistical Manual of Mental Disorder's fifth Edition (DSM-V), SUD can affect workplace functioning due to dependence, abuse, intoxication, delirium, withdrawal, induction of psychotic disorder with hallucination or delusions, induced mood disorder, and many other negative consequences. And there are many adverse events that may require immediate medical attention whether or not the substance is legal (such as alcohol), prescribed by a physician, or obtained illegally. This potential for an adverse drug reaction is further heightened when multiple drugs/substances are ingested.



Emergency Department Admissions (2011). (Source: DEA.org)

51.4 Alcohol Testing

The relationship between blood alcohol concentration (BAC) and accident risk is well established. The US National Transportation Safety Board (NTSB) is currently campaigning to reduce the BAC limits for all drivers.

For other substances like opioids and amphetamines, discerning impairment and accident risk is not well defined and can be extremely challenging for an MRO to assess. Even in cases where an employee has a legitimate prescription and qualifying diagnosis, dosage and impairment are not linear and clearly defined, as is the case with alcohol consumption.

Levels of alcohol intoxication

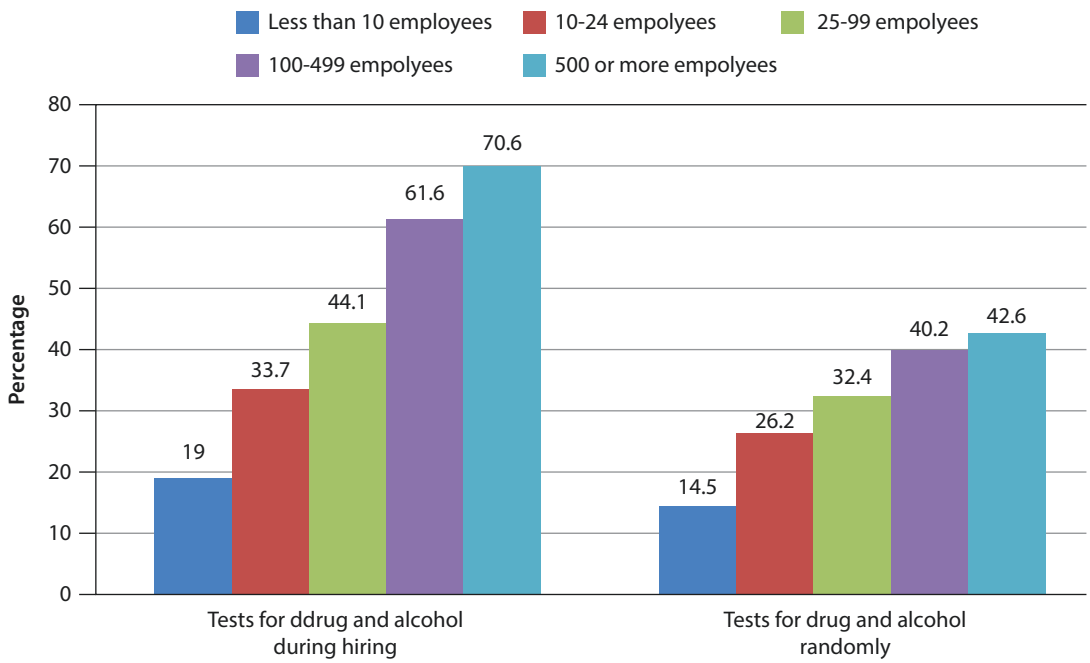
Blood alcohol concentration (BAC)	Percent of drivers too intoxicated to drive	Increased risk of accident
0.02% Restraint/ awareness	5%	^1
0.04% Comprehension	15%	1×
0.06% Judgment	35%	2×
0.08% Muscle control	65%	4×
0.10% Coordination	100%	8×
0.20% Equilibrium/ sleep		65×
0.30% Stupor		600×
0.40% Coma		
0.50% Death		

Because alcohol is rapidly metabolized, it is detectable only for approximately 6–8 hours when utilizing urine as the medium for drug testing. However, alcohol metabolites are present in the urine for up to 72 hours as ethyl glucuronide (EtG) and ethyl sulfate (EtS). The standard NIDA-5 does not include tests for these metabolites. In the event the MRO deems necessary, tests for EtG and EtS are available.

Identification of SUD in the workplace requires appropriate training and professional evaluation. As emphasized by Dr. Wesley H. Clark, former Director of the Center for Substance Abuse Treatment (CSAT) and faculty member of the now-discontinued ASAM MRO course, a positive toxicology report or an adverse drug reaction does not necessarily indicate substance misuse, abuse, or a diagnosis of SUD. Research has indicated there is a spectrum of substance use ranging from "I Like….I Want….I NEED." The DSM-V defines addiction as disease resulting in a pathological state with characteristic signs and symptoms.

Over time, morphological changes in the brain progress and impair rational thinking and decision-making. Predictable and often catastrophic consequences result when SUD is left untreated. It is characterized by the compulsive desire for the substance (or behavior known as *process* addiction), a loss of control when exposed, and continued use despite negative consequences. Though many individuals use alcohol and other substances and engage in unhealthy behaviors in the workplace, it is worth stating that only approximately 10% of those exposed actually progress to a diagnosis of SUD and require intensive treatment before returning to work.

Drug testing in the workplace is an essential component of a comprehensive workplace program. It provides objective evidence to accurately assess alcohol and drug consumption. Unfortunately, implementation in US industry is quite variable.



Type of drug and alcohol testing program, age 18–64. (Source: Worker Substance Use and Workplace Policies and Programs, 2007 NSDUH)

Treatment for SUD will assist those afflicted personally and professionally and foster a healthy workplace environment. Studies prepared by the Division of Workplace Programs of SAMHSA have shown that individuals' physical and mental health improve significantly during and after treatment, resulting in a major reduction in health care utilization. Recognizing that SUD is a disease has benefits for the employer when the employee is referred to treatment and is willing to accept and engage the process. If the employee successfully completes initial treatment, the employer is able to retain a trained, experienced employee and eliminate the cost of recruiting and training a new employee. And with continued treatment and monitoring, the employee provides a positive example for other fellow employees who may be suffering in silence.

51.5 Drug Testing in the European Workplace

In Europe and other countries, drug testing in the workplace is far less standardized and much more controversial than the United States. Varied social norms and cultural trends must be balanced with the need for safety in the workplace. National legislation varies widely in terms of the following: the employees' rights and obligations for being subject to testing, the conditions under which testing takes place, whether specimen collection is "observed," processed, and transported. Many other challenges exist when legislation and protocols are not clearly defined, for example, the need and availability of a qualified individual to interpret drug test results and the process of how these results are communicated to employer and employee. Further complicating the matter is that amounts of allowable intake of alcohol and other substances in the workplace setting vary widely.

Without consistent regulations and policies, it is difficult to create a standardized drug use prevention in the workplace program in Europe (and other countries), although efforts are underway to address this gap. Some countries have no specialized programs, while others have limited programs, but attitudes are beginning to change. In fact, the UK and several Scandinavian countries have developed comprehensive workplace drug testing policies and programs. Corral, Duran, and Isusi [9] examined the types of regulations in place

across a wide swath of the European countries in their report, "Use of Alcohol and Drugs at the Workplace," for the European Foundation for the Improvement of Living and Working Conditions (Eurofound). As in the United States, drug testing is mandated by a variety of governmental regulatory agencies and industries, but in many of these countries, employees have a much "louder voice" than is acceptable in the United States.

A sampling of study results cited in the European Foundation for the Improvement of Living and Working Conditions [11] document are listed below:

(a) There is a cultural tolerance of alcohol use (and sometimes other substances) in the workplace that varies from country to country. This approach is diametrically opposed to the United States where the model is a zero-tolerance policy.
(b) A majority of employers and employees do not agree with the use of alcohol and drugs in the workplace; however, cultural views on alcohol consumption and various substances are less rigid than the United States, so protocols for implementing policies are quite difficult to enforce and are highly variable.
(c) The cultural stance on alcohol and drug use in the workplace has grown more conservative over the years and has been addressed in a variety of studies. The Swedish Construction Federation reported that it was no longer socially acceptable to consume drugs in the workplace, a stark contrast to attitudes in the construction industry 40 years prior.
(d) In Portugal, there has been a growing awareness of the consequences of alcohol and drug use in the workplace. In early 2010, 90% of Portuguese enterprises had concerns related to employees' general health problems, increased incidence of sick leave and short-term absenteeism, reduced performance levels, labor conflicts, and an unsettled work environment.
(e) One Italian study reported that employees addicted to drugs/alcohol had more than double the rate of absenteeism compared to employees that did not use these substances [16].
(f) In Austria, alcohol-dependent employees took sick leave 16 times more frequently and reported "feeling sick" 2.5 times more often than those employees who were not alcohol dependent.

Other European studies investigating the use of alcohol and drugs in the workplace demonstrated that their use negatively impacted work performance, attitude, and morale and contributed to workplace accidents resulting in harm to a fellow employee. A 2008 Latvian report indicated that there were substantial economic losses and a damaged public image when accidents occurred in the workplace. As community members continued to discuss these incidences, the employer's reputation declined.

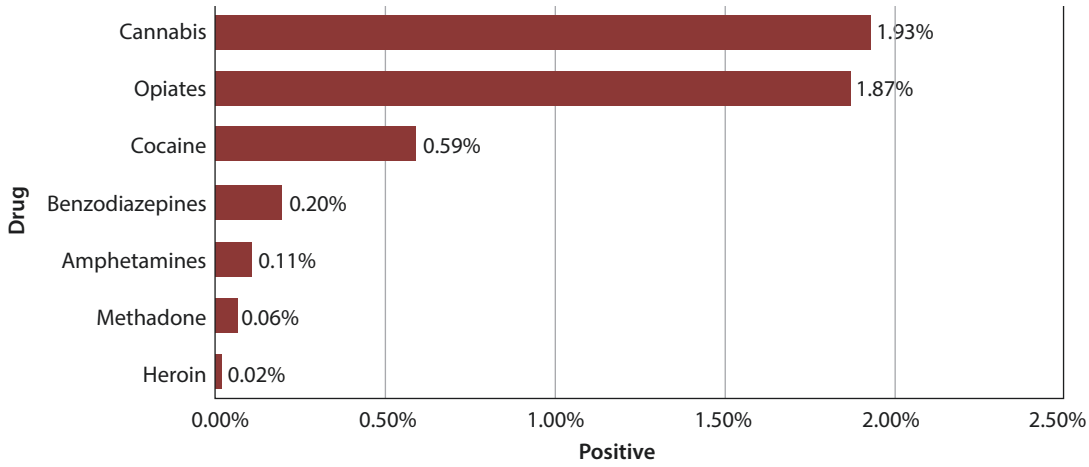
Other studies and reports have documented significant economic costs of substance misuse in the workplace. In Norway, alcohol-related illness accounted for substantial financial losses in millions of euros. And in the early 2010 period, Austrian alcohol use accounted for 1.5–2.5% of total payroll costs. The Austrian Federal Economic Chamber (*Wirtschaftskammer Osterreich*, www.wko.at) stated in this same era that a worker with alcohol and drug problems performed at roughly 75% of potential. Considering this information and more gathered since that time, European employers are closely examining the need for a new approach to strictly limit the use of alcohol and other substances in the workplace.

Unfortunately, there is often a delayed recognition of an employees' excessive consumption of alcohol/other drugs in the workplace. A German study indicated the delayed response time was nearly 10 years for men and 2–5 years for women. And more often than not, at this point, the employee was terminated. In contrast, the approach in the United States for first-time offenders is a strategy of intervention, treatment, continued monitoring, and reintegration into the workplace.

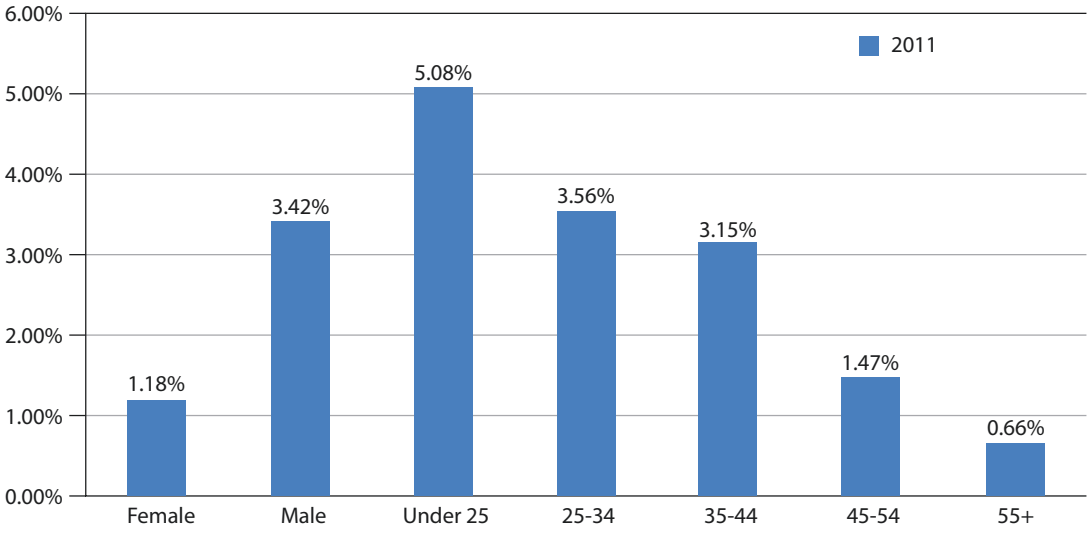
The European Workplace Drug Testing Society (www.EWDTS.org) works to examine issues relating to workplace drug testing and organizes annual conferences, providing an opportunity for all stakeholders to share ideas

and discuss best-practice approaches. EWDTS' mission statement is in part "….to ensure that drug testing in Europe is performed in a standard and legal manner…." The website provides brief summaries of workplace drug testing in various countries [27].

Though there is no centralized statistical information source in Europe and surrounding countries, the European Monitoring Centre for Drugs and Drug Addiction [4] reported that cocaine consumption was second to cannabis. A slightly different conclusion on drug prevalence in the UK workplace by drug testing provider Concateno [8] reported cannabis was the most frequently consumed, closely followed by opioids. The report also discussed the fact that patterns of drug use change with age. For instance, cannabis use appears to decrease with age, while the use of opioids increases. Amphetamines, methamphetamine, and the stimulant class as a whole have been and continue to be a growing problem.



UK drug prevalence within the workplace 2007–2011



UK workplace drug prevalence demographic for 2011

In France, the National Research and Safety Institute for the Prevention of Occupational Accidents and Diseases in the workplace has a program to train employers and supervisors to identify employees of concern and assist them in actionable plan forward. The German Centre for Addiction Issues commissioned an expert report on the practice of company-based drug prevention, and in 2006, it was debuted by policy makers, health insurers, and other social partners.

Several European nations have recognized that alcohol and drug use represents a severe problem for a significant percentage of the working population. National estimates indicate that 5–20% of workers are impaired by substance use, and particular work settings such as construction, transportation, and farming are at greater risk. Alcohol and drug consumption in the workplace often results in negative consequences such as a higher incidence of sick leave, reduced productivity, impaired performance, and avoidable accidents. Because the United States has more consistent national polices in workplace testing, comprehensive data is available to assess interventions, rehabilitation, and workplace reentry. Unfortunately, this type of information is lacking in the European countries.

Most European countries have some general legislation and agreements in place to prohibit or regulate the consumption of alcohol and other substances in the workplace, but there is considerable diversity regarding implementation and legal enforcement. In Germany, Belgium, and Denmark, "collective social agreements" are implemented in lieu of pure coercive measures. Until national labor codes and statutes are collectively agreed upon, many interventions are loosely labeled as "disciplinary," and corrective actions are taken to merely limit the use of alcohol and drugs in the workplace. However, companies that operate in multiple nations are forced to institute more formal drug-prevention and drug-interventional policies. International airlines and shipping firms illustrate this example.

European studies appear to place more emphasis on work-related reasons for alcohol and substance use, including strenuous physical work, poor working conditions, low job satisfaction, personal issues, relationship challenges, and lack of recognition of employees' rights. The intention appears to focus on what leads to substance use rather than flatly banning use and consumption in the workplace. Additionally, European cultures generally have a more tolerant view of alcohol use during the workday. Until the 1970s, this sentiment was more pervasive in the United States, and it was not unusual for a businessmen of the time to engage in a "three-martini lunch." But for the past several decades, the emphasis in the United States is for a drug-free workplace and zero-tolerance policy. Several recent reports indicate that European nations are changing their views and positions on alcohol/drug consumption in the workplace. As the economy globalizes, further study is needed to determine the most effective workplace programs to mitigate accidents and provide healthy and safe working environments. There is certainly a vested interest on behalf of employer groups to ensure productivity and safety.

51.6 Employee Assistance Programs

The key to an effective workplace program is a comprehensive Employee Assistance Program (EAP) [22]. Identification of the behaviorally impaired employee due to alcohol or substance misuse and/or abuse provides an opportunity for evaluation and referral to appropriate treatment, as opposed to a sudden disciplinary termination. The American Society of Addiction Medicine (ASAM) assessment and patient placement criteria [1] are most effective for such evaluation and referral. Although companies in the United States are not required to have workplace EAPs and treatment programs, many do because of insurance and liability risks. SAMHSA studies and reports have established that these programs result in excellent benefits, both economic and social. It has been shown that treatment averts many negative outcomes, saves money in overall health care costs, and reduces accident risk in the workplace.

EAPs for alcohol-use disorder gained prominence after World War II, largely due to the influence of Alcoholics Anonymous (AA), which was established in the 1930s. Individuals influential in the AA movement, such as Marty Mann, who helped found the National Committee for Education on Alcoholism (now known as the National Council on Alcoholism and Drug Dependence (NCADD)), and Dr. Ruth Fox, who helped form the New York Society of Alcoholism, were among the guiding forces behind the formation of the American Society of Addiction Medicine (ASAM).

ASAM [5] has developed a very clear clinical definition of the disease of addiction:

> Addiction is a primary, chronic disease of the brain reward, motivation, memory, and related circuitry. Dysfunction in these circuits leads to characteristic biological, psychological, social, and spiritual manifestations. This is reflected in an individual pathologically pursuing reward and/or relief by substance use and other behaviors.
>
> Addiction is characterized by an inability to consistently abstain, impairment in behavioral control, continual craving, diminished recognition of significant problems with one's behaviors and interpersonal relationships, and a dysfunctional emotional response. Like other chronic diseases, addiction often involves cycles of relapse and remission. Without treatment or engagement in recovery activities, addiction is progressive and can result in disability or premature death.

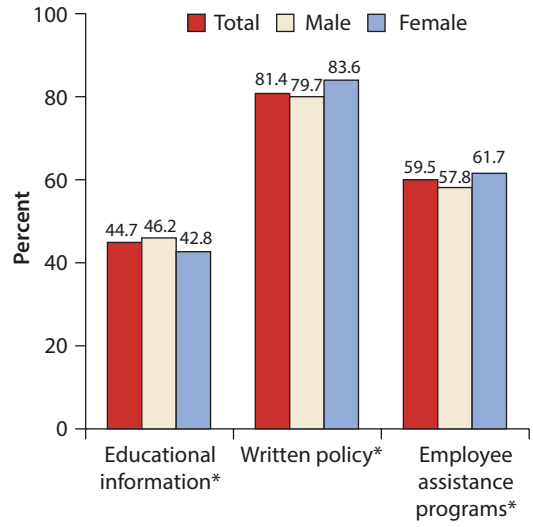
The 4 Cs of Addiction:

- *C*raving
- Loss of *C*ontrol
- *C*ompulsive Use
- *C*ontinued Use Despite Harm

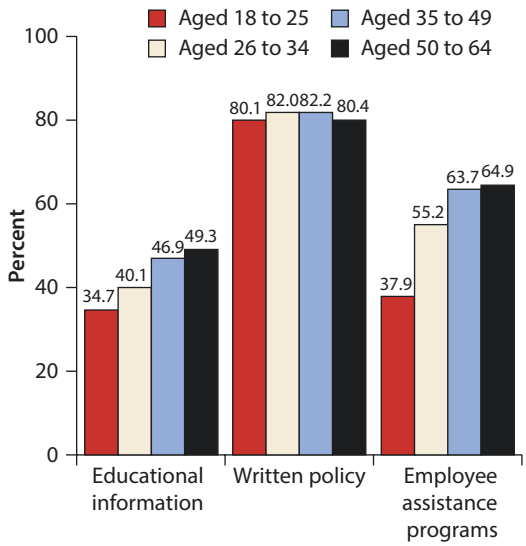
That said, some employees use narcotic pain medication under the care of a physician with a valid prescription. Differentiating appropriate use and potential misuse, abuse, addiction, or diversion in the workplace is crucial so that legitimate pain management is not confused with misuse. Evaluation and selection of an appropriate laboratory for drug testing are essential. In addition, it is necessary to engage a highly qualified MRO to interpret the drug test results in order to clarify false positives or negatives and to ensure that appropriate reporting and assessment take place.

EAPs may be funded by employers, employee benefit organizations, or unions and are often provided at no cost to the employee. They are designed to provide short-term counseling for a variety of personal issues, including legal, financial, relationship challenges, life events, and substance use disorders (SUD) – all of which may affect workplace performance. For issues that cannot be resolved quickly, referrals and other resources are provided. One might compare the services provided by an EAP to that of an ambulance – get to the patient quickly, stabilize the condition, and transfer to a facility for further evaluation and care if necessary. Confidentiality of an employee's visit with a counselor is required, as the session content cannot ethically be reported to the employer for any reason.

EAPs are available internationally. The Employee Assistance Professionals Association is a worldwide association (www.EAPASSN.org), and there are other national organizations focused in Europe, Canada, Australia, the UK, Ireland, and the Asia Pacific Region.



Workplace provides educational information, written policy, or employee assistance program concerning drug or alcohol use among full-time workers aged 18–64, by gender: annual averages, 2008–2012. *Difference between male and females is significant at the .05 level. (Source: SAMHSA, Center for Behavioral Health Statistics and quality, National Surveys on Drug Use and Health (NSDUHs), 2008–2010 (revised March 2012), and 2011–2012)



Workplace provides educational information, written policy, or employee assistance program concerning drug or alcohol use among full-time workers aged 18–64, by gender: annual averages, 2008–2012. (Source: SAMHSA, Center for Behavioral Health Statistics and quality, National Surveys on Drug Use and Health (NSDUHs), 2008–2010 (revised March 2012), and 2011–2012)

EAPs typically have a strong component of the recognition, referral, and treatment of substance misuse and abuse. Some large programs may engage Substance Abuse Professionals (SAPs) who have specialized training to identify potential drug problems and provide referral to treatment. They may also identify practitioners who enable employees to abuse drugs, misuse their medications, or divert for sale and profit. As many employer benefits include a prescription drug plan for the employee, there is a vested interest in containing unnecessary costs.

Many times, the EAP will play a role in monitoring the return to work process for employees suffering from SUD. This outcome is "best-case scenario" and benefits both the employer and employee. Monitoring with objective markers such as random drug testing, assuring the employee is attending psychotherapy sessions, and encouraging utilization of a 12-Step program are some of the ways the employee can be supported toward successful outcomes.

51.7 Summary

In reviewing the topic of alcohol and substance use in the workplace, drug testing, and management, it is clear there is no uniform approach. When considering the topic from an international prospective, cultural norms and views further vary the landscape of management approaches.

The United States has a well-defined and structured approach, including strict discipline, mandates, treatment, rehabilitation, and drug test monitoring prior to reentry into the workplace. In the European countries, the approach is less rigid and focuses more on the reasons why employees ingest alcohol/substances in the workplace, which appears to engage an approach of prevention and rehabilitation without placing the employee immediately at risk of consequence and potential job loss.

EAPs offer benefits to both employers and employees. For the employer, they provide an avenue for maintaining productivity, reducing absenteeism and workplace accidents, and retaining experienced and seasoned employees. For the employee, an EAP provides a lifeline in the event of serious life challenges and, in the event of a developing substance use disorder, a structured path with a compassionate and medically proven venue for treatment and continued monitoring.

Harm-Reduction Interventions

52

Dagmar Hedrich and Richard Lionel Hartnoll

Contents

Abstract

The goal of harm reduction is to reduce both the individual and societal harms of drug use through knowledge-based interventions that change risks, risk behaviours and risk settings. This chapter describes the main harm-reduction interventions implemented in many countries around the world, synthesises evidence on their effectiveness and risks and summarises key lessons learned. The focus is on illegal drugs, especially opioids and the central nervous system stimulants. The interventions covered are opioid substitution treatment; needle and syringe programmes; supervised drug consumption facilities; drug overdose prevention; outreach, peer education and health promotion; testing, vaccination and treatment of drug-related infectious diseases; and interventions for stimulant users. Key themes stressed include the following: that harm reduction does not replace the need for treatment but adds to the capacity to respond effectively to the wide range of health and social challenges raised by drug use; that the scientific evidence shows that harm-reduction interventions are effective in terms of their stated goals, as long as they are implemented appropriately within their contextual settings,

52.1 Introduction

The goal of harm reduction is to reduce individual and societal harms of drug use through policies and interventions that change risks, risk behaviours and risk settings. Harm reduction is based on the concept of harmful drug use and does not assume that drug use per se is harmful. It is a pragmatic approach that aims to reduce harmful correlates and consequences of drug use through a package of evidence-based, targeted interventions tailored to local settings and needs.

Drug-related harm refers both to individual consequences, such as dependence, overdoses or infectious diseases, as well as to social, economic and public health harms to the community (crime, healthcare costs and high HIV prevalence). The underlying public health paradigm is broader than individual-centred treatment and involves balancing individual and societal needs.

Harm reduction as a policy started to gain acceptance in Europe with the emergence of HIV/AIDS amongst drug injectors in the mid-1980s and is now a major pillar of drug policy in all EU member states [38]. Globally it is supported by at least 87 countries [90] and promoted by the WHO, United Nations and European Union as a key element of a comprehensive approach.

Harm reduction entails a coordinated response from a range of actors, including treatment, prevention, public health, law enforcement, community groups and local authorities [21, 74, 79, 100]. It goes beyond interventions for individuals by stressing enabling environments to enhance protective factors, reduce harms and promote public health.

Harm reduction incorporates an important ethical dimension concerning human rights, equality of access to services, respect for privacy and confidentiality and efforts to counteract social exclusion and stigma [79].

Much drug-related harm is linked to heavy consumption of opioids, the central nervous system (CNS) stimulants or multiple drug combinations, including alcohol and other CNS depressants. There is a strong relationship between drug injecting and more severe levels of harm, though problems can arise with other routes of administration. Heavy drug use is often strongly correlated with unsafe sexual practices, including unprotected sex, multiple partners and sometimes selling sex for money or drugs.

Risk behaviours occur within a wider social context. Structural factors such as the policy and legislative framework can generate risk environments that increase social exclusion, deter help seeking for fear of arrest or exacerbate the spread of infectious diseases [17, 75, 80]. The diversity of settings implies diversity of risks and responses [34].

This chapter describes the major harm-reduction interventions, synthesises evidence on their effectiveness and summarises key lessons learned. It draws on a wide range of sources from research and practice, including scientific reviews, evidence-based guidelines and practical manuals. The interventions covered are the following:

- Opioid substitution treatment
- Needle and syringe programmes
- Supervised drug consumption facilities
- Overdose prevention interventions
- Outreach, peer education and health promotion
- Testing, vaccination and treatment of infectious diseases
- Interventions for stimulant use

The focus is on illegal drugs, especially opioids and the central nervous system stimulants. Harm-reduction approaches have been applied to other drugs including alcohol, cannabis and tobacco and to other user groups such as young recreational drug users [79, 83].

52.2 Interventions

52.2.1 Opioid Substitution Treatment

Other chapters in this textbook cover opioid substitution treatment (OST) as treatment for opioid dependence. In this section, the emphasis is on OST for reducing individual and social harms associated with illicit opioid use. Methadone is the main drug employed, though buprenorphine has become more common following the 1990s. In some European countries and Canada, heroin-assisted treatment is provided to long-term heroin dependent individuals who have not responded well on methadone [64, 91]. Whilst naltrexone, an opioid receptor antagonist, has also been researched as treatment for relapse prevention, its effectiveness is limited by poor adherence, and maintenance with methadone or buprenorphine remains the preferred treatment [18]. OST is usually combined with psychosocial treatment, counselling and other health and social services.

Within a harm-reduction paradigm, OST consists of the (usually long term) prescription of opioid agonists to prevent withdrawal symptoms and craving, enabling users to lead more stable lives and reduce illicit heroin use, risk behaviour and criminal activity. Apart from reduced illicit heroin use, which has been demonstrated in numerous studies (see Chap. 10 in this textbook), specific harm-reduction outcomes that are sought include reductions in prevalence and frequency of drug injecting, prevalence and frequency of sharing drug using paraphernalia, incidence and prevalence of infectious diseases (especially HIV and hepatitis C), rates of drug-related mortality (especially overdoses) [70] and rates of drug-related crime. Reductions in high-risk sexual behaviours, as well as improvements in health and social functioning, are also the objectives.

Reviews of multiple studies with robust designs all found strong evidence that OST is effective in reducing self-reported prevalence and frequency of injecting, sharing of injecting equipment and injecting risk behaviour scores [30, 44, 49, 50, 53]. The same reviews found clear, consistent evidence that OST in community settings is effective in reducing HIV transmission, especially amongst those in continuous treatment and when dosages are adequate [26]; for example, MacArthur [49] estimated that OST is associated with a 54% reduction in risk of HIV infection amongst people who inject drugs.

The effectiveness of OST in reducing HCV transmission has been harder to determine. This is probably because HCV is more easily transmitted through injecting risk behaviours and because baseline prevalence levels of HCV in drug-injecting populations are often high. However, a recent systematic review [73] found that OST is associated with a reduced risk of HCV acquisition, which is strengthened in studies assessing OST and needle and syringe programme (NSP) in combination. There is accumulating evidence on the impact of combining these prevention interventions on hepatitis elimination (e.g., [63, 67, 97]), and a recent global mathematical model [39] underlines the importance of bringing harm-reduction services up to scale, highlighting their key role in prevention.

There is long-standing, strong evidence that OST reduces substantially the risk of overdose mortality, as long as doses are sufficient and continuity of treatment is maintained [16, 43, 52].

There is clear and consistent evidence from many studies that criminal activity, arrest and incarceration rates decline markedly after patients enter OST and that this effect is stronger the longer they remain in treatment [62]. This is particularly true of drug-related criminal activity such as drug-dealing and acquisitive crime. Where sufficient coverage of the opioid-using population is achieved, decreases in drug-related crime at the individual level are reflected in reduced levels of crime at community level [62].

A systematic review of 21 studies conducted in prison settings concluded that the benefits of OST provided in prison are similar to those obtained in community settings [36]. OST was significantly associated with reduced heroin use, injecting and syringe-sharing in prison if doses were adequate. Prerelease OST was significantly associated with increased treatment entry and retention after release if arrangements existed to continue treatment. For other outcomes, associations with prerelease OST were weaker. Whilst some post-release reductions in heroin use were observed, evidence regarding crime and re-incarceration was equivocal. Due to lack of studies, there was insufficient evidence concerning HIV/HCV incidence, either in prison or post release. Disruption of OST continuity, especially due to brief periods of imprisonment, was associated with very significant increases in HCV incidence [19]. In a national prospective, observational study in England prison-based opioid substitution therapy was associated with a 75% reduction in all-cause mortality and an 85% reduction in fatal drug-related poisoning in the first month after release [51]. In a meta-analysis and systematic review by Moore et al. [59], opioid substitution treatment with methadone provided during incarceration was found to be effective in reducing post-incarceration illicit opioid use and injecting.

Benefits of OST that have been clearly established include reduced illicit heroin use, injecting and risk behaviours, reduced overdose mortality and criminal activity and reduced HIV and HCV incidence – especially in combination with high-scale NSP. There is also evidence that OST facilitates improved adherence to HIV treatment [65] and leads to reductions in high-risk sexual behaviours [30].

In prison settings, OST presents an opportunity to recruit problem opioid users into treatment, to reduce illicit opioid use and risk behaviours in prison, and potentially to minimise overdose risks on release [22]. If liaison with community-based programmes exists, prison OST facilitates continuity of treatment and longer-term benefits can be achieved. For prisoners in OST before imprisonment, prison OST provides treatment continuity, especially important for drug users who are incarcerated for short periods. A population-based retrospective cohort study amongst Canadian convicted offenders documents that the adherence to OST had a positive impact not only on overdose deaths but also on other causes of mortality after release [84].

There are also limitations. OST is suitable neither for users of non-opioid drugs nor for drug users who have only recently started to use opioids, even though during the early stages of use they may be at particular risk of becoming infected (especially with HCV) through using another person's paraphernalia. Even in countries with high levels of OST provision, coverage of the total opioid-dependent population rarely exceeds 60% [24, 25]. Whilst other treatment modalities meet some of the shortfall, there remain important populations of problematic drug users who do not come for treatment or who do not fare well in treatment. As described above, other approaches need to be pursued alongside or in combination with OST to optimise its effects.

Specific risks of OST include increased mortality risk during induction into treatment and immediately after leaving treatment, which should be dealt with by both public health and clinical mitigation strategies [89]. Methadone overdoses can occur in association with careless overprescribing or use of illicit methadone from diversion or thefts. A different challenge arises from the accumulation of ageing, long-term patients on OST, many with multiple comorbidities. A harm-reduction approach not only includes encouraging OST clients to become drug free when they can but also accepts that for some this is not possible.

Several important lessons learned should be stressed. Adequate doses are essential. Whilst individual dosage levels vary, positive outcomes are mostly achieved when average programmed methadone dosages are in the 60–120 mg range [26, 102]. Continuity too is vital, accompanied by appropriate socio-psychological support and health education input.

52.2.2 Needle and Syringe Programmes

A needle and syringe programme (NSP) is a specialised service, offered by low-threshold drugs- and health agencies including through outreach, and that consists of distributing syringes, needles and other sterile injecting equipment to people who inject drugs. These agencies are usually located close to areas where drug injecting is prevalent and form part of a wider network of local services. Their primary objective is to facilitate more hygienic injecting practices and reduce sharing or reuse of needles, syringes and other items in order to prevent drug-use-related complications, especially the transmission of HIV and HCV. Most needle and syringe service providers also offer equipment for safer non-injecting use of drugs.

NSPs often serve as important contact points for drug users who have little contact with treatment or other health services. Thus, a supplementary objective is to deliver health promotion and facilitate access to healthcare, including entry to OST or other treatment. They routinely distribute condoms and offer advice on safer sex. They may also provide counselling and testing for infectious diseases and sexually transmitted infections (STIs), as well as vaccination for hepatitis B and basic healthcare. In some countries, NSPs are mainly implemented through national networks of pharmacies. In other settings pharmacy-based programmes and vending machines supplement specialised NSPs. In some countries, NSPs have been established in prisons.

A broad body of evidence indicates that NSPs are effective, as part of a multicomponent set of responses, in limiting the transmission of bloodborne infections, without increasing the prevalence or frequency of injecting [2, 13, 66, 95]. There are methodological difficulties in separating the impact of NSPs from the influence of other interventions and local contextual factors, which means that rigorous scientific studies of the effectiveness of NSPs as a single intervention are limited. Evidence from systematic reviews of NSPs across a range of settings and countries indicates that they are effective in reducing self-reported risk behaviours associated with injecting [50] and in reducing the transmission of HIV amongst people who inject drugs [2]. A recent systematic review [73] found greater heterogeneity between studies and weaker evidence for impact of NSP on HCV acquisition. High NSP coverage (defined as regular attendance at an NSP or all injections being covered by a new needle/syringe) was associated with a reduction in the risk of HCV acquisition in studies in Europe, whilst the effect was not clear for studies conducted in North America. The lack of evidence from US studies can be attributed to a mixture of confounding, differences in injecting patterns, potential selection bias and misclassification of exposure [73]. There is also evidence that NSPs and other harm-reduction interventions are cost-effective [101].

Benefits of NSPs, when implemented appropriately and at sufficient scale, include important reductions in injecting risk behaviours and HIV transmission. In combination with opioid substitution treatment, they make a significant contribution to reducing not only HIV but also HCV transmission. There is no evidence that the establishment of NSPs encourages non-injectors to start injecting or that injection frequency increases amongst attenders [79]. There were no reports of adverse events involving syringes in studies of prison-based NSPs.

Important lessons have been learned over the past three decades. It is essential to aim for full coverage of clients' injecting needs. Restrictions on the number of needles and syringes distributed, or insistence on returning used equipment, can be counter-productive, especially for high-frequency injectors such as cocaine users, since this can facilitate reuse and sharing. The underlying principle should be at least 100% coverage of each injection and distribution according to need rather than one-for-one exchange. It is also important to achieve wide coverage of local populations of drug injectors. Many NSPs allow secondary distribution, where clients distribute clean needles and syringes to partners or peers. Mobile units and outreach are valuable to further extend coverage.

Injecting equipment should take account of local context and the type and preparation of drugs

injected. Injectors in different settings often have preferences for certain types or sizes of equipment. Apart from needles and syringes, NSPs should provide other injecting-related items, including alcohol swabs, sterile water, filters, mixing vessels (e.g., spoons or "cookers") and acidifiers to assist with dissolving the substance to be injected [21].

Health promotion activities among people who use drugs should address viral infections such as HIV and hepatitis B and C, that is, how they are transmitted and how they can be avoided, practical advice on hygiene and safer injecting, as well as information on STIs and reducing sexual risks. They should also include provision of condoms, information on health and social services and, when appropriate, referral to drug treatment. Whilst staff can encourage clients to consider entering treatment or changing to safer routes of administration, this should not be linked to pressure such as implied withdrawal of services. Since NSPs come in contact with out-of-treatment drug injectors, it is valuable if they can carry out on-site counselling, testing and monitoring of HIV, viral hepatitis, STIs and TB, as well as vaccination for hepatitis B. Some NSPs also provide basic healthcare (e.g., wound dressing) or train clients in overdose prevention and management, including giving out naloxone. Testing and behaviour change counselling are essential not only for those who are seropositive but also for those who test negative since it is important to avoid complacency (see Sect. 52.2.6 in this chapter).

Reuse of injection equipment for administering injections to more than one person or introducing the syringe in a shared repository of drugs, reuse of syringe barrels or of the whole syringe and informal cleaning have been identified by WHO [105] as high-risk practices. To increase one-time use of injection equipment in medical settings, WHO issue a recommendation for the use of syringes with a reuse prevention feature. Research on low dead space syringes (LDSS) suggests that they reduce the amount of blood remaining in the syringe after completely pushing down the plunger – and subsequently, after rinsing with water, HIV viral burden may be reduced by a factor of 1000 compared to high dead space syringes [106]. A model described LDSS as a potential powerful HIV prevention strategy, and recent real-life data from the UK show an association between exclusive LDSS use with lower prevalence of HCV amongst people who had started injecting recently, suggesting LDSS use may be protective against HCV [96]. However, there is a risk that promoting LDSS may appear to accept sharing, in contradiction to the clear message that syringes should never be reused or shared.

Safe disposal of used equipment is important. NSPs can facilitate safe disposal by receiving used syringes or by providing puncture-resistant disposal containers to clients. However, if carrying used needles and syringes is a criminal offence or may be used as evidence of drug use, clients may be reluctant to bring used equipment back.

Accessibility and acceptability to target populations are important. This means setting up NSPs in locations with easy access and a minimum of bureaucratic entry requirements. Opening hours should include evenings and weekends. Staff should be positive and sympathetic.

NSPs are mostly implemented in urban settings with a higher prevalence of injecting. In smaller towns and rural settings, a pharmacy-based model may be more appropriate. Apart from (free) distribution through NSPs, needles and syringes can be purchased at pharmacies in many countries, though various formal or informal restrictions can discourage people from using this option, and even a low price may be a disincentive for low-income populations.

The distribution of non-injecting paraphernalia such as safer smoking kits is among the main harm-reduction measures suggested for people who smoke heroin, crack cocaine or methamphetamine (crystal) [82]. A pilot study by Pizzey and Hunt [72] suggested that distributing foil and smoking materials from needle and syringe programmes helps to promote transitions from heroin injecting to chasing. An online survey amongst managers of 80 NSPs in Canada showed that efforts to reduce harm of non-injecting routes of administration are increasing. A majority of programmes educated clients on reducing risks

associated with sharing crack cocaine smoking equipment and most of them also distributed equipment (crack pipes). The most common reasons for not distributing safer smoking equipment were not enough funding and lack of client demand [93].

Despite clear evidence on the benefits of NSPs, opposition from local policymakers, professionals and community groups can limit the possibilities of establishing an effective network of NSPs. Thus, a process of consultation with relevant local bodies is essential. Careful planning and co-ordination with local health and treatment services are important to establish clear procedures for referral links. Agreement needs to be reached with justice and police officials to avoid counter-productive interventions.

52.2.3 Supervised Drug Consumption Facilities

Drug consumption rooms (DCRs) are professionally supervised healthcare facilities where drug users can use drugs in safer and more hygienic conditions [37]. DCRs seek to attract hard-to-reach populations of drug users, especially marginalised groups and those who use drugs on the streets or in other risky and unhygienic conditions. They aim to reduce morbidity and mortality by providing a safe environment for more hygienic drug use and by training clients in safer drug use. At the same time, they seek to reduce public drug use and to improve public amenity in areas surrounding urban drug markets. A further aim is to promote access to social, health and drug treatment facilities [42]. Since 1986, more than 150 DCRs have been set up in 10 European countries as well as in Canada, Australia and Mexico [24, 25]. They are highly targeted services addressing specific local problems within a wider network of services, and access is typically restricted to registered service users. They usually operate as an integrated part of low-threshold facilities for drug users or the homeless, though some are stand-alone units. Most target drug injectors, though increasingly also cover users who inhale or smoke drugs. At times, their establishment has been controversial due to concerns that they may encourage drug use, delay treatment entry or aggravate problems of local drug markets, and initiatives to establish DCRs have been prevented by political intervention.

Evidence shows that DCRs succeed in reaching their target populations and achieve immediate improvements in terms of better hygiene and safer use for clients who use the services. There is consistent evidence that DCR use is associated with self-reported reductions in injecting risk behaviour such as syringe sharing as well as reductions in improperly discarded syringes, so DCRs are also likely to be beneficial in reducing drug use in public and related problems of public disorder. Studies on overdose-related morbidity and mortality suggest a protective effect of DCRs [37, 42]. Regarding transmission of HIV and HCV, due to a lack of robust studies and methodological problems such as isolating the effect of DCRs from other interventions or low coverage of the risk population, there is insufficient evidence either to support or discount the effectiveness of DCRs [3, 50].

Benefits of DCRs include improvements in safe, hygienic drug use, especially amongst regular clients, increased access to health and social services and reduced public drug use and associated nuisance. The availability of safer injecting facilities does not increase drug use or frequency of injecting; it facilitates rather than delays treatment entry, and does not result in higher rates of local drug-related crime.

DCRs have mostly been established in specific urban settings with problems of public drug use and overdose or where there are subpopulations of drug users with limited possibilities of hygienic injection (e.g., homeless, living in insecure accommodation or shelters). As with NSPs, consultation with local key actors is essential to minimise community resistance or counter-productive police responses.

52.2.4 Overdose Prevention

Large increases in opioid overdose deaths in the USA and Canada over the last decade

raised alarm about the overprescribing of strong opioids and the significantly increased presence of fentanyl (a highly potent opioid) in the illicit heroin market [54, 85], trends not observed in Europe. However, although rising overdose deaths often trigger concern, efforts to develop interventions specifically targeted at reducing overdose deaths have historically emerged more slowly than responses to other drug-related problems like dependence, crime or HIV/AIDS.

As noted above, effective drug treatment, in particular OST, significantly reduces overdose mortality, and DCRs can contribute at local level if capacity is sufficient. A more specific and promising approach to reducing opioid overdose deaths is offered by community-based overdose prevention programmes that include peer naloxone distribution.

Naloxone is an opioid-antagonist used in medical emergencies to reverse respiratory depression caused by opioid overdose. It has no effect on non-opioid drug overdoses and has a high safety margin. It is available in injectable form and also as an intranasal spray since 2015.

The aim of naloxone distribution programmes is to increase the availability of effective medication in places where overdoses are more likely to occur. Overdose is common amongst opioid users, and most overdoses happen in the presence of a witness, often in the users' home. Many people who die from opioid overdose fail to receive proper medical attention because witnesses (often other drug users) do not recognise the seriousness of the situation, delay, or do not call emergency services for fear of police involvement.

Peer naloxone distribution programmes work by training drug users and other likely first responders (e.g., peers, families), as well as frontline services such as healthcare providers, staff in homeless shelters and, in some cases, police officers, on how to recognise and respond to an overdose, including administration of naloxone, until emergency medical help is obtained. Naloxone is distributed to trained participants, to be at hand if they witness an overdose.

While local naloxone projects started in the USA and Europe in the 1990s [92], they have only recently been scaled up in some locations. Given the dramatic rates of fatal opioid overdoses in the USA and Canada, federal, state and local governments have prioritised increased access to naloxone and overdose education, and naloxone distribution programmes are implemented as a harm-reduction strategy. Nationwide take-home naloxone programmes exist in European countries with high rates of drug-related deaths (including the UK, Norway and Denmark).

A study covering the first 8 years of naloxone provision by community-based organisations across the USA documented that over 150,000 laypersons had been trained and 26,463 overdoses reversed [99]. A systematic review of 21 studies reporting outcomes of take-home naloxone programmes found evidence that educational and training interventions, complemented by naloxone distribution, may decrease overdose-related mortality and that opioid-dependent patients and their peers involved in such programmes improve their knowledge on the correct use of naloxone and management of witnessed overdoses [57]. A meta-analysis of pooled data from four studies on bystander naloxone administration and from five studies on overdose education programmes [29] confirmed an association of naloxone programmes with increased odds of recovery and improved knowledge of overdose recognition and management in nonclinical settings. Furthermore, naloxone distribution was found to be cost-effective [12]. In a pre-post evaluation of a national naloxone programme (Scotland), brief training and standardised naloxone supply for individuals at risk of opioid overdose in prison were effective in reducing by 36% the proportion of opioid-related deaths occurring in the 4 weeks following release from prison [5]. A recent study in the USA analysed whether different laws affecting the accessibility of naloxone correlated with the number of overdoses and deaths [1]. The researchers found that only laws allowing widest access via direct dispensing by pharmacists appeared to be useful in reducing opioid-related fatalities, but noted an increase in

non-fatal overdoses in communities where access to naloxone is improved.

Benefits include substantial reductions in opioid overdose deaths, if sufficient coverage of risk populations can be achieved. Giving people, who are likely to witness an overdose, access to naloxone is recommended by WHO in guidelines on community management of overdose and as a component of a comprehensive package of services for people who use drugs. The introduction of naloxone nasal sprays promises to ease the administration of naloxone and improves safety through avoidance of needlestick injuries when treating a population at high risk of blood-borne infections.

Raising overdose risk awareness and increasing response skills amongst professionals in contact with drug users, and disseminating overdose risk information to users, their peers and families constitute an other important part of a comprehensive programme to reduce overdose mortality. Counselling on overdose risk should be a key component of prison release or treatment discharge protocols. Crisis intervention and counselling at hospital emergency rooms following admission for overdose have been tried in some countries.

Since in the USA a significant proportion of drug overdose deaths are associated with prescription opioids and sedatives, prescription monitoring and co-prescribing of naloxone to long-term pain patients have been suggested among various responses to curb the epidemic of overdose deaths [11].

52.2.5 Outreach, Peer Education and Health Promotion

Community-based outreach aims to facilitate improvements in health and reductions in risks and harms for individuals and groups who are not effectively reached by fixed-site services or through traditional health education channels [76]. It seeks to achieve this through identifying and contacting target groups of drug users in different community settings in order to deliver in situ interventions to hard-to-reach populations as well as to provide a contact point for increasing access to a range of other services. Depending on circumstances, interventions may include dissemination of information on drug- and sex-related harms and risk behaviours; provision of advice and counselling on individual behaviour change; distribution of prevention and safer use materials such as sterile injecting equipment, condoms and lubricants; overdose prevention training, including take-home naloxone distribution; and measures to facilitate access to healthcare, social services and drug treatment. The focus may be on individual risk reduction, or it may also include attempts to change social norms concerning risk behaviours amongst the target populations concerned.

Outreach projects may operate from a standalone base, but they are often attached to other community health and social services such as NSPs, street-level low-threshold services, treatment centres, etc. Target groups may include homeless, migrant or minority group users with limited access to services, street users, sex workers, chaotic stimulant and multiple drug users or more private, closed groups.

Different models of outreach have been described [60, 76, 77, 78]. Some are based on professional youth or community health workers, others originated from ethnographic research involving indigenous leaders to target risk networks and individuals, others have focussed on promoting peer-driven outreach, whilst others have developed out of advocacy or self-help organisations. Some concentrate more on the individual level (e.g., information and awareness raising, referral or support for change), whilst others give greater emphasis to a network approach involving peer education and modification of peer norms or empowerment of vulnerable groups.

Reviews of studies of outreach interventions to prevent HIV infection conclude that outreach is an effective strategy for reaching hard-to-reach, hidden populations of people who inject drugs, enabling them to reduce their risk behaviours and increase protective behaviours [50, 60, 88].

Studies of network approaches suggest that, given guidance and nominal incentives, injecting drug users can play a more extensive role in community outreach efforts than the traditional model allows. New models of care, developed in the context of viral hepatitis elimination, show that referrals made by peer outreach teams or using specialised liaison nurses help to engage with homeless individuals with multiple comorbidities and help undiagnosed people who inject drugs to access voluntary testing [33, 46].

Outreach is a flexible and effective component of local harm-reduction strategies. It is essential that outreach workers can establish rapport with target populations and gain acceptance as trusted and knowledgeable sources of information and advice. It is vital to ensure confidentiality and to communicate messages clearly. Outreach workers need adequate training, support and protection, especially in peer-driven interventions. This is helped by clear guidelines covering objectives, services offered, responsibilities and limits (personal, professional, legal, etc.). Concrete procedures with other local agencies are important to maximise the uptake of referrals. Drug users and user organisations should be actively involved as partners in planning and conducting outreach.

52.2.6 Testing, Vaccination and Treatment of Infectious Diseases

Public health guidelines recommend a comprehensive and integrated approach to preventing and treating infectious diseases amongst high-risk populations with focus on the individual's overall health and social conditions. This section highlights key points for practitioners and managers involved in harm-reduction interventions for people who use drugs. Innovative technologies are influencing algorithms for diagnosing infections, and new highly effective treatments have led to rapid changes regarding hepatitis C. Extensive, up-to-date information on public health policy, scientific evidence and clinical practice can be found in reviews and guidelines by public health institutions (e.g., ECDC, CDC and WHO) [8, 20, 21, 22, 104].

Recommended core measures include provider-initiated offer of voluntary, confidential screening for HIV, hepatitis B and C, common STDs and TB; vaccination for hepatitis A and B, and where clinically indicated for tetanus, influenza and pneumococcus (HIV positive) and antiviral treatment for HIV and hepatitis C; as well as treatment for STDs and TB [21]. Care should be taken about potential medication interactions, including methadone, especially in the treatment of people with co-infections.

Many people who inject drugs may be unaware that they are infected. Accessible testing in settings where people who use drugs are reached offers an opportunity to provide information and health education and to identify cases for vaccination or treatment. Knowledge of sero-status provides an informed basis for discussing changes in drug use and sexual behaviour with clients and has been found to be associated with positive behaviour changes [20].

Access to and uptake of testing and treatment of infectious diseases and STIs can be increased through on-site screening at services for drug users (drug treatment centres, NSPs or DCRs). Rapid testing techniques now allow this in diverse contexts, including low-threshold services and outreach. Where possible, treatment should take place at the same sites to improve uptake. If not possible, then active referral pathways to public health facilities should be established.

Screening programmes for infectious diseases need to be tailored to clients' life situations and be highly accessible and quick. Thus, the use of point-of-care rapid tests is common. For HIV antibodies, inexpensive enzyme immunoassays using unprocessed blood (finger stick) or oral fluid specimens provide results within 20 minutes. HIV self-testing (HIVST) is recommended by WHO for reaching as-yet undiagnosed populations. Rapid HIV testing kits for home use are approved in the USA and other countries and are available from major pharmacies; some harm-reduction agencies include HIVST kits amongst a range of prevention materials.

When positive, rapid tests require laboratory confirmation with serum or plasma. Delays between first test and confirmation (and treatment start) often cause loss to follow-up. New technical devices (platforms) allow detection and quantification of HIV nucleic acid and HCV viral load at the point of care using unprocessed whole blood specimens. Mechanisms linking those infected to treatment need to be established; as infections can be asymptomatic, starting treatment may not be a priority from the client's perspective. Whilst testing has already moved towards point of care, a new approach to prevent loss to follow-up is to combine diagnosis and start of antiviral treatment in the same visit.

Testing can also provide opportunities to encourage partners to be tested and to participate in changes needed to reduce risks. Periodic health checks and monitoring of seronegative individuals, as well as those successfully treated, help to reinforce protective behaviours and identify reinfection. It also contributes to monitoring programme effectiveness.

52.2.6.1 Agenda 2030 for Sustainable Development

Target 3 of the agenda for global development (SDG 2030) aims at ending the epidemics of AIDS, tuberculosis, malaria and neglected tropical diseases and combat hepatitis, water-borne diseases and other communicable diseases by 2030. Recent advances in the treatment of hepatitis C led WHO to add the elimination of viral hepatitis as a public health threat by 2030 as an additional goal.

Antiretroviral treatment (ART) is a highly effective treatment for HIV and reduces viral load amongst those who adhere to it to undetectable levels. A policy of universal test and treat – making ART available to all HIV-infected persons regardless of CD4 count – is recommended by WHO since 2014. Earliest ART initiation results in successful treatment outcomes amongst PWID with no increase in self-reported risk behaviour. Early diagnosis and engagement in OST should be promoted whilst enhancing care for those with advanced HIV disease and history of imprisonment [61].

New hepatitis C treatments with combinations of drugs called direct-acting antivirals (DAAs) achieve high cure rates even amongst active PWID – in terms of a sustained virologic response (SVR) – with few side effects and after treatment periods of 12 weeks or less. Treating HIV and HCV in those infected not only benefits individuals but has an important preventive effect since it reduces infectivity and thus the risk of transmission to others [100].

Recommendations by the European Association for the Study of the Liver (EASL) on treatment of hepatitis C [68] recommend prioritising groups with high risk of transmission – including active PWID and people in prison, for viral hepatitis treatment as a way to significantly decrease incidence. As reinfection can occur amongst those who remain involved in high-risk practices, maintaining an offer of high-scale harm-reduction measures alongside treatment of infection is essential. This includes education and support to reduce risks, access to clean injecting equipment, effective treatment of drug dependence and reducing stigma related to drug use and infection. For populations exposed to high-risk drug use environments, DCRs can complement other measures. Active PWID are not eligible for direct-acting antiviral treatment in some health systems, and research on how to overcome further client- or provider-related barriers to treatment initiation is needed [98].

For those uninfected, taking ART as preventive measure (pre-exposure prophylaxis PrEP) has been shown to be effective in men who have sex with men (MSM) and heterosexually active men and women [8, 41]. A randomised controlled trial of tenofovir covering over 2400 PWID in Bangkok showed a 49% reduction in HIV incidence related to PrEP over placebo. Based on these findings, the US Centers for Disease Control and Prevention (CDC) recommend PrEP be considered 'as one of several prevention options for persons at very high risk for HIV acquisition through the injection of illicit drugs' [7]. PWID may still be largely unaware of PrEP, but recent studies show that they are interested in taking it [4, 86].

Universal vaccination of children for hepatitis B and vaccination campaigns targeting high-risk groups mean that hepatitis B should become increasingly rare. Meanwhile, it is valuable to continue screening for HBV and, where appropriate, offer vaccination using the Accelerated Schedule [103].

STIs increase the risk of sexual transmission of HIV [9]. Thus, identification and treatment of common STIs is one of the principles of HIV prevention strategies amongst sexually active individuals, especially in high-risk populations.

Investment in prevention, scaling up harm-reduction interventions for PWID, remains a crucial priority for halting the HIV and HCV epidemics [39, 47].

52.2.7 Interventions for Stimulant Use

After alcohol and tobacco, amphetamine-type substances and cocaine are the most prevalent substances used worldwide. It is estimated that one in five to seven recent stimulant users develop a problematic consumption pattern [15, 69]. Apart from dependence, harms especially associated with chronic stimulant use include cardiovascular and cerebrovascular diseases; pulmonary damage; mental health problems such as acute psychotic episodes, depression and anxiety; chaotic behaviour, including higher rates of needle sharing associated with intensive, high-frequency injection; and sexual behaviours that increase transmission risks of HIV and STIs. In high cocaine prevalence areas, significant numbers of acute cocaine episodes ('overamping' [1]) are seen by medical emergency services, and deaths involving cocaine (injected or smoked) and psychostimulants have increased in the USA in recent years [40].

The likelihood of harm varies according to context. For example, crack cocaine is more common amongst highly marginalised groups and is associated with elevated levels of HIV transmission risk, especially for women who trade sex for money or drugs [23, 56]. Crack is sometimes injected as well as smoked, adding a further risk dimension [81]. Transmission of HCV may occur through sharing crack pipes via oral sores and cracked lips [27, 55]. Methamphetamine use, especially by men who have sex with men (MSM), is associated with high levels of sexual risk behaviour [87]. 'Chemsex', the intentional combination of sex with the use of certain psychoactive drugs amongst MSM can bear high risks of infection transmission, and concerns small subgroups of MSM who typically present further risk factors [94]. High levels of cocaine use may also be found amongst socially integrated users who sniff rather than inject or smoke the drug. Whilst health risks are lower, they still remain, especially through sexual risk behaviour and sharing straws (HCV). The social networks and economic resources of socially integrated cocaine users may enable them to resolve problems without contacting services [14]. For the most part, problem stimulant use is associated with lower socioeconomic status and a range of social and legal problems, in addition to a variety of psychiatric comorbidities [31].

Harm-reduction interventions for stimulant users include safer smoking equipment (pipes and foil), outreach and peer-driven programmes, sexual risk reduction education, information campaigns including web-based dissemination, assertive community treatment, environments to reduce anxiety and increase control over use in a non-rushed environment, such as supervised consumption facilities, as well as various innovative approaches based on alternative medicine [71].

There are few high-quality scientific studies of interventions to reduce specifically the harms of CNS stimulants. Systematic reviews on treatment for psychostimulants indicate that the addition of

[1]The term 'overamping' is used to describe the variety of negative of uncomfortable physical and psychological effects; can include paranoia, increased heart rate, discomfort, violence, anxiety, sweating and other experiences – See: https://harmreduction.org/issues/overdose-prevention/overview/stimulant-overamping-basics/what-is-overamping/

psychosocial treatment such as contingency management, cognitive behavioural therapy, motivational interviewing and others may offer modest improvements compared to treatment as usual (usually characterised by group counselling or case management), probably reducing the dropout rate and increasing the longest period of abstinence [58]. Retention rates in treatment tend to be low, reducing the potential for systematic efforts to reduce risk behaviours.

A systematic review addressing pharmacotherapy for cocaine use [10] found no evidence of effectiveness of any class of drug in increasing abstinence, reducing use or improving treatment retention rates. There were some indications that particular drugs may be beneficial, such as sertraline to maintain abstinence, antipsychotics to improve treatment retention and psychostimulants and anti-depressants to increase abstinence in comorbid opioid users. Work on a cocaine vaccine progresses slowly and is still in early stages of optimising vaccine formulations to improve efficacy [45].

A review of whether substitution with medications that have psychostimulant effect is effective for treating patients with cocaine dependence [6] assessed nine CNS stimulants (bupropion, dexamphetamine, lisdexamfetamine, methylphenidate, modafinil, mazindol, methamphetamine, mixed amphetamine salts and selegiline) and found mixed results, suggesting research to further evaluate the approach in combination with behavioural and psychosocial input to stabilise drug use and lifestyle.

NSPs are an effective intervention to reduce injecting-related risks for injecting stimulant users as well as opioid users. However, as noted earlier, people who inject stimulants inject frequently and need a plentiful supply of sterile syringes and needles. Given the chaotic lifestyle, frenetic drug-using behaviours and disturbed sleep patterns often seen in compulsive stimulant injectors, providing adequate coverage of injecting needs, potentially for up to 24 hours per day, is a challenge for any service. Mobile units and syringe dispensing machines can help extend coverage in terms of times and places.

Most DCRs were initially established for heroin injectors and often did not admit cocaine injectors or smokers but have increasingly adapted to client needs by setting up separate rooms for those who smoke or inhale drugs. This has proved to be feasible, attracting important subgroups such as crack-using sex workers, and appears to provide benefits similar to those that obtain for heroin users [35, 82].

It has been suggested that traditional harm-reduction services fail to reach problem stimulant users due to opiate-centred services and social barriers to young or female users [31]. Thus, greater emphasis needs to be placed on outreach and peer education approaches (see Sect. 52.2.5), especially for younger users. In response to the risks associated with smoking crack, some programmes in the USA, Brazil, Canada and France have developed ‘crack kits’ [82]. These include a Pyrex Tube, rubber mouthpieces, filters, lip balm, sterile compresses, chewing gum for salivation and condoms. Initial results suggest that sharing of crack pipes decreased dramatically, whilst crack users reduced injecting and more often smoked cocaine [48]. However, crack kits are controversial and rarely funded.

Regarding crack, there is some evidence that the severity of mental health harms associated with cocaine is related more to the intensity and context of use than to the specific form of cocaine used [32]. Harm-reduction measures aimed at safer, more controlled, less intensive use of cocaine together with steps to stabilise the social situation may help to decrease mental health problems.

Other approaches include acupuncture as an adjunct to treatment to reduce craving, though a systematic review of controlled trials found no evidence of effectiveness [28], or providing accessible and flexible walk-in calming environments to reduce agitation and anxiety levels. Advice, counselling and treatment services for socially integrated users may be more attractive if separated from services for opioid users and

drug injectors and if they operate at appropriate hours, for example, evenings.

Interventions for less intensive users include information dissemination on managing mental health risks or on stimulant use via flyers, websites, personal messaging via mobile phones or "pill testing" in nightlife settings [31, 82].

Patterns of stimulant use and risks can vary greatly from one setting to another. For example, in some former Soviet Union republics, home production of stimulants is associated with specific and highly risky patterns of drug consumption [31], and in the UK, groin injection of crack cocaine raises special challenges [81]. In some settings, women are particularly at risk. This means that interventions need to be thoughtfully planned to take account of local circumstances and vulnerable groups. This should include critical reflection on whether any unintended negative effects might arise. Whilst there is much room for innovative development of harm-reduction responses, it should be stressed that all interventions for stimulant users need to give high priority to sexual risks as well as to drug-related risks.

52.3 Conclusion

This chapter has provided an overview of interventions that contribute to reducing drug-related harms. Above and beyond any particular intervention, it must be emphasised that single interventions are far more effective when implemented together as part of a broader package, including policies to facilitate enabling environments that foster healthier and safer living.

Harm reduction does not replace the need for treatment but adds to our capacity to respond effectively to the wide range of health and social challenges raised by drug use. Apart from skills in dealing with individual clients, practitioners need an understanding of the social, community and public health settings within which drug use and drug-related harms arise, as well as an awareness of how social responses can have unintended consequences. Willingness and ability to co-operate within a local network of agencies and listen to the concerns of drug users themselves is essential. This involves a broad vision of drug use, harms and responses and willingness to think outside of traditional individual psychiatric and social casework paradigms.

Alexander M. Baldacchino and Barbara Broers

Content

Worldwide, around 271 million people (5.5% of the global population) aged 15–64 years, used illegal drugs at least once during 2017 [1]. These drugs predominantly include cannabinoids, opioids, cocaine and/or amphetamine-type stimulant (ATS) groups. Some 31 million people who use drugs suffer from drug use disorders (DUDs), meaning that their drug use is harmful to the point where they may need advice or treatment. Some 585,000 people are estimated to have died as a result of drug use in 2017. Opioids take a large share, accounting for 76% of deaths amongst people using drugs. About 11.3 million persons in 2017 have a recent history of intravenous drug use. This subgroup endures the greatest health risks with almost half of them living with Hepatitis C, 1.4 million living with HIV and one million living with both of these preventable conditions. The disability-adjusted life year (DALY) in 2017 attributable to illicit drug use was estimated to be 27.8 million. This was compared with tobacco use and alcohol use, accounting for 170.9 million and 85 million in the DALY [2].

Surveys on drug use amongst the general population show that the extent of drug use amongst young people remains higher than that amongst older people, although there are some exceptions associated with the traditional use of drugs, such as opium or khat. Most research suggests that adolescence (12 to 17 years old) is a critical risk period for the initiation of substance use and that substance use may peak amongst young people aged 18–25 years [1].

There have been steps taken at a global level to set strategies for response to the world drug problem. The Joint UN Ministerial Political Declaration and Plan of Action in 2014 [3] explicitly reaffirmed that DUD is a health problem with a need to further strengthen public health systems that are responsive to current and

emerging drug-related problems. The adoption of target 3.5 of the Sustainable Development Goals [4] also reaffirms this vision of strengthening the prevention and treatment of substance abuse, including narcotic drug abuse and harmful use of alcohol.

The outcome document of the special session of the United Nations General Assembly on the World Drug Problem held in 2016 [5] contains more than 100 recommendations on promoting evidence-based prevention, care and other measures to address both supply and demand. Additionally, World Health Organization (WHO) and United Nation Office for Drug Control (UNODC) have developed close collaborations to support the implementation of development of comprehensive, integrated health-based approaches to drug policies that can reduce demand for illicit substances, relieve suffering and decrease drug- and alcohol-related harm to individuals, families, communities and societies [6].

In order to benefit optimally from the international covenants and policy environment, a series of consultations with the WHO technical focal points from all member states was conducted. With close collaboration with sister UN and other international drug policy agencies, a framework to strengthen public health responses to drug and alcohol problems was agreed. The underpinning principles behind this framework include interventions that are evidence based, adopt a life-course approach, promote multi-sectorial action and observe standard of care across a continuum which is gender and culture sensitive. The drivers behind this framework include an active engagement of civil society that has the voices of both service users and care providers that value the protection and promotion of equity and universal rights to access optimal treatment and harm reduction interventions.

The framework incorporates five overarching strategic domains:

1. *Governance:* This includes the adoption of evidence-based and cost-effective interventions as part of the universal health coverage benefit package; develop and update evidence-informed national substance use policies and associated legislation with a strong public health component in consultation with stakeholders from public, private, as well as civil society sectors; set up an inter-sectoral coordination mechanism to facilitate implementation and monitoring of evidence-based substance use policies and legislation and allocate specific budget allocations within the health and welfare sectors to address prevention, management, rehabilitation, recovery and monitoring and evaluation of drug- and alcohol-use problems; develop programmes offering alternatives to incarcerate illicit drug offenders.
2. *Health Sector Responses:* Integrate screening and brief interventions for substance-use disorders and management of overdose in primary health care and emergency rooms; develop and strengthen specialised services for holistic and integrated management of substance use disorders, including pharmacological and psychosocial interventions; introduce and/or rapidly scale up the comprehensive package of services for harm reduction; ensure availability of essential medicines in management of substance-use disorders; facilitate and promote establishment of self- help and mutual aid groups and develop/strengthen capacity to conduct and utilise implementation research.
3. *Promotion and Prevention:* Embed universal substance-use prevention programmes in the broader health policies and strategies based on rigorous local needs and resource assessments and design and implement age-specific substance use prevention programmes in community, education and work place settings.
4. *Monitoring and Surveillance:* Identify a standard set of comparable core indicators to monitor the substance use situation including for inclusion in the existing surveys and develop a system for national substance use monitoring and surveillance system to collect and report core set of indicators using standardised data collection tools and methodologies.

5. *International and Regional Cooperation:* Promote active sharing of information and evidence between professionals and civil society organisations from countries of the region at national and international policy forums on substance use.

The second edition of this ISAM Textbook reflects the increasing importance of the interplay amongst policy, legal, quality and other governance-led standards within the field of addiction medicine as summarised by the above framework. The quality standards will be discussed by Marica Ferri et al. from the EMCDDA with ethical and legal aspects addressed by Ambros Uchtenhagen. Evidence-based policy can only be delivered if the appropriate methodologies are established. This will be addressed separately by Robin Room and Ambros Uchtenhagen.

However, one aspect that as yet has not been fully developed in the above framework is the global recognition to increase and improve our addiction medicine workforce. The framework recognises the need to develop capacity of personnel in health and social welfare sector for substance-use prevention, treatment, care and rehabilitation through integrating the component in preservice and in-service teaching/ training and as a part of continuing professional education/recertification processes. This is the International Society of Addiction Medicine's core mission and involves the long-term commitment from relevant stakeholders to improve undergraduate addiction medicine training and postgraduate specialisation in addiction medicine. This is most relevant to the future medical workforce who will increasingly be treating complex cases with multi-morbidities (mental and physical) directly or indirectly related to polydrug misuse and/or multiple dependencies (pharmacological and behavioural). Additionally, this is as equally relevant to other clinicians working in the field of addiction medicine who, with the medical workforce, are increasingly encouraged to work within an environment that encourages shared decision and multidisciplinary teamwork.

Training in addiction medicine needs to be both knowledge and competence based, especially when one reaches postgraduate/specialisation stage of the professional career [7]. This has been shown to influence positively the clinical, educational, information and research governance requirements to complex interventions. The result will be a competent and confident workforce that enables and sustains delivery of efficacious and effective health sector and culturally sensitive and non-stigmatising responses. Further challenges faced with establishing such a competitive-based informed learning environment are discussed by Nady el-Guebaly et al., Steve Gust et al., Christine Goodair et al. and Cor de Jong et al. separately addressing some of the solutions.

Good Practice and Quality Standards

54

Marica Ferri and Paul Griffiths

Contents

Abstract

The present chapter is aimed at enabling the readers to understand the methods and the available tools to ascertain whether an evidence-based recommendation is appropriate for real-world patients in specific contexts. In times of a wide availability of real-time information on potentially anything, it is crucial to develop an individual capacity for critical assessment of scientific literature including strategies to search for updated and reliable sources of evidence. The methods, the processes, and the practical meaning of the most popular tools for the promotion of quality are presented with links to current projects and free-of-cost resources for professionals. The ultimate goal of evidence-based medicine is to provide patients with the best possible interventions. To reach this goal, knowledge has to be translated into practice. Guidelines and standards are popular instruments to disseminate and implement evidence-based recommendations. Nevertheless, to implement them into specific contexts, some decisions are needed. The chapter includes a description of the main approaches used to adapt or adopt guidelines and standards.

Quality is never an accident. It is always the result of intelligent effort. There must be the will to produce a superior thing. —John Ruskin

54.1 Introduction

The promotion of quality of health and social interventions and the exchange of good practices are recognized as an important strategy both to improve the effectiveness of drug-related interventions and to ensure the efficient use of limited resources. Guidelines and standards, in particular, are among the most frequently used tools for the promotion of quality through the translation of knowledge into the daily practice of treatment of drug addiction. But publishing new guidelines and standards is not always needed; often the existing good-quality guidance documents can be adapted to suit a specific national or local context.

New disciplines focusing on methods for successful knowledge transfer to action, such as implementation science, translational science, and knowledge mobilization, have emerged. A common recommendation to successful implementation is the promotion of participation among all the stakeholders, starting with medical doctors and health professionals and including decision makers, patients and their families, and the public in general. It is therefore important that the professionals in the treatment of drug addiction are familiar with the terminology and the methods of quality promotion, as these are increasingly part of their daily activity.

The contents of the evidence base change rapidly, as new studies contribute to new results. This is why it is important to master the methods to ascertain whether a recommendation is appropriate for real-world patients in specific contexts. It becomes crucial to develop an individual capacity for critical assessment and to know where to search for updated and reliable sources of evidence. This chapter seeks to address these concerns. It describes the evolution from evidence base to implementation and provides details on the terminology and references for further reading. The methods, processes, and the practical meaning of the most popular tools for the promotion of quality are also presented here with links to current projects and free-of-cost resources for professionals, researchers, and patients. In particular, it details how time and resources can be saved by *adapting* or *adopting* already published evidence-based guidelines to specific needs and contexts. The current initiatives for the development of quality standards in drug addiction treatment at international and at the national level are described and compared, and for each of them, the links for free downloading of documents are included. To complement the information on implementation, the chapter includes also a description and references to some recent initiatives in the medical field, in which the participation of drug addiction treatment professionals is crucial but still not sufficient. All these initiatives are studying strategies to effectively communicate with decision makers and patients. In addition, two examples of the use of standards are compared more in-depth: one case as part of an accreditation system, and the other as support for implementation and the measuring of quality criteria.

54.2 From Knowledge to Implementation

54.2.1 Knowledge Translation into Practice: From Evidence to Change

The overall aim of good practice sharing and standards development is the achievement of improvement in the quality of treatment. Quality is not an abstract concept but rather an umbrella definition for a series of measurable achievements in the health and well-being of the treated patients.

"*Primum non nocere*" – first of all, do not harm –, the phrase attributed to the Hippocratic Oath, reminds us that the first aim of a health intervention is to avoid harm. And it is exactly with this intention that the pioneers of the evidence-based medicine called the attention on the discrepancies between research results and medical practice, which would have cost human lives [11]. According to their claims, the timely application to the practice of the results from clinical research would have saved many lives and reduced subsequent costs to society [16]. For example, randomized controlled trials proving the effectiveness of systemic glucocorticosteroids administered to pregnant women at risk of preterm delivery to reduce respiratory distress syndrome in newborn

babies were available already in the 1970s, but it took almost 20 years before this intervention became common practice [39].

The possible effect of the delay in the adoption of this practice was that a significant number of premature babies probably suffered and possibly died and needed more expensive treatment than was necessary [38].

The movement for the systematic collection of scientific results for dissemination outside the restricted circles of researchers and academics became known worldwide at the beginning of the 1990s [41] and was boosted by the foundation of the Cochrane Collaboration, an international organization aimed at helping "healthcare providers, policy-makers, patients, their advocates and carers, make well-informed decisions about health care, by preparing, updating, and promoting the accessibility of Cochrane Reviews" [10].

In 1998, an editorial group specifically devoted to the study of interventions for drugs and alcohol-related problems was founded with its base in Rome [13], and since then around 70 reviews on prevention, treatment, and harm reduction have been published and systematically updated.

The availability of good quality research on the effectiveness of treatment for drug problems has dramatically increased over the last years, even though important gaps remain to be bridged with evidence [47]. The availability of studies and systematic reviews nurtured the production of clinical guidelines as a major tool for the dissemination and application of evidence in practice.

For example, a survey for the identification of treatment guidelines in Europe identified more than 140 sets of guidelines for the treatment of drug addiction [18]. Nevertheless, the practical effects of such a massive effort to produce clinical guidelines were not clear. When measured, the impact on the quality of treatment seemed not impressive. Some surveys performed in the medical field, not specifically in the drug addiction one, showed that clinical guidelines are applied to practice in only 50–70% of day-to-day decisions, and the main reason given for not applying them is that they are of limited relevance to patients and healthcare staff [36]. Moreover, in a debate promoted by the British Medical Journal about the effectiveness of guidelines [23], it was pointed out that to ensure clinical guidelines have an impact on actual care and practice, activities beyond the mere production and dissemination should be instigated [21].

This type of considerations along with the need to reduce cost and improve quality and outcomes must be at the base of the evolution toward the *knowledge translation into practice* approach [5]. Moving from the concept of evidence to that of knowledge expands an idea already present in the definition of evidence-based medicine. The practice of evidence-based medicine integrates clinical expertise with the best available evidence from systematic research, explained David Sackett [41]. "Without clinical expertise, practice risks becoming tyrannized by evidence, for even excellent external evidence may be inapplicable to or inappropriate for an individual patient" reinforced. Probably "knowledge" is a better term to put together evidence with expertise. *Knowledge translation* has been defined as a "dynamic and iterative process that includes the synthesis, dissemination, exchange and ethically sound application of knowledge to improve health, provide more effective health services and products, and strengthen the health care system" [9]. Knowledge translation is not the only term that has been used to name this tendency toward the practical use of knowledge to improve practice. According to Straus et al. [45], more than 90 terms were identified in the literature. According to them, in Europe, preferences are for "implementation science" or "research utilization," whereas the terms "dissemination and diffusion," "research use," and "knowledge transfer and uptake" are more frequently preferred in the United States. The Canadian "knowledge translation" has been adapted by others, including the United States National Center for Dissemination of Disability Research and the World Health Organization (WHO).

The lowest common denominator among the above-described different terms is a move beyond the dissemination of knowledge into the actual use of it to transform practice. "Knowledge creation (i.e., primary research), knowledge distillation (i.e., the creation of systematic reviews and guidelines) and knowledge dissemination (i.e., appearances in journals and presentations) are not enough on their own

to ensure the use of knowledge in decision-making" [45].

A definition of the "best-practice" concept was recently developed by a group of European experts convened by the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA). In brief, best practice is the best application of the available evidence to current activities in the drug field. Several factors were identified as contributing to making an intervention qualify as "best practice." In summary, a best-practice intervention is based on the most robust scientific evidence available regarding what is known to be effective in producing successful outcomes, and it is tailored to the needs of those it addresses. Methods used will be transparent, reliable, and transferable and can be updated as the knowledge base develops. Concerning implementation, local contextual factors will be taken into account, and the intervention will be harmonized with other actions as a part of a comprehensive approach to drug problems. A best practice is closely linked to the concept of "evidence-based practice," and it requires the careful integration of both scientific knowledge and implementation expertise to appropriately adapt the intervention to the single individual and/or to a specific context. A best-practice intervention should provide better outcomes than other interventions and therefore also allow a rational allocation of resources [21].

There remain challenges associated with the promotion of best practice through guidelines, standards, and other similar tools. The first is to make sure that they are based on reliable scientific evidence and that they are regularly updated when new systematic reviews are published. The second is to make the best use of the currently existing guidelines. Finally, it is important to ensure that guidelines and standards are appropriately implemented.

54.2.2 Quality of Interventions: The Main Tools and Their Life Cycle

Clinical guidelines are the main instrument to disseminate evidence-based interventions via recommendations for practice that are based on a clear methodology for the appraisal, synthesis, and grading of the available evidence [12]. Evidence-based guidelines are produced by convening multidisciplinary groups of experts who systematically assess the quality of the available evidence and classify the recommendations according to the level of supporting evidence. The level of evidence is determined by a synthesis of relevant studies' design (systematic reviews), the number of participants studied, and the number of studies sharing the same results along with the overall measure of effect found by pooling the results of the studies. Each recommendation should be accompanied by an indication of its strength, which clarifies how and when this applies to the patients. Although the level of evidence influences the strength of a recommendation, there are conditions under which, even where there is a lack of evidence from studies, the appointed group of experts may attribute a high strength to some recommendations. This is the case for some interventions, such as hydration for hospital patients or blankets to prevent heat loss in trauma patients, that are supported by practical experience and do not need to be based on experimental evidence. Guidelines may, therefore, include a statement such as "we recommend that this intervention is offered to most patients, even though there are no studies which prove or refute the effects, and this recommendation is based only on expert opinion." In some milestone manuals for guidelines development, these are indicated as *good practice points* [44].

Another example is where patients cannot be directly studied for ethical reasons (such as exposing newborn babies to different drug therapies). In such cases, the recommendations can be based on the results of studies on other types of patients, by analogy. In practical terms, this system, which separates the level of evidence from strength of recommendations, produces two separate – but not completely independent – scores. In general, evidence-based guidelines are published by independent organizations that can assemble experts who are free from conflicts of interest and who represent different fields and professions. These groups generally involve as many stakeholders as necessary to ensure they

appropriately address all the different aspects of a question, including patients' preferences and practical concerns arising from the experience of the carers [18].

In 2000, a collaboration was established of people interested in addressing the shortcomings of the grading systems used in guideline development, "the grading of recommendations assessment, development, and evaluation" (GRADE) working group [26]. Over the years, this group has developed and continuously updated a common, sensible, and transparent approach to grading the quality of evidence and the strength of recommendations. This system has been adopted by several international organizations among which are the EMCDDA (the Best Practice Portal); the World Health Organization (WHO); Agency for Healthcare Research and Quality (AHRQ), United States; and the National Institute for Clinical Excellence (NICE) in the United Kingdom. The complete list of the organizations that have adopted GRADE can be found in its website (http://www.gradeworkinggroup.org/).

The evidence-based clinical guidelines are meant to facilitate the application of updated evidence to practice, and therefore, they are supposed to be timely revised. An indication of a specific date for revision should be stated clearly, and the choice of this date should be based on an assessment of the time in which new evidence is likely to be available.

This anticipation of a date for the availability of new evidence is in general possible because evidence-based clinical guidelines are based on systematic reviews of studies. These reviews are identified through structured "search strategies" based on a list of "clinical questions" that the guidelines should address. Based on those questions – which should be relevant to the patients and detailed enough to allow the appropriate search for the available evidence [42] – the methodologists search, identify, and select some systematic reviews of evidence. The latter are based on published and unpublished studies and should also identify – in ad hoc created registries [51] – the ongoing studies. Those registries collect information from the very beginning of the clinical studies and follow up each step until the publication. The entity (or the individual researcher) registering a clinical trial is requested to include a date of completion. Although these dates can be changed during the study period, they provide an idea when new results can be available.

Several tools have been developed to assess the quality dimensions in guidelines, one of them being the "appraisal of guidelines for research and evaluation" [1], which was created to address the issue of variability in guideline quality by assessing methodological rigor and transparency. The updated version, "AGREE II" (AGREE Next Steps Consortium [2]), is composed of six domains aimed at assessing whether or not the scope and purpose of the guidelines is clearly indicated; the stakeholders' involvement is sufficient to represent the views of the intended users; the process of development is rigorous; the presentation and text are clear; and the guidelines are fit for purpose and free from conflicts of interest.

Worldwide, there are currently several international inventories of guidelines that can be consulted to find relevant documents. Among those, the more important are the inventory maintained by the Guidelines International Network (http://www.g-i-n.net/library) containing over 6000 sets of guidelines for evidence-based healthcare (in multiple languages) and the National Guidelines Clearinghouse (http://www.guideline.gov/), an initiative of the Agency for Healthcare Research and Quality (AHRQ) in the United States, which publishes guidelines from any countries provided they are in English. The website of the National Guidelines Clearinghouse offers an automated function to compare different guidelines and obtain the synthesis of guidelines. The main aim of the inventories of guidelines is to avoid duplication of efforts making good quality guidelines available for adoption or adaptation in different contexts.

54.2.2.1 Adaptation of Guidelines to Everyday Practice Under Local Circumstances

Clinical guidelines can be elaborated and published at several levels: international, national, or local level. The World Health Organization, for

example, published guidelines and principles on the treatment of drug addiction [50].

Being a very resource-intensive activity, guidelines are in general commissioned to specialized national agencies that have the capacity for convening many stakeholders from all the involved parts and reduce the risks of conflicts of interest. Examples of agencies to develop clinical guidelines are the National Institute for Clinical Excellence in the United Kingdom; the Scottish Intercollegiate Guidelines Network; the Finnish STAKES, National Research and Development Centre for Welfare and Health; the French National Health Authority (HAS); the New Zealand Guideline Group (went in voluntary liquidation in 2012); the Canadian Task Force on Preventive Health Care; and many others. An indicative list of organizations that develop and publish guidelines is available on the website of the Guidelines International Network [25].

Guidelines that are published at a general level may require some further elaboration before they can be effectively applied to everyday practice. The translation of evidence-based recommendations into practice is the so-called implementation process.

Implementation activities can follow two general approaches mainly depending on the "distance" between the context where the guidelines were issued and that where they have to be implemented. In some cases, it is sufficient to *adopt* the guidelines through the development of protocols at the service level in which the guidelines' recommendations are broken down into actions and responsibilities, agreed by the healthcare personnel. This type of protocols (which can be also called *clinical pathways*) supplements clinical recommendations with hospital (or service)-specific details and, in some cases, can emend those recommendations which are considered not fitting with the local context [24]. These protocols can be disseminated in the realm of some peer-led educational activities, and they can include reminders and other initiatives aimed at reinforcing the application of recommendations in practice [7] (Table 54.1).

In other cases, an *adaptation* process is put in place, where the source guidelines are further analyzed by a group of local experts who draft new contextual-wise recommendations. Customizing clinical practice guidelines to a particular context and involving local stakeholders and the end-users of the guideline in this process have been identified as ways to improve acceptance and adherence [27]. In general, but not necessarily, the *adaptation* occurs when (inter) national guidelines are to be applied at the local level. In this case, the adaptation process can consider more than one set of guidelines and imply a process similar to the one needed for drafting a new guideline. The major difference lies in the search for source documents that, in the case of an *adaptation*, focus on guidelines rather than on systematic reviews of evidence (and or primary studies) as in the case of development of a new guideline.

ADAPTE (www.Adapte.org) is an international organization of methodologists, researchers, guideline developers, and guideline implementers who aim to promote the development and use of clinical practice guidelines through the adaptation of existing guidelines. The organization created a resource toolkit that can be freely downloaded in the Guidelines International Network website (www.g-i-n.net).

Quality standards are becoming an increasingly popular tool for ensuring the quality of interventions in healthcare. In general terms, standards are principles and sets of rules about what to do and what to have [6] presented as voluntary to many potential adopters. According to one of the most known organizations for standards development, a standard is a document, established by consensus and approved by a recognized body, that provides, for common and repeated use, rules, guidelines, or characteristics for activities or their results, aimed at the achievement of the optimum degree of order in a given context [28]. Typically, the standards proposed in the health field refer to content issues, processes, or structural (formal) aspects of quality assurance, such as environment and staffing composition.

Quality standards can be developed by private sector organizations as it is the case for the International Standards Organization [29]; national private, nonprofit organizations like the American National Standards Institute (ANSI); the Association Franc¸aise de Normalisations (AFNOR); and the British Standards Institute (BSI). The great majority of these organizations have been founded at the beginning of the twentieth century and some after the Second World War. Standards can also be developed by international governmental organizations like the United Nations, the Organization for Economic Co-operation and Development, and the European Union. Standards are a good way to propose harmonization, especially by those organizations whose members are sovereign states that cannot be obliged to follow some rules [6]. Nevertheless, there are also several national organizations, especially in the health field, which develop quality standards. In the case of these organizations, quality standards are intended as sets of rules based on evidence and used to implement the interventions recommended in clinical guidelines. The standards which are developed by the National Institute of Clinical Evidence in the United Kingdom, for example, are typically composed of a general statement and a measure that can be used to assess the quality of care or service provider specified in the statement. "The quality statements are clear, measurable and concise and describe high-priority areas for quality improvement. They are aspirational (they describe high-quality care or service provision) but achievable" [34].

Several international organizations are undertaking standards development for health interventions in drug demand reduction.

The European Commission financed a study on the Development of a European Union Framework for minimum quality standards and benchmarks in drug demand reduction (EQUS) [43], proposing a set of 22 quality standards for treatment (the study included also 33 standards for prevention and 16 for harm reduction).

According to the background paper of this project, in the medical sciences, quality standards are determined by different stakeholders: health authorities, insurance companies, service providers, professionals, and patients. Each of these

professional categories brings different goals, interests, and priorities that need to be reflected in the standards in the light of the underlying scientific evidence. The project, whose lead investigator was Ambros Uchtenaghen [48], divided the quality standards into three dimensions:

1. *Structural quality*, for example, standards relating to the physical environment, staff, training, etc.
2. *Process quality*, for example, standards relating to the process of an intervention, diagnostic assessment
3. *Outcome quality and economic quality*, for example, standards to measure the cost-benefit ratio

The *structural standards for services* cover areas like the physical accessibility of treatment services (which need to be located in places easily reached by public transport) or the environment where the treatment takes place, which should be adequate (to allow privacy during consultations) and safe. Another important aspect is the need for a documented diagnosis as a basis for treatment choice. Staff education and composition are also mentioned in terms of ensuring the presence of medical and nursing staff along with psychologists or social workers and multidisciplinarity with at least three professions represented.

The *process standards at the service level* included the assessment of substance use history, diagnosis, and treatment history along with the somatic and the social status for each patient including an assessment of the psychiatric conditions.

Each patient should be provided with information on the treatment options available and should be provided with a treatment plan tailored to his/her individual needs.

Treatment plans, assessments, changes, unexpected events, and any relevant information should be recorded and kept confidential. Each treatment service should promote cooperation with other agencies and services to ensure an appropriate response to the needs of their patients (whenever a service is not equipped to deal with all needs of a given patient, another appropriate service is at hand for referral) and should ensure continuous education for the staff members.

The *outcome standards proposed at the system level* included the goals of health and social stabilization of patients and the reduction of illegal or non-prescribed psychotropic substances. Monitoring included the level of utilization (each service should provide information on the number of slots or bed utilized) and the ratio of discharges occurred as planned or for different reasons.

Internal and external evaluation of services was also proposed as a standard.

Beyond the list of proposed standards, the project-added value lies in the process adopted to consult the stakeholders and to identify several levels of standards. Namely, the stakeholders were interviewed by rounds of Internet-based consultations about the level of implementation status and acceptability of the proposed standards in their respective countries. Through this strategy, it was possible to identify a long list of standards and grade them by priority of implementation. The European Minimum Quality Standards (EQUS) study also included a review of existing quality standards already implemented at the national level, involving experts from 24 European countries. Concerning drug treatment processes, the standards most frequently reported as already implemented were in the areas of client data confidentiality and assessment of clients' drug use history, whereas the standards concerned with routine cooperation with other services, and those focusing on continuous staff training, were less often implemented. In the area of treatment outcomes, the two types of the standard most frequently reported as implemented were those with goals linked to health improvement and reduced substance use. Among the standards less likely to be applied were those focusing on external evaluation and monitoring client discharge; problems related to the implementation of these standards were reported.

This approach may allow the participating countries to set their own goals and to pace their achievement according to their own capacity and

priorities. This process would also be greatly facilitated by the existence of the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA), a decentralized agency whose aim is to provide sound and comparable information on drugs in Europe. Thanks to its impartiality and comprehensiveness of information, EMCDDA can support the countries volunteering for the adoption of the quality standards in setting their goals and measuring their successes.

In September 2015, the Council of the European Union adopted Council conclusions on the implementation of minimum quality standards in drug demand reduction in the EU. The list of 16 standards was the result of an initiative of the Italian Presidency that, taking over the priority of defining quality standards based on the project EQUS, set by the Greek Presidency, convened a group of European experts. The expert group cross-analyzed different sets of international standards, comparing them against the principles of the European Drugs Strategy.

These standards represent a minimum benchmark of quality for interventions in: drug use prevention, risk and harm reduction, treatment, social integration, and rehabilitation. Although non-binding for national governments, the document represents the political will of EU countries to address demand reduction interventions with an evidence-based approach. These guidelines have been drawn up in the context of Action 9 of the EU Action Plan on Drugs (2013–2016) (Table 54.2).

In general terms, it can be observed that the existing standards (at their different level of implementation) seem to be triggered by several reasons: the harmonization of the existing services, the translation in practice of the evidence-based guidelines, the consistency between policy decisions and service provision, and the need to measure the results of interventions. These reasons are diversely reflected in the initiatives mentioned mainly about the level, where the standards are proposed. The life cycle of quality standards depends on the supporting evidence, but not completely. When it comes to human rights or general safety measures, the relevant principles are imperishable.

Clinical pathways are structured, multidisciplinary plans of care designed to support the implementation of clinical guidelines and protocols. In the recent past, it was considered that this definition was variedly interpreted by different stakeholders until a recent systematic review [31] clarified the concept.

The clinical pathways are essential to the translation of evidence-based guidelines at the service level. They are meant to "detail essential steps in care of patients with a specific clinical problem" and sequence "the actions of a multidisciplinary team" [14]. In clarifying which actions should be undertaken to practice evidence-based recommendations, clinical pathways "facilitate translation of national guidelines into local protocols" [8] and allow continuous improvement by monitoring and evaluating variances.

Clinical pathways are commonly adopted in the United States, where, in 2003, it was reported that almost 80% of the hospitals used this tool [31]. Evidence supports the adoption of clinical pathways at the hospital level for the reduction of

Table 54.2 Processes for the adaptation of guidelines at the local level

Document	Process	Professionals' involvement	Output	Definition
Guidelines (national or international)	Adoption	Service personnel	Service protocol/ clinical pathway	A comprehensive set of rigid criteria outlining the management steps for a single clinical condition or aspects of the organization (http://www.openclinical.org/guidelines.html#gandp)
Guidelines	Adaptation	Stakeholders	Locally adapted guidelines	The local adaptation of national guidelines has been proposed as a way of increasing the benefit of local ownership while maintaining scientific validity [30]

in-hospital complications (such as infections, bleeding, and pneumonia), improved documentation, and possibly a reduction in the length of stay [40]. An experience of integrated clinical pathways in mental health has been reported in Scotland, where the National Health Service (NHS) Scotland is taking a national approach to improving the quality and safety of mental health services. The program started with the publication of national standards by NHS Quality Improvement Scotland (NHS QIS), setting out the framework for development at the local level.

The emphasis of development and implementation of the ICPs lies with local NHS boards to ensure they are developed with local ownership and to meet the needs of the local population. However, to ensure accreditation by NHS QIS, the local ICPs must incorporate the national standards and evidence improvement to the quality of care provided [17]. In Belgium, there is the European Association for the development of clinical pathways (http://www.e-p-a.org/about-epa/index.html). Among the objectives of this organization, there is the setup of an international network for pooling know-how on clinical pathways and the promotion and fostering of international cooperation between healthcare researchers, managers, and healthcare providers from European countries and the wider international community. The association has a journal that publishes research results on the development of clinical pathways.

54.2.3 Participation: A Key for Successful Implementation

Two core elements underlie all the instruments for quality improvement mentioned above (evidence-based clinical guidelines, quality standards, and clinical pathways): (i) the evidence base and (ii) stakeholders' consensus. The last three decades have been devoted to define and share a valid methodology for the identification assessment and synthesis of the available evidence. This activity successfully brought to a general understanding of the terminology and the sources of correct information. Nowadays the role of evidence to base decisions is widely recognized, and the access to good quality sources of evidence is increasingly available.

The new challenge seems to lie on the promotion of an authentic participatory implementation of evidence-based interventions.

The same pioneers of the evidence-based medicine are now exploring strategies to communicating and involving two crucial stakeholders: the decision makers and the patients (this latter category includes also family members, civil society organizations, community representatives [15]). Projects like SUPPORT, financed by the European Commission's 6th Framework Programme [32], and the most recent DECIDE [46], co-funded by the European Commission under the Seventh Framework Programme, are both aimed at supporting decision makers in the use of evidence.

SUPPORT targets policymakers as a diverse group that includes cabinet members (e.g., Ministers of Health or Finance), elected officials (e.g., chairs of legislative committees), senior civil servants (e.g., directors of primary healthcare programs), and high-level political appointees (e.g., heads of government agencies). In spite of being aware of the differences that can exist among the countries due to the different political systems, the leading project managers of SUPPORT state that what all the decision makers have in common is the authority to make or influence decisions directly. The project encompasses several tools for boosting evidence-based decision making in various settings including low- and middle-income countries and high-income countries. As the other mentioned project, DECIDE, also SUPPORT, sought strategies for the involvement of the public in evidence-based decision making [35]. In particular, DECIDE, whose target is Europe, is composed of eight work packages, three of which are devoted to identifying best strategies to communicate with specific target groups such as health professionals, policymakers and managers, and patients and public.

The two projects have similar objectives though following different approaches: DECIDE focuses on guidelines and recommendations,

while SUPPORT aims to support policy-relevant reviews and trials. DECIDE on the other hand is developing tools that will help policymakers to decide about, say, whether to pay for particular healthcare innovation in their region. Additionally, it is developing tools to make understanding the research information that forms the basis for guideline recommendations easier for a wide audience, including policymakers and the public. To some extent, DECIDE builds on the work of SUPPORT.

Even though these projects are important, quite often the exercise of knowledge translation brings to the appreciation of huge gaps in knowledge, gaps that are difficult to fill with methods for gathering consensus and taking decisions in the lack of evidence. The only possible way forward to fill those gaps is to propose new studies to find answers. These new studies should rely on mixed methods to get sound evidence from several sources and, of course, to be based on the priorities of the end-users of the answers they should provide, such as the patients [33]. In the United Kingdom, Sir Iain Chalmers, one of the founders of the Cochrane Collaboration, has undertaken a new initiative for the proactive involvement of patients in the setting of research priorities through the James Lind Alliance initiative (Petit-Zeman S FAU – Cowan and Cowan [2]). The James Lind Alliance brings together patients, carers, and clinicians to identify and prioritize the uncertainties, or "unanswered questions," about the effects of treatments, which they agree are most important, and makes the list of research questions public and available for researchers and research funders. Not always is the area of addiction represented in these initiatives. The main linkages are granted by the Cochrane Group on Drugs and Alcohol and by the European Monitoring Centre for Drugs and Drug Addiction which is working in partnership to bring the typical problems of this field in the broader perspective of knowledge translation.

Some of the characteristics of the drug addiction field can be shared by other medical conditions. For example, the behavioral component calls for research that cannot be only based on experimental studies. An important aspect of knowledge can be found in long-term observational studies, and in some cases, they require qualitative analysis which is more difficult to be systematically retrieved with the typical search strategies adopted in systematic reviews and even more difficult to be assessed for quality and included in the meta-analysis [22]. Nevertheless, there are some added values in the drug addiction field which compensate for those extra efforts. The impact of interventions on public health and security makes drug addiction an important point on every political agenda and needs to be based on the best available evidence.

54.2.3.1 Implementation Strategies

In recent years, it became clear that implementation is key to effective evidence-based interventions. Particular attention has been paid to the identification of strategies to implement interventions in specific contexts and for specific targets. The implementation of evidence-based interventions can be particularly challenging in the case of drug-related interventions for a number of reasons: (i) these interventions involve not only health but also social and policy elements; (ii) some drug-related interventions are highly controversial, as is the case with drug consumption rooms, for example, and (iii) they involve all relevant communities.

For these reasons, it is helpful to consider the lessons learnt in other fields, that is, not only in health but also in education, social work, and so on [20]. For example, Powell et al. (2015) consulted experts through a DELPHI consultation and identified 73 strategies for implementing interventions in education [4]. The list of actions and strategies proposed by the experts included:

- Obtaining funding
- Using train-the-trainer strategies
- Creating new teams
- Obtaining formal commitments
- Changing physical structure and equipment
- Developing tools and processes for the monitoring of quality
- Promoting ongoing consultation
- Using data experts
- Working with educational institutions

A prerequisite for implementation is the setting of objectives and measurable outcomes; tools such as Support and DECIDE, mentioned above, support this exercise. Another important aspect to consider is that the process of implementation can be also assessed through dimensions such as the implementation climate in an organization; the degree to which an evidence-based practice is adopted over time; the level of fidelity with which an intervention is implemented by staff; or the costs of an implementation process [4].

The deeper reflection on the importance of implementation resulted in the establishment of several initiatives and collaborations around the world. Examples include the Society for implementation research collaboration (SIRC http://societyforimplementationresearchcollaboration.org) and the European Implementation Collaborative (https://implementation.eu/). These initiatives are devoted to improve the implementation of evidence-based interventions by facilitating communication and collaboration between implementation research teams, researchers, and community providers. They hold conferences and develop tools and materials to facilitate implementation. A large number of aspects are covered in these resources, some of which are developed by other researchers and made available on institutional websites. Topics covered span from measuring the fidelity of implementation to dimensions needed for effective changes, decision-making tools, and evaluation tools.

54.2.3.2 Training Initiatives

The training of professionals is a central element for the implementation of good quality interventions. Training sessions can address behavior change as well as skills to deliver specific interventions. A recent example of training for professionals is the Universal Prevention Curriculum, which was adapted to the European context through a European-funded project (UPC-ADAPT).

Many European countries offer training programs for intervention providers. These range from specialist university programs, as it is the case in Germany and Czechia, to specific courses offered in many countries as part of the university curricula for health or social welfare degrees.

54.2.4 Examples of Frameworks for Quality Standards

Several evidence-based guidelines, issued at the international and national levels, are currently available for the treatment of drug addiction, in particular for the combined pharmacological and psychological approaches to opioid dependence. Quality standards are also becoming widely available, and combined also with training initiatives for professionals. As the majority of quality standards have been developed in the context of prevention, the first training initiatives target prevention professionals [19].

Two examples of national quality standards for drug addiction treatment in Europe can be drawn from Czechia and the United Kingdom.

In Czechia, the implementation of quality standards for the treatment of drug addiction dates back to 1995 for an initiative of the Interdepartmental National Drug Commission (now Government Council for Drug Policy Coordination). Called minimal standards, these were adopted by the Association of Non-Governmental Organizations (ANO) for Addiction Prevention and Treatment for evaluating the quality of member organizations and newly established facilities. After further elaboration occurred in the subsequent 4 years, those standards became the basis for a certification process, which recognizes that a specific service provider is in line with predefined quality standards. Since 2004, the adherence to quality standards has been assessed by specifically trained external evaluators. The current process for the certification of treatment providers was kicked off in 2005, and it included a transition period to allow the treatment provider services to start the certification process. After that period, certification became a prerequisite for applying for state grant programs. The overall aim of the certification process was the improvement of the quality of the network of services including a cost-effective

administration of public funds. With the certification process came the integration of drug addiction services into the medical and social national system.

The underlying principles are as follows: (i) voluntariness – certification is not required to provide drug services but only to apply for public funds; (ii) transparency – the evaluation process is carried out according to published criteria; and (iii) objectivity – the actual evaluation of quality is performed by an independent agency who appoints trained evaluators, and the facility providers can point out any possible conflict of interest.

The standards are at the base of the certification and accreditation process. The core activity of the certification process includes that a group of trained assessors visit the service providers to collect relevant information. Active participants in this process are the facilities requesting the certificate of quality (those wishing to apply for public funds); the certification agency (an independent institution that arranges on-site examinations, communication between the parties of the certification processes, and training of certificators); the certification team carrying out on-site examinations (composed by at least three trained certificators); the Certification Board of the Government Council for Drug Policy Coordination (deciding about certification request results and validity of certification ranging from 1 to 4 years); and the Executive Board of the Government Council for Drug Policy Coordination – to which the facilities can address their complaints about, for example, the composition of the certification team. Before the certification can start, the agency and the requesting facility have to agree on the date and the composition of the team of assessors. Subsequently, several previously identified employees and clients are interviewed with semi-structured questionnaires. The on-site examination, in general, lasts 1 day, at the end of which the team of assessors drafts a report with a proposal for certification or suggestions for improvement. The report is shared with the interested facility, which is allowed to comment in writing.

The report is therefore completed and forwarded by the certification agency to the Certification Board of the Government Council for Drug Policy for the final decision.

Overall the process takes around 2 months, and the facilities requesting certification have 15 days to contest the results.

In the United Kingdom, the National Institute for Clinical Excellence (NICE) publishes evidence-based clinical guidelines for many different medical disciplines including drug addiction. Sets of quality standards are derived from the best available evidence such as NICE guidance and other evidence sources accredited. They are developed in collaboration with NHS and social care professionals, their partners, and service users. The standards consider issues like evidence of effectiveness and cost-effectiveness, people's experience, safety, equality, and cost impact. The quality standards are considered central to supporting the government's vision for an NHS and social care system focused on delivering the best possible outcomes for people who use services [37]. This act clarifies that the Secretary of State "must have regard to the quality standards prepared by NICE." The care system should consider those standards in planning and delivering services to secure continuous improvement in quality. NICE quality standards do not provide service specifications but rather define priority areas for quality improvement. Nevertheless, those standards are the basis to ensure that the providers of health and adult social care in England meet the standards of quality and safety required by the Care Quality Commission.

The standards developed by NICE are typically composed of a general statement complemented by a measure. These quality measures are drafted only after the quality statement wording has been agreed and addresses the structure of care or services, process of care or service provision, and, if appropriate, outcome of care or service provision. The majority of measures refer to process and are expressed as a numerator and denominator to define a proportion, in which the numerator is a subset of the denominator popula-

tion. For example, for the standard "People who inject drugs have access to needle and syringe programmes in accordance with NICE guidance," there is a measure at the structure level, which is "Evidence of local arrangements to ensure people who inject drugs have access to needle and syringe programmes in accordance with NICE guidance," complemented by a measure of outcome: (i) proportion of people who inject drugs who access needle and syringe programs, wherein the numerator is the number of people who access needle and syringe programs and the denominator is the estimated prevalence of injecting drug users and (ii) incidence of blood-borne viruses among people who inject drugs.

To clarify the implications of the standard, a breakdown of meanings of the standard for each stakeholder is included: service providers ensure systems are in place for people who inject drugs to have access to needle and syringe programs in accordance with NICE guidance; needle and syringe program staff ensure people who inject drugs have access to needle and syringe programs in accordance with NICE guidance; commissioners ensure they commission services for people who inject drugs to have access to needle and syringe programs in accordance with NICE guidance; and people who inject drugs have access to needle and syringe programs that are nearby, have suitable opening hours, and provide injecting equipment and advice on reducing the risk of harm. The standards include also that the sources of data be considered in the measurement. Furthermore, at NICE, there is an implementation team to support key audiences and organizations to maximize the uptake of guidance and quality standards. The team assesses the aids and barriers to implementation and provides practical support tools for commissioning, service improvement and audit, education, and learning. The team prepares reports on the uptake of guidance that are used to inform the development of the quality standard. The implementation team collaborates with national bodies and local organizations, through local implementation consultants, to support the use of quality standards and to facilitate shared learning. Overall, the process to produce standards at the National Institute for Clinical Excellence lasts indicatively for 42 weeks.

These two examples suggest the possibility of different approaches to the use of quality standards. In the Czech experience, the development of the standards represents an initial effort, whereas the actual focus seems to lie on the certification and accreditation process including several levels of training and a "learning by experience" process. Furthermore, the entire experience initiated around 20 years ago has been conceived and developed specifically in the treatment of drug addiction.

On the other hand, the National Institute for Clinical Evidence has created, along with the Department of Health and other key partners, a core library of topics for quality standard development in health-related topics, among which alcohol dependence and drug use were included. In this case, the focus seems to be on the development itself of the standards which *translate the evidence-based guidelines* into general statements and measures of outcomes at the system level including the indication of the sources of data to be used for the assessment of the implementation. Furthermore, NICE offers the support of an implementation team to enhance local adoption initiatives.

54.3 Conclusion

Quality of intervention is entrenched to the evidence base, and in the last 20 years, important progress has been made in the availability of good quality systematic reviews of effectiveness in the field of drug addiction treatment. Nevertheless, important gaps in knowledge still exist and need to be addressed by further investment in research. To ensure that research answers concrete problems arising from the daily experience of those affected by the drug problems at several levels, it is crucial that the end-users of research results – such as practitioners, patients, and decision makers – are involved in the selection of priority for investigation.

Currently, the attention seems to be focused on how to better communicate evidence to policymakers, patients, and the general public. The achievement and maintenance of quality in the treatment of drug addiction need the participation of all the stakeholders. The agencies providing data to assess the current situation and set the future goals, the decision-makers at the system level, and those managing the local, regional, and national services, have to collaborate with the practitioners to offer the best possible treatment to the drug users. The drug users, the families, and the public have to proactively be involved in any decision and should be able to speak out their needs and problems.

The tools to translate evidence into the quality of treatment have to be understandable by all the relevant stakeholders to empower them in a reiterative process of testing and learning lessons.

Quality is a continuous process where each new achievement has to be seen as a step toward new goals.

Glossary

Accreditation is the process by which an institution delivering a service is independently assessed for quality against some predefined criteria. Accreditation requires a set of minimum standards, which are set by the accrediting body.

Benchmarking is the process of comparing service processes and performance metrics to best practices from other services. Dimensions typically measured are quality, time, and cost.

Clinical pathways are structured, multidisciplinary plans of care designed to support the implementation of clinical guidelines and protocols.

Guidance is a general term that covers documents such as guidelines and quality standards.

Guidelines are "statements that include recommendations intended to optimise patient care that is informed by a systematic review of evidence and an assessment of the benefits and harms of alternative care options" (Institute of Medicine 2011). They are designed to assist carers' and clients' decisions about appropriate interventions in specific circumstances.

Protocols in general, are documents that specify the procedures to follow to perform some tasks, typically those used to conduct a study or to implement some guidelines at the individual service level.

Standards and quality standards are principles and sets of rules based on evidence [6], which are used to implement the interventions recommended in guidelines. They can refer to content issues, processes, or structural (formal) aspects of quality assurance, such as environment and staffing composition. In some cases, standards are legally binding.

The United Nations Drug Conventions: Evidence on Effects and Impact

55

Robin Room

Contents

Abstract

The three international drug treaties cover many psychoactive substances ("drugs"), although not tobacco (now under a separate treaty) or alcohol. They include a penal regime to enforce the limitation of use to medical or scientific purposes, a trade regime concerning drugs for medical use, and a planning scheme to ensure adequate supplies of medical opiates. The system, initiated in 1912, had shifted its main focus by the time of the 1988 treaty to combating the illicit markets, which accompany a prohibitory system. The place of the drug treaties in the United Nations system and the bodies which make up the system are briefly characterised. Nearly every country has signed each treaty, though often with reservations. The option this opens up of denouncing and re-acceding with reservations has also been successfully used by Bolivia concerning coca leaves. The system has assured access to pain medication in most high-income countries, but not in much of the world, where the system's emphasis on law enforcement has often indirectly but effectively cut off supplies. In terms of controlling legal medical markets, the system has had mixed success. But the

system has mostly failed in cutting off the illicit drug trade. In a system that has been committed to a prohibitory approach, there are recent signs of change, particularly in the Americas; the legalisation of cannabis in Canada and much of the USA poses a new challenge to the status quo in the international system.

55.1 Introduction

The United Nations drug control system is organised around three international treaties: the Single Convention on Narcotic Drugs of 1961, as amended by a Protocol of 1972; the Convention on Psychotropic Substances of 1971; and the UN Convention against Trafficking in Narcotic Drugs and Psychotropic Substances of 1988. Their texts, and the official commentaries on them, are conveniently available online: https://www.unodc.org/unodc/treaties/index.html

The treaties, of course, do not cover the whole range of psychoactive substances. There is a separate treaty on tobacco, the Framework Convention on Tobacco Control of 2003, negotiated under the auspices of the World Health Organization (WHO), and an International Convention against Doping in Sport (many of the substances covered by it are psychoactive), which was adopted in 2005 under the auspices of UNESCO. Notably absent from the list of substances under international control is alcohol, although it was actually the subject of the first international drug treaty, controlling "trade spirits" in colonial Africa, negotiated in 1889 but now in abeyance [8]. The 2012 WHO Expert Committee on Drug Dependence briefly discussed whether alcohol would qualify for listing under the UN drug conventions, but though this was referred for consideration at a future Expert Committee meeting [30:16], as of 2019 this has not occurred.

From the perspective of the inherent harmfulness of different psychoactive substances (e.g. [19]), what is included and excluded in the three "drug treaties" is not easily defensible, except as reflecting the vagaries of history. But despite the ongoing convergence in scientific thinking about psychoactive substances [10], it is still true that discussions of international drug control which take account of the whole range of drugs and their regulation are rare (for an exception, see [7]).

In this chapter, however, attention remains focused on the three UN drug treaties. We consider the intended functions of the treaties, the institutional arrangements for their implementation, and what evidence is available on effects and impact of the system. A brief discussion of potential future developments is also included.

55.2 Intended Functions of the Treaties

The treaties have three main functions: as a penal regime to enforce limitation of use of scheduled substances to medical or scientific purposes; as a specialised trade treaty, controlling international trade in psychoactive substances for medical use; and as a central planning scheme to ensure adequate supplies, particularly of opiates for medical use.

55.2.1 A Penal Regime to Enforce Drug Prohibition

The Single Convention, as its name conveys, replaced an array of treaties and protocols, which had accumulated since the first opium treaty, the Hague Convention of 1912. But the Single Convention went well beyond what was in the previous treaties, signalling a change in the system's orientation [9]. Whereas the prime concern of the previous treaties had been with regulating international trade in plant-derived drugs (opiates, cocaine and cannabis), the 1961 Convention introduced requirements that possession and

delivery, along with a wide variety of market-related actions concerning the drugs covered, be criminalised under a country's domestic laws [4]. What had been a system concerned primarily with controlling international movement of drugs became a system committed to enforcing prohibitions on nonmedical use of the drugs, with each country's criminal laws as means of enforcement. The international prohibition system, as it now exists, can thus be said to have begun with the 1961 treaty.

The 1971 treaty greatly expanded the scope of the system by including a wide range of synthetic substances, many of them with pharmaceutical uses. The market controls in the 1971 treaty are weaker than those in the 1961 treaty, reflecting the powerful influence of the pharmaceutical industry on the treaty negotiations [18]. The requirement concerning criminalisation under domestic law is more simply stated than in the 1961 treaty, requiring penalisation of "any action contrary to a law or regulation adopted in pursuance of its obligations under this Convention". Since the Convention requires a medical prescription to authorise use of a covered drug, any possession or use without a prescription should thus be criminalised.

The 1988 treaty, as its name reveals, represented a further shift in the system's focus, with more attention focused on combatting the illicit markets which had emerged as a by-product of the prohibition system, including, for the first time, controls on precursor chemicals used in the preparation of controlled drugs. But, in an effort to eliminate any remaining ambiguity, it also included a further provision on criminalisation at the level of the individual drug user: that a signatory country should "establish as a criminal offence under its domestic law, when committed intentionally, the possession, purchase or cultivation of narcotic drugs or psychotropic substances for personal consumption".

The system of treaties inaugurated by the 1961 Convention, then, has as a main goal the elimination or at least suppression of any nonmedical use of drugs, aiming to eliminate illicit markets in drugs by a five-pronged approach: (1) particularly for drugs covered by the 1961 treaty, by restriction of the supply of the drugs, limiting production to the estimated medical need for the drugs; (2) by a system of export and import permits, restricting legitimate trade in the drugs in accordance with a receiving country's wishes; (3) by requiring that most substances covered by the treaties be in a prescription system, as a way of confining availability to medical control and use; (4) by criminalising production, sale, and other market activities outside those permitted for drugs for medical use; and (5) by criminalising users for purchase or possession of drugs other than for medical purposes.

55.2.2 A Trading and Marketing Control Regime

The treaties also set up a trading and marketing regime, a special kind of trade treaty which aims more to structure and direct international trade, rather than the more usual main aim of trade treaties – to facilitate trade. Requiring that an import permit be issued by the receiving country before drugs can be shipped to it means that a country can control and indeed cut off the legal supply of a drug to its residents.

Although the drug treaty system was established before the formation of the current system of international trade treaties, it has served an informal function of protecting the substances under its jurisdiction from any trade disputes seeking to open up markets for controlled drugs. This contrasts with the situation for alcohol and tobacco [3, 21, 26].

55.2.3 A Central Planning Scheme to Supply Medical Needs

Particularly through the 1961 treaty and its predecessors, and particularly for opiates, the international system is intended to ensure that supplies of opium-derived drugs for medical use are available globally. Each signatory country is supposed to send to the International Narcotics Control Board (INCB) annual data on medical use of opioids and estimates of requirements for the next

year. There is a system of permits for countries to grow opium to meet the demands of the medicinal market (in the mid-2010s, around half the legal supply was grown in Tasmania – [14]). Particularly with respect to opium, the aim is to create a globally controlled system of cultivation, manufacture, and supply, which will ensure that medical needs, everywhere, for opioid medications are met.

55.3 Institutional Arrangements for Implementation of the Treaties

In the United Nations system, the drug treaties come under the jurisdiction of the UN's Economic and Social Council (ECOSOC), which serves as the final deciding body for issues, such as the scheduling of drugs under the treaties, and determines whether a conference should be called to consider amendments to the treaties. The political body governing the drug system is the Commission on Narcotic Drugs (CND), with 53 member states elected by ECOSOC, but with proceedings open to attendance by other UN member states. The CND meets annually for several days in March in Vienna, in proceedings including plenary sessions, a Committee of the Whole for the discussion of proposed resolutions, and committee meetings. Each year, the CND adopts resolutions following discussions which are often lengthy, since its decisions are customarily made by consensus.

The administrative body for the system is the UN Office on Drugs and Crime (UNODC), which has responsibility also for the two UN crime treaties (on transnational organised crime and against corruption). UNODC has a limited "regular budget" as part of the UN system, and relies, for 90% of its funding, on "voluntary contributions", mainly from governments. Since these contributions are usually earmarked for specific projects, donor countries have a large say in determining the directions of the UNODC's work. In 2012, UNODC had about 500 employees, spread around the world – a smaller number than the US Drug Enforcement Agency had posted outside the USA [25].

The International Narcotics Control Board (INCB) is a board consisting of 13 individual members elected by ECOSOC, 3 of them from a list of 5 nominated by the World Health Organization. They are supposed to serve as independent experts, not as representatives of any state; a unit within the UNODC serves as the INCB's secretariat. In addition to technical duties such as running the international market for opiate medications, the INCB has regarded itself as the "guardian of the treaties", issuing an annual detailed global report on the state of compliance as the INCB defines it [5].

The World Health Organization also has responsibilities, under the 1961 and 1971 treaties, for providing scientific and medical expertise, particularly concerning the classification and scheduling of psychoactive substances under the Conventions. According to the 1971 Convention, its assessments "shall be determinative as to medical and scientific matters". These responsibilities are primarily assigned to the Expert Committee on Drug Dependence, which is supposed to be constituted every 2 years for a process involving first pre-review and then 2 years later a detailed review concerning classification of particular substances. However, the meetings were less frequent in the decade of the 2000s, due to WHO's limited resources, but have become annual since 2014, with two meetings in 2018. Recognising that the present scheduling of many substances had not been re-examined in the light of scientific and other developments for many years, an Expert Committee meeting proposed that each scheduled substance be re-reviewed every 20 years; the first ECDD review ever on cannabis was conducted in late 2018 [17], recommending that cannabis be rescheduled under the treaties to legitimate medical use. The ECDD is also charged with tackling classification of the diverse category of new psychoactive substances, of which 750 have been reported to the system since 2009. Despite the increased frequency of meetings, resources remain inadequate for the tasks the ECDD system is assigned. An ECDD meeting has also pointed out that the language of the Conventions does not map easily onto current scientific language concerning drugs [30:16, 23–35].

Over a number of years, the drug treaty system and the WHO drifted apart. A signal of this has been the divergence between the CND and WHO's Expert Committee on scheduling of specific substances [1:213–214, 2:232]. Another signal of the division had been over the place of harm reduction in the treatment of drug problems. In public health in general, the reduction of harm is a central commitment and strategy, and as the global public health agency, WHO was necessarily committed to its promotion. However, prior to 2009 the USA had insisted that the concept and term "harm reduction" not be used in the work of the international treaty agencies. After 2009, relationships between UNODC and WHO improved again, including joint work on treatment guidelines [25]. But in general, the UNDCP has operated in substantial isolation from other UN bodies [2:237].

55.4 What Can Be Said About the Effects and Impact of the System?

One measure of the success of the system is its near-universality, in terms of formal adherence to the treaties. Each year's INCB report notes with some pride the tally of countries which are signed up to each treaty. The desire for universality triumphed in the case of Bolivia's denunciation and reaccession to the 1961 treaty, despite disapproval by the INCB and other guardians of the system. Bolivia took this route to add a reservation to the treaty, which would then allow Bolivians to chew coca leaves without contravening Bolivia's treaty commitments. Thwarted in an attempt to make this change by international consensus, Bolivia denounced (announced its withdrawal from) the treaty, proposing to reaccede with a reservation concerning coca-chewing if the reservation was accepted [23]. If one-third of countries acceding to the treaty had objected, Bolivia's reaccession would not have gone into effect. It is a mark of the system's commitment to universality that there were only a few objections, despite considerable displeasure expressed by the INCB and others about Bolivia's reservation.

A second measure is in terms of its success in ensuring access to pain medication. For developed countries, this is not generally a problem. But the WHO has estimated that 80% of the world's population lacks adequate access to effective pain medication [29]. Part of the problem, of course, is a lack of resources to procure or supply the medication. But another part is the indirect result of the treaty system. In consequence of the system's emphasis on law enforcement, decisions on importation of controlled drugs are often in the hands of police, who may choose to restrict or stop imports in order to impede diversion of the medicine to illicit markets. Reflecting concern about this, the WHO Expert Committee decided that ketamine, a cheap and relatively safe anaesthetic widely used in poor countries, should not be brought under the treaties. "Concerns were raised that if ketamine were placed under international control, this would adversely impact its availability and accessibility. This in turn would limit access to essential and emergency surgery, which would constitute a public-health crisis in countries where no affordable alternative anaesthetic is available. On this basis, the Expert Committee decided that bringing ketamine under international control is not appropriate" [30:9]. Reflecting a greater priority still being placed on the prohibition of nonmedical use than on the availability of needed medications, many national delegations and three regional groupings expressed concerns or regret about the WHO's decision at the May 2013 meeting of the CND [13:11], and China pressed again on this issue for two further years [2:232].

A third measure is in terms of success in controlling legal markets. Here the system can show some success, among mixed results. The pre-Single Convention system succeeded (aided by the Depression) in substantially reducing world consumption of opium in the years prior to World War II. The current system, however, has not impeded the substantial rise, in recent years, in prescribed use of opioids in North America, which accounts for the lion's share of global use of prescribed opioids. In general, the conclusion of Bruun et al. [8] remains true: the system's suc-

cesses tend to occur where "it has been the conduct of professions and private enterprise which has been influenced". Large firms and state-licensed professionals have something to gain from cooperation with a control system, and with such levers of influence drug control systems have had some successes, for instance, in getting chemical industries to control chemical precursors, and in changing doctors' prescribing patterns when drugs, such as the barbiturates, prove to be more dangerous than was thought. Nevertheless, the sharp rise in opioid use and deaths in the early twenty-first century, particularly in North America [11, 12], was to a substantial degree fuelled by prescribed medications; pharmaceutical firms and professionals involved were not sufficiently persuaded or deterred from profit-seeking by the control system. The lack of any trade disputes about drugs under the system's control, in an era when free-market ideology has been dominant, might also be regarded as an unheralded success for the system.

A fourth measure, of course, is the system's degree of success in eliminating or at least reducing illicit trade, markets, and use. Here the overall result must be viewed as a failure. In 1998, the UN system set a 10-year goal of "eliminating or significantly reducing the illicit cultivation of coca bush, the cannabis plant, and the opium poppy by the year 2008". The UNODC's 2014 Annual Report concluded "that overall the global situation … is generally stable" [27]. Twenty years after it was set, the goal of reducing illicit markets remained a vain hope.

55.5 Signs and Directions of Change

The failure of the international drug prohibition system in terms of its most public goal, of eliminating or minimising illicit markets, has been apparent for some decades. At national and subnational levels, there have been initiatives and experiments since the 1960s in moving in other directions, although these initiatives have been greatly hampered by the perceived necessity of operating within the constraints of the international system. Thus even the Dutch "coffee shop" system for quasi-legal retail sale of cannabis, the most far-reaching attempt prior to 2010 to move from an illicit to a regulated market, was handicapped by the "back door" problem – that cannabis which was sold under license at the front door had come in the back door illegally, since no way could be found to reconcile a legal wholesale supply with national obligations under the treaty [16].

But there have been signs of change in the 2010s, particularly in the Americas. A diverse array of Latin American countries have shown a growing impatience with the status quo and have been willing to push against the longstanding "Washington consensus" for the status quo on drug policies. First, several retired Latin American presidents, and then some sitting presidents, have expressed the need for new directions. The motivations have been diverse. In Mexico and Central America, the primary issue has been the carnage in their populations from a "war on drugs" aimed at cutting off the supply to the insatiable demand from northern neighbours. In Bolivia, as mentioned, legalisation of the folk custom of coca-leaf chewing has been a main concern. In countries like Uruguay, efforts to create a regulated legal cannabis market are aimed primarily at removing a main source of criminalisation of young people. With a report from the Organization of American States (OAS) exploring alternative scenarios for the future [20], these impulses at national levels took on a collective form in the region's intergovernmental agency.

At least as important have been the changes in North America, particularly concerning cannabis. In November 2012, votes on popular initiatives for regulated cannabis markets in Colorado and Washington began concrete processes of change likely to have lasting effects, no matter how the US federal government may position itself. At about the same time, trends in opinion polls among US adults for the first time showed a popular majority for legalising cannabis [28]. By the end of 2018, 9 US states had legalised commercial sales of cannabis for recreational use and 14 more had decriminalised possession [31]. Cannabis became legal throughout Canada on 17 October 2018, sold in some provinces in government stores [6]. Changes in the legal status of

cannabis do not, of course, deal with the drug problem as a whole. But, since three-quarters of the illicit drug users in the world use only cannabis, in numeric terms, such changes in the status of cannabis will have a large effect.

The direction and extent of any changes in the international drug treaties and control system are still unclear. The OAS report lays out some alternative scenarios for the future. Other recent reports have laid out options for change in the treaties and have discussed more and less likely scenarios [24], including a potential Framework Convention on Cannabis, which might supersede the handling of cannabis in the Single Convention [22]. But, at least in the short run, it is more likely that changes will be piecemeal and country-specific, rather than at the system level – whether involving changes made within the rules of the system, as in the case of Bolivia, or beyond the rules, as with cannabis buyers' clubs in Spain and other parts of Europe [15] and with the North American shifts on cannabis.

Key Points

- The international drug control system is nearly universal, but somewhat ossified and resistant to change.
- It classifies psychoactive drugs in terms of their potency and potential harm but provides for potential medical use of most controlled drugs. It does not deal with some drugs in wide use in Western societies, notably alcohol.
- It has not succeeded in its goal of eliminating illicit supply of drugs for nonmedical use. It succeeds in ensuring supplies for medical use in wealthy countries, but not in much of the world, where actions against the illicit market also cut off medical supplies. Particularly in North America, there has been an oversupply and overuse of medicinal opioids.
- The system's prohibition of nonmedicinal cannabis and restrictions on medicinal cannabis are under siege and increasingly ignored at national and subnational levels. The system has also been overwhelmed by the large number of "new psychoactive substances" for potential control. But there is, as yet, little appetite within the system for reform.

Clinical Relevance

In considering both patient drug use patterns and whether and what psychoactive medications to prescribe, a clinician needs to take into account the legal status of a substance. However, in terms of the drug's actions and utility, the clinician should look beyond the legal divisions between medications, illicit drugs, and legal substances like nicotine and alcohol.

There has been substantial overpromotion, in affluent societies, of psychoactive medications, particularly medicinal opioids, and clinicians need to exercise care in their prescription.

56 Ethical and Legal Aspects of Interventions in Addiction Treatment

Ambros Uchtenhagen

Contents

Abstract

The United Nations (UN) conventions present the international legal framework; they urge member states to provide treatment and rehabilitation but prohibit consumption and possession of scheduled drugs. This creates problems for providing treatment and harm reduction programs to patients who are not or not yet ready to stop illicit drug use. Other international documents, notably from the World Health Organization and the United Nations Office on Drugs and Crime, are strongly in favor of agonist substitution treatment and harm reduction measures. Within this framework, national legislation has much room for diverse preferences; the International Narcotic Control Board regularly comments the national practices, as well as the European Monitoring Centre for Drugs and Drug Addiction for the EU member states. An international trend gradually prefers therapeutic measures over criminal sanctions for drug users.

The international ethical framework is set by the universal declaration and European convention on human rights, striking a balance between individual rights and societal interests. Less ambiguous guidance comes from medical ethics claiming the full range of patient's rights for addicted persons.

Note: Some of the material is based on earlier work of the author about ethical aspects of treatment and care in addiction [50–53].

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment*,
https://doi.org/10.1007/978-3-030-36391-8_56

The respective conduct codes for medical professions are regional or national and include procedures how to deal with ethical conflicts. Conflicting situations frequently occur, for example, around the principles of autonomy or of confidentiality.

An essential ethical element of treatment is its effectiveness and avoidance of harm, asking for scientific evaluation of therapeutic approaches, services, and systems. The ethical acceptability of agonist substitution treatment and of harm reduction measures is based on rigorous evidence of their effectiveness. Other aspects concern the limits of social acceptability of addictive behavior and the limits of what can be attained for an individual patient by therapeutic interventions; avoidance of harm often is the more immediate objective than full recovery. In a public health perspective, effects at population level rather than at individual level are a priority, aiming at good coverage of treatment needs by good accessibility and affordability of services.

56.1 Introduction

Addiction treatment is historically, and until present, guided by the basic understanding of addictive behavior. Interventions are shaped accordingly to prevailing paradigms explaining substance use and substance dependence. Legislation is a preferred instrument to limit consumption and addictive behavior, through preventive interventions as well as sanctions. The development of liberal societies caring for individual freedom and responsibility, less interference with lifestyles and personal choices, and the need for ethical standards in human behavior came to the forefront and resulted in various rules guiding interventions and therapist's conduct. This process in the area of addiction treatment has been taken at hand, but with persisting differences in orientation and a need for conflict management.

56.2 International Frameworks and National Diversities

56.2.1 Legal Aspects

56.2.1.1 The International Framework: The United Nations Conventions

The UN conventions of 1961, 1971, and 1988 have some implications for delivering addiction treatment.

The Single Convention urges "to take all practicable measures for the prevention of abuse of drugs and for the early identification, treatment, education, after-care, rehabilitation, and social reintegration of the persons involved." While this Article 38 does not indicate how treatment should be delivered, Resolution II declares that "one of the most effective methods of treatment for addiction is treatment in a hospital institution having a drug free atmosphere," and urges the provision of such facilities [56].

The Convention on Psychotropic Substances of 1971 [57] restricts the "use and possession of, substances in Schedules II, III and IV to medical and scientific purposes," thereby criminalizing patients in treatment who continue, sporadically or regularly, to use illicit drugs (schedules II, III, and IV include drugs such as barbiturates, benzodiazepines, and buprenorphine). Art. 7 states, for schedule I drugs, to "prohibit all use except for scientific and very limited medical purposes by duly authorized persons." What the limitations are is open to interpretation. Art. 9 requires "that substances in Schedules II, III and IV be supplied or dispensed for use by individuals pursuant to medical prescription only, except when individuals may lawfully obtain, use, dispense or administer such substances in the duly authorized exercise of therapeutic or scientific functions." Licensed pharmacists, however, may "supply, at their discretion and without prescription, for use for medical purposes by individuals in exceptional cases, small quantities, within limits to be defined by the Parties, of substances

in Schedules III and IV." Art. 20 urges to "take all practicable measures for the prevention of abuse of psychotropic substances and for the early identification, treatment, education, aftercare, rehabilitation and social reintegration of the persons involved." Also, treatment may be provided either as an alternative to conviction or punishment or, in addition to punishment, if abusers of psychotropic substances have committed such offences (Art. 22).

According to the 1988 Convention [58], preparatory acts for personal use of scheduled substances are criminal offences (Art. 3,2):

> Subject to its constitutional principles and the basic concepts of its legal system, each Party shall adopt such measures as may be necessary to establish as a criminal offence under its domestic law, when committed intentionally, the possession, purchase or cultivation of narcotic drugs or psychotropic substances for personal consumption contrary to the provisions of the 1961 Convention, the 1961 Convention as amended or the 1971 Convention.

Implicitly, this includes criminalization of use (no use without preparatory acts). The International Narcotic Control Board (INCB) was set up in 1968, with the main task to control and facilitate the implementation of the Single Convention at national level. The following conventions have revised and restated the functions of the Board.

In summary, the UN conventions urge the treatment and rehabilitation of drug abusers but prohibit the consumption of narcotics and psychotropic substances (including tranquilizers and sedatives), which creates problems for patients in treatment (continued use is often a reason to exclude patients from treatment) and even more problems for harm reduction approaches designed to diminish the medical risks of substance use (for persons in addiction treatment and outside of treatment). Agonist maintenance treatment is viewed critically by INCB as a potential source of diversion of narcotics to the illegal market [29]. However, the conventions allow diversion to treatment as an alternative to punishment.

56.2.1.2 Other International Frameworks

Some international documents are mentioned here with relevance to addiction treatment and specifically in regard to agonist maintenance treatment and harm reduction interventions. These evidence-based documents present strong recommendations which are not legally binding.

The World Health Organization (WHO) and the United Nations Office on Crime and Drugs (UNODC) published Principles of Drug Dependence Treatment in 2008. This chapter is in strong support of agonist maintenance treatment for opioid dependence: "Opioid agonist pharmacotherapy is one of the most effective treatment options for opioid dependence when methadone or buprenorphine are administered at an individualized dosage for a period of several months to years." The chapter also urges to implement legal frameworks, which guarantee protection from potential sanctions for those seeking treatment [69].

The UNODC, WHO, and United Nations Programme on HIV/AIDS (UNAIDS) "Technical Guide for countries to set targets for universal access to HIV prevention, treatment and care for injecting drug users," published in 2009, has a range of preventive measures (e.g., needle and syringe exchange programs) among its recommendations, thereby complementing the treatment recommendations [59].

In Europe, the EU Action Plan 2005–2008 [16] foresaw harm reduction measures as a specific action for the implementation of Objective 14 (prevention of health risks related to drug use) and Objective 15 (availability and access to harm reduction services). The implementation process and the available evidence on outcomes are presented in a monograph [41].

56.2.1.3 Diversity of National Legislation

At the national level, narcotic laws and policy guidelines mirror a diversity of principles, priorities, and preferences, even when countries have ratified the UN conventions. Treatment of

substance abuse is one of the essential elements, but how it is defined, for whom it is available, under which circumstances, and which approaches are officially accepted are all subject to major differences. One example is the national guidelines for substitution treatments of opiate dependence; an analysis of 28 national guidelines found a large variety of indication criteria and practices [53].

At present, the diversity of legislations and regulations is best documented in regard to Cannabis. The alternatives to prohibition, in the sense of the UN conventions, range from decriminalization of use and preparatory acts for personal use to a replacement of illicit markets by tolerated controlled markets without legalization, to partial or full legalization in analogy to alcohol and tobacco. *Decriminalization* means or preferring administrative instead of criminal sanctions, or no sanctions within age limits and allowed quantities. A *tolerated controlled market* is based on issuing licenses for production, marketing, and sale of cannabis products under specified conditions. Compliance with the conditions is controlled and licenses are withdrawn in case of non-compliance. License holders pay taxes for their profits. *Legalization* may be restricted for defined target groups (e.g., residents only, medical cannabis prescribed to patients suffering from specified conditions, adult members of cannabis social clubs). Legal availability of cannabis may be restricted with age limits, quantities allowed per time period, and Tetrahydrocannabinol (THC) content in order to prevent negative effects of use. Maximum prices apply in certain jurisdictions, in order to avoid a competitive illegal market with lower prices (overview in Uchtenhagen 2016).

An official source of information on problems with the implementation of the UN conventions is presented in the annual reports of the International Narcotic Control Board (INCB). The 2011 report includes, for example, information on unacceptable treatment problems, such as diversion of prescribed pain medications or allowing safe injection rooms ([29], p. 38). The setting up of the lack of aftercare is admonished (p. 59). On the other hand, large compulsory treatment centers are mentioned (p. 78), as well as detoxification, rehabilitation, and counseling services (p. 83); opiate substitution treatment (p. 51, 78); and needle/syringe exchange programs (p. 51), without indicating their acceptability and outcomes.

The 2018 report provides, in Chap. 1, recent developments in the use and regulation of the medical use of Cannabinoids and Cannabis, as well as recent changes in national legislation in regard of non-medical cannabis use (legalizing production, sale, possession, and consumption). Concerns are expressed about diversion of medical cannabis for non-medical use, weakening public awareness of risks resulting in facilitating legalization of non-medical cannabis. Chap. 2 provides information about the compliance with the treaties by national authorities in member states. Chap. 3 gives a detailed overview on the worldwide situation in the production and use of scheduled drugs worldwide, followed by Chap. 4 with recommendations (not legally binding) to governments and involved organizations.

A complete and updated collection of national drug laws and drug policies is presented by the European Monitoring Centre on Drugs and Drug Abuse (EMCDDA); it includes not only the EU member states but also acceding and candidate countries as well as neighboring and Central Asian countries [15]. The same source provides systematic information on treatment approaches and harm reduction approaches in these countries.

56.2.1.4 Sanctions

Use and possession of illegal drugs for personal use are prohibited in a range of countries. For Europe, an analysis of national practices is presented [14]. Only rarely, prison sentences are handed out in case of infraction. In other regions, imprisonment and compulsory treatment are more common, for example, in labor camps [67].

In some countries, drug possession is an offence, which may entail imprisonment or even capital punishment. A systematic overview is not available. In Islamic law, use of any drugs including alcohol is prohibited and sanctioned, but it also provides care for those suffering from medical conditions.

A high-level organization, the Global Commission for Drug Policy, strongly recommends to avoid criminal sanctions for the use of all scheduled drugs and the stigmatization of all substance users [21].

Agonist maintenance therapy is prohibited in Russia [37], while a growing number of countries support and expand this approach, replacing criminal sanctions.

56.2.2 Ethical Aspects

56.2.2.1 Ethical Basis of Interventions: Human Rights

The Universal Declaration of Human Rights [54] contains a number of relevant conditions, such as no discrimination (Art. 2), no degrading or inhuman treatment (Art. 5), and right of equal access to medical care and social services (Art. 25/1), but also that everyone has duties to the community (Art. 29/1) and that limitations of rights and freedom are admissible on the basis of "just requirements of morality, public order and the general welfare" (Art. 29/2).

In view of conflicts this may create, a recent initiative proposes the formulation of meta-rules, providing guidance on how to resolve conflicts in human rights [4].

The European Convention on Human Rights [7] further stipulates that a person's liberty may be deprived in case of lawful detention of alcoholics or drug addicts (Art. 5/1/e), with a right to appeal to a court (Art. 5/4).

In summary, these statements try to establish a balance between protecting the individual rights of the person and respecting the needs of society for public order, general welfare, and even morality. There is large room for interpretation, so that every society can decide on the compatibility of addictive behavior with the nature and extent of the above-mentioned requirements. Compulsory measures against persons with substance dependence may be admissible on the basis of national laws.

A step further is made in the EU, where the Commission has issued guidelines on the regulation of patient rights. A growing number of member states have adopted laws or regulations, granting patients the right to self-determination (no interventions without informed consent) and confidentiality [17]. Only exceptionally, involuntary interventions are allowed, for example in cases of criminal behavior or deficient power of judgment. This creates a new ethical dilemma in case of serious destructive behavior as a symptom of the patient's condition. It is argued that treating physicians in such a case have a responsibility to protect the patient from the negative consequences of behavior, even through involuntary intervention.

Again a new situation has been created with the UN Convention on the Rights of disabled persons (CRPD), in force since May 2008, ratified by 177 member states [55]. This convention grants all human rights to persons with any kind of disability, including psychiatric conditions and therefore also with substance use disorders. Some of the specific rights cover the freedom of accommodation, of mobility, of social participation, not easy to be reconciled with addictive behaviors. All signatories are obliged to send annually a report to the Secretary General on how these rights are implemented at the national level.

56.2.2.2 Ethical Basis of Interventions: Medical Ethics

Medical ethics apply only if and inasmuch as substance dependence is understood as a medical condition. This has been the official position of the leading medical organizations since decades (and brain research has identified it as a "brain disease," thereby giving it a biological basis) [33]. The substance-dependent person is a patient and should enjoy the status and all the rights of patients.

The current medical science defines substance dependence as a condition with diagnostic criteria, described in the generally acknowledged diagnostic systems, such as International Classification of Diseases ICD-10 of World Health Organization [68] and Diagnostic-Statistical Manual of Mental Disorders DSM-IV TR of the American Psychiatric Association [2]. The criteria include biological

symptoms (tolerance, withdrawal symptoms in case of discontinued use), psychological symptoms (craving, desire to reduce consumption), and behavioral symptoms (loss of control over consumption, consuming in spite of perceived negative consequences).

ICD-10 includes a diagnosis of harmful use (with negative health consequences of use), while DSM-IV includes a diagnosis of abuse. These conditions are also considered to be a medical condition inviting therapeutic interventions.

What are the consequences for the treatment of addiction? Examples of the general conduct codes are the Standards of Conduct of the American Medical Association [1] and the Good Medical Practice of the British General Medical Council [22]. Main issues are the patient's autonomy of decision, informed consent, dignity and confidentiality, nondiscriminatory beneficence, and non-maleficence, but also keeping up professional standards by continued education and networking with other services and colleagues in order to provide the best possible care. In addition, the American recommendations include a responsibility to seek change in official or legal requirements, which are contrary to the best interests of the patient. These codes usually acknowledge the occurrence of ethical conflicts and provide links for support in such cases.

In the absence of specific rules for the treatment of substance dependence, the general ethical rules for good medical practice apply. The four major principles are as follows: do no harm, improve the well-being, respect the autonomy, and apply justice. It is obvious that even these few principles cannot be followed without creating conflict [43].

Involuntary intervention to prevent harm is in conflict with the autonomy of an unwilling patient. Treating all patients as being equal (principle of justice) is impossible where the resources are limited. Also confidentiality and data protection often are in conflict with administrative and law enforcement interests in case of illicit drug use. All such conflicts must be carefully examined, in the best interest of all concerned. When the patient's interests collide with those of relatives or other third parties, a common solution must be found to the extent possible. It is advisable to recur to an ethical consilium if major consequences are expected from the decision. The principle of respecting the autonomy of the patient must never be overruled in the name of some abstract societal value without the presence of concrete harm implications for others.

56.2.2.3 Ethical Justification of Interventions

Human rights as well as medical ethics mention the interests of society, which may be in conflict with the interests of the individual. In fact, the ethical justification to interfere with a person's substance use or dependence resides in negative societal consequences. In the case of substance dependence, treatment is justified in order to avoid such negative consequences. Among the appropriate measures are all treatments which help to bring a majority of people with addictive behavior or dependence into treatment, without disregarding their autonomy, and to optimize accessibility of treatment services. In the case of hazardous and harmful use, treatment by early and short interventions (e.g., motivational interviewing) can have positive effects.

As in other medical fields, therapeutic interventions are justifiable if efficient and effective. This principle is part of what is named "consequential ethics," in contrast to dogmatic ethics which call for complying with a given norm whatever the consequences may be. A good example of consequential ethics is the acceptance of harm reduction measures for persons using drugs. On the one hand, a growing number of research findings on positive effects of harm reduction measures justify their integration into the range of interventions for substance users and substance dependence. On the other hand, a dogmatic position is exemplified with the refusal of all interventions except detoxification and abstinence-oriented treatment.

Substance use is a factor in many social and cultural events, as a facilitator of social contact and a source of emotional well-being but also of destructive or aggressive behavior. The acceptable limits of intoxication and behavior, of substances used, and of opportunities for consumption, are

culture specific and are to be respected when dealing with substance dependence [11]. For instance, a major difference between Western and Asian cultures is the place of the individual within the family system; while the individual's interests and autonomy are a core concept of most Western psychotherapies, the integrity and the interests of the family are the higher value in many Asian societies.

In a paternalistic attitude, substance-dependent persons must be protected against wasting their personal resources and potential achievements. However, such an attitude collides with the present position that interference is only justified on the basis of negative consequences of a person's behavior for others. Also, many people have lived or live a productive life in spite of their substance dependence, and to interfere with their lifestyle would cause more ethical concerns than to respect their autonomy.

Developing one's own resources and shaping one's own life is to be facilitated by education and by societal organization, but it is ultimately in the responsibility of the person itself. Conditional are the freedom of choice and the freedom of the will. Is addiction leaving any room for choices, is it a negation of free will and therefore the basis for involuntary intervention? This has been debated extensively. At present and on the basis of research evidence, we have a more differentiated view. The decision of many to change their lifestyle and go to treatment [5, 12] or to stop the dependence without professional support (the so-called self-healers) [31] demonstrates the ability of many persons with substance dependence or addictive behavior to make a choice and stick to it.

This notion is reinforced by observations of regaining consumption control by former addicts [30], and that not the substance alone but also the personality and the social environment had a role in the development of dependence, and that many users keep their consumption under control or regain control under more favorable conditions [42, 71].

A basic ambivalence – substance dependence as a medical condition or a moral weakness – is reflected in the opposition of medical and moral treatment. Moral treatment is understood to be educational and admonishing. The medical approach is to help the addict in getting motivated for change by appropriate empathy and information, while confrontation and reproaches risk reinforcing the resistance against any change. It is important to give the patient the feeling that they are taking the decisions and doing the necessary steps forward themselves. Special methods have been developed for enhancing the motivation for change, and they have become an important element in today's treatment of alcohol and other drug problems [25, 39].

In summary, treatment of substance dependence is expected to help the individual to make his own choices and to regain self-responsibility, rather than to make the decisions for him.

56.2.2.4 The Goals of Treatment: A Hierarchy of Objectives

The goals to be reached through treatments of substance dependence (and which therefore are the criteria for measuring outcome in treatment evaluation research) have changed over the last decades. While the goal of abstinence was traditionally on top of the list, the present situation can be summarized as follows: the primary goal is the patient's survival, moving to health improvements (or at least prevention of deterioration), to improvements in social integration, to reductions in substance use (moving away from addictive behavior), to improvements in quality of life (as defined subjectively by the patient), and ultimately resulting in a responsible and satisfactory lifestyle. Abstinence is not always needed for reaching these objectives, nor does abstinence guarantee to reach them.

A national example of listing the objectives is given in the report on Models of Care by the UK Department of Health [8]:

- Reduction of psychological, social, and other problems directly related to drug use
- Reduction of psychological, social, or other problems not directly attributable to drug use
- Reduction of harmful or risky behaviors associated with the use of drugs (e.g., sharing injecting equipment)

- Attainment of controlled, nondependent, or non-problematic drug use
- Abstinence from main problem drugs
- Abstinence from all drugs

This document fully endorses the principle of consequential ethics in prioritizing the reduction of the various forms of drug-related harm, including social, medical, legal, and financial problems, until the drug-dependent patient is ready and able to come off drugs.

56.2.2.5 Cure or Care?

Treatment is often identified with cure (in the sense of healing an illness), while care means serving a chronic patient without chances for healing. As such, care is an equivalent to harm reduction, meaning all interventions designed to improve the health and social status of a chronic addict who continues a dependent behavior (harm reduction is more than HIV prevention). The present debate on treatment and harm reduction is often a debate on opposing principles of action which cannot be reconciled. In this debate, harm reduction has been disqualified as an approach to prolong dependence, to make substance use acceptable for young people, and to undermine the readiness of addicts for treatment. A recent movement to promote recovery as a complete resocialization without drugs disqualifies agonist maintenance treatment, which is only accepted as "maintenance to abstinence."

Today, in the light of the updated treatment objectives, harm reduction is considered an ally rather than an opponent of treatment. Accordingly, the treatment system must be an integrated system that enables abstinence and harm reduction services to work together, in order to provide a continuum of care, including:

- Easily accessible low threshold services that meet the immediate needs of continuing drug users
- Clear processes for motivating users to move away from drug-dependent lifestyles
- Clear processes for referring users into structured treatment programs that promote stabilization or abstinence (quoted from Ref. [46], p. 6)

56.2.2.6 Tailoring Treatment to Individual Needs

Bearing in mind the diversity of etiology, symptoms, and stages of substance dependence, it becomes obvious that treatment cannot be uniform for all dependent persons. In addition, treatment needs in different age groups and other target groups (gender, ethnicity, comorbidity, etc.) may differ considerably as well. Treatment must respond to the specific needs of an individual patient, on the basis of a comprehensive needs assessment and a treatment planning process where patient and therapist work together on a shared understanding of what is needed and what should be done.

This concept of a needs-based treatment has been intensively researched. I mention two large studies from USA: the National Treatment Improvement Evaluation Study (NTIES) documented the results of needs-based treatment planning and found a significant correlation between 1-year outcomes (measured as drug-free urines) and the number of needs included in the treatment plan [24]. A comparison of basic, average, and enhanced services for heroin dependence evidenced better retention and outcomes in services, where psychiatric and social care was available to patients [35]. In both studies, covering the needs for psychiatric care and living conditions (housing, jobs) was found to be especially important. This again has consequences for the hierarchy of objectives: a reduction of substance use is facilitated by improved living conditions and not necessarily their precondition. "Matching treatment settings, interventions, and services to an individual's particular problems and needs is critical to his or her ultimate success in returning to productive functioning in the family, workplace, and society" is therefore one of the principles of addiction treatment [40].

56.2.2.7 Public Health Interventions Versus Individual Care

Coverage of Treatment Needs Reaching the majority of drug injectors became a primary objective in order to slow down the HIV epidemic. The public health priority is to offer treatment to all persons in need of treatment.

Individual care is optimized by high-quality treatment, but public health cannot accept high-quality standards for a few as long as the many are not reached adequately. This principle includes monitoring of the treatment needs in a given population and, accordingly, careful planning of the treatment system as a whole. The responsibilities – ethically and professionally – are well distributed: medical practitioners are responsible for good individual care, service directors are responsible for good practice in their services, and health authorities are responsible for good coverage of treatment needs.

Cost Effectiveness of Interventions When caring for the treatment system as a whole, the next step is to take the responsibility for making best use of the available human and financial resources for treatment. This means to look at how much effective treatment is provided at what costs. It does not suffice to give a priority to treatments with good evidence for effectiveness but to treatments which provide effectiveness at the lowest costs in terms of staff and budget. A recent approach was efforts which intend to make best use of resources through models of stepped care, matching patients to specific treatments, on the basis of their characteristics and needs (see Chap. 82 "Stepped Care Models in Addiction" in this section).

Harm Reduction An efficient protection of public health goes beyond providing treatment for substance-dependent persons. It includes all measures which are effective in protecting the health and social status of active users, in the interest of users as well as of the population at large.

Accessibility and Affordability of Treatment Neglect of patients in need of treatment can take many forms. For instance, an analysis of national guidelines for substitution treatments of opiate dependence showed a range of restrictive access criteria, such as minimal age, minimal duration of dependence, polydrug use, and lack of confidentiality, and likewise restrictive criteria for a continuation of treatment, such as persistent illicit substance use or bureaucratic limitation of treatment duration [53]. Other examples are the denial of social support and/or medical care to active alcohol or drug users or smokers. Examples are the denial of liver transplants to persons with alcohol problems, in spite of research evidence that survival rates in those who continue to drink are not lower than in other patients [19], and the denial of Hepatitis C treatment with Interferon to active drug injectors on the basis of wrongly presumed lack of compliance [10]. Excluding addiction treatment from health insurance and reserving treatment to those who can pay for it are other examples.

In summary, the ethical implications are obvious: without appropriate accessibility and affordability of treatment, there is no way to reach the "health for all" goal of good coverage and of treating all patients as equal.

Quasi-Compulsory and Compulsory Treatment Is it advisable to force individuals with addictive behavior or dependence into treatment, when they are not motivated to engage in it by themselves, in view of an objective of optimal coverage? It is a common understanding that those individuals do not opt for treatment unless there is some external or internal force behind such a decision. The forces are quite different, ranging from health concerns to social pressure by family or employer to legal pressure in order to avoid losing the driver's license or going to prison. This is called the "continuum of coercion" [61]. The scientific evidence on the effectiveness of such "coercion" is contradictory [23, 70]. A recent multi-country study on quasi-compulsory treatment (QCT, treatment on court order as an alternative to imprisonment, with the consent of the patient) documented that perceived pressure does not translate into higher motivation; no significant differences in outcome were found between QCT patients and control groups of voluntary patients [46].

Coercion through mutually agreed consequences of substance use during treatment (contingency management) is recognized to be

helpful, but more so when using positive reinforcers than sanctions [38, 44]. From an ethical standpoint, it is reluctantly accepted under the term of "Ulysses coercion" (Odysseus wanted to be bound to the mast of his ship in order to resist the temptations of the sirens, [48]).

In summary, the findings indicate that coercion may have a role in supporting patient motivation for change, on the basis of informed consent, but it cannot replace motivation by compulsory measures without consent.

56.2.2.8 The Case of Agonist Maintenance Treatment

Rationale and Origins At first view, prescribing agonists with dependence liability to persons suffering from substance dependence seems to be paradox. One of the main arguments against agonist prescribing refers to a prolongation of dependence, which is considered to be unethical. How can we understand the rise and successes of this therapeutic approach (also known under the terms substitution or replacement treatment)? The main objective is to replace uncontrolled use of an addictive substance, by the controlled provision of a medication acting on the same receptors, as the original substance. The secondary objectives to be reached are reduction of the uncontrolled substance use, reduction of adverse health and social effects of uncontrolled use (including a reduction in drug-related delinquency), and normalization of lifestyle (including drug-free social contacts, improved housing, and employment conditions). These objectives are in line with the hierarchy outlined above. The primary objective is reached by prescribing and controlled intake of an agonist, the secondary objectives by eliminating the need to purchase the original substance of dependence and by ancillary care.

The introduction of agonist maintenance treatment is closely linked to the experience of unsuccessful detoxification and abstinence-based treatment. Maintenance without substitution of the problem drug was practiced in Roman times (the emperor Marc Aurel was maintained on opium by Galenus, the eminent physician), and daily dosages of opium were provided to dependent persons in Southeast Asia in the nineteenth century [62]; ironically, after the ban of opium, these persons switched to heroin [63]. First attempts at substitution were to replace opium by alcohol in the sixteenth century [13], morphine by heroin [32], and morphine by cocaine [20] in the nineteenth century. These attempts were far from being successful. A first well-designed and scientifically based model was developed by Dole and Nyswander: the methadone maintenance scheme [9]. They used oral methadone, a full opiate agonist with a longer half-life than injected heroin (controlled intake of one dose per day can block the heroin craving effectively). The model included ancillary care for medical and social conditions of enrolled patients.

Apart from opiate replacement, only nicotine replacement has been introduced into present medical practice, while former alcohol maintenance for alcoholics is discontinued.

Result Methadone maintenance is one of the most frequently and best researched therapeutic approaches. Extensive reviews of the pharmacological aspects, of service delivery, and of therapeutic outcomes, have been published [3, 18, 27, 49, 60]. In addition to methadone, buprenorphine and retarded morphine have been introduced and researched as replacement medicines in the treatment of opioid dependence, with similar outcomes. For chronic opiate individuals who failed to profit from those agonist maintenance treatments, pharmaceutical heroin was tested and introduced as a "last resort" therapeutic approach with equally good results [47]. The positive findings in terms of health and social improvements, including a massive reduction of delinquency, were complemented by the fact that agonist maintenance treatment has the greatest potential to bring heroin-dependent persons into contact with therapy and care. It therefore became one of the most welcome instruments for limiting the spread of blood-borne diseases – HIV/Aids and hepatitis – among drug injectors. The reduction of risky injecting behavior and of seroconversion rates in methadone patients became evidenced for community-based programs [36] and for prison-based

programs [45]. Economic evaluation documented the cost-effectiveness of methadone and buprenorphine maintenance treatment [6].

Based on the evidence, methadone and buprenorphine have been scheduled by the World Health Organization as essential medicines [64, 65]. Also, international evidence-based scientific guidelines for agonist maintenance treatments have been published [66].

Concerns A major concern was a weakening of the motivation to change and therefore a prolongation of addictive behavior through agonist maintenance treatment. There is no evidence for this claim. A multisite major cohort study showed a relapse rate of methadone maintenance patients to daily opiate use of only 27% at 12-year follow-up [34]. The Drug Abuse Treatment Outcome Study (DATOS) study from USA and the National Treatment Outcome Research Study (NTORS) study of the UK, both multisite prospective cohort studies, found comparable outcomes at 5-year follow-up in patients who were enrolled in residential drug-free and in methadone maintenance treatment [26, 28].

In summary, the ethical justification of agonist maintenance treatment in the modern form was to provide otherwise treatment-resistant heroin addicts with an effective approach to improve their health and social situation without asking for total abstinence from narcotic substances.

56.2.2.9 Conflicts in Ethical and Legal Orientation

In numerous concrete situations, human rights and medical ethics are difficult or impossible to respect as well as national or local legal conditions. A number of such situations has have been indicated throughout this text. Sometimes, an appropriate conflict management may help, especially if the application of an opportunity principle is permitted. In other situations, there is no such solution. The way out is indicated by the ethical code of AMA: to engage in an effort to change laws which prove to be incompatible with responsible care for the addicts [1].

56.3 Conclusion

The essential ethical message is well summarized in the WHO international guidelines for the psychosocially assisted pharmacological treatment of opioid dependence [66]:

Clinical Relevance

When making clinical decisions for the treatment of people with opioid dependence, ethical principles should be considered, together with evidence from clinical trials; the human rights of opioid dependent individuals should always be respected. Treatment decisions should be based on standard principles of medical care ethics – providing equitable access to treatment and psychosocial support that best meets the needs of the individual patient. Treatment should respect and validate the autonomy of the individual, with patients being fully informed about the risks and benefits of treatment choices. Furthermore, programs should create supportive environments and relationships to facilitate treatment, provide coordinated treatment of comorbid mental and physical disorders, and address relevant psychosocial factors.

There is not much to be added. The statement applies fully as the main recommendation for all treatments of substance dependence. It is a perpetual agenda for future generations. The task is to update the key elements of this chapter: the legal framework for the treatment of addictive behavior and dependence, at international, national, and local levels; to reflect the ethical positions, their consequences, and limitations in the best interest of patients and all other concerned population segments; the changing societal norms as well as the changing background and needs of the individual patients.

Key Points

Clinicians engaged in the treatment and care of addicted persons find, in this chapter, the necessary information needed to keep their interventions within legal and ethical guidelines and to shape institutional care concepts accordingly, in the interest of acceptability and adequacy to societal and patient expectations.

Monitoring and Evaluation of Addiction Treatment

57

Ambros Uchtenhagen

Contents

Abstract

Monitoring and evaluation (M & E) are research activities dedicated to document and analyze the processes and outcomes of addiction treatment. Before starting M & E, some conceptual issues apply, such as considering the objectives of a given treatment or treatment system, the outcome indicators to be used, the characteristics of the target population, and the basic understanding of the nature of addiction.

A range of different goals can be envisaged in M & E projects, from measuring treatment implementation and the use of the available resources to measuring efficacy and effectiveness. The overall goal, in general, is the improvement of services and treatment systems. The main steps in developing M & E projects are determining the research questions, the appropriate type and design of evaluation, and the resources and partners needed. Also, it is helpful to identify expected problems and obstacles.

Lists of evidence-based guidelines and instruments for evaluation are attached, as well as lists of high-quality publications reviewing the outcomes of evaluation studies.

57.1 Introduction

Monitoring and evaluation (M & E) are essential instruments for an optimal drug demand reduction through treatment and prevention. They serve the commitment to effective interventions, which are based on scientific evidence. Only a good knowledge on the effects of interventions can provide the evidence base for an adequate substance abuse policy.

The main objective of M & E is to assess the available intervention system at country, regional, or local level, to determine its adequacy for covering the treatment needs in the respective population, and to measure its intermediate, short-term, and long-term outcomes. This is instrumental for a targeted improvement of available intervention systems, as well as for an adaptation to new challenges from changes in substance-using populations, and the health and social consequences of use. Monitoring trends in substance-using populations out of treatment is helpful in order to observe such changes, for example, the arrival of new drugs.

M & E also covers structural and procedural properties of services and systems, as major instrumental elements for outcomes.

M & E can also serve other purposes, such as providing arguments for legitimizing the treatment or prevention approach against repressive approaches.

57.2 Main Aspects of Monitoring and Evaluation

57.2.1 Definitions and Rationale

There are no universally accepted definitions. Monitoring and evaluation are performed in many fields of activities, such as health and education, and the aims and definitions are adjusted to the respective field. For this chapter, the following definitions and rationale apply.

57.2.1.1 Monitoring Treatment

Monitoring is an activity to continuously document defined indicators of treatment implementation and outcomes.

Rationale: To determine the level of service performance and treatment results, as a starting point for improvements and for measuring change as a result of improvements.

57.2.1.2 Process Evaluation of Treatment

Process evaluation is a one-time or repetitive activity to document how therapeutic interventions are implemented, in terms of coping with predetermined rules and criteria.

Rationale: To determine the level of service responsiveness to needs and compliance with expected performance, in order to facilitate the expected results.

57.2.1.3 Outcome Evaluation of Treatment

Outcome evaluation is a one-time or repetitive activity to document the consequences of therapeutic interventions for the target population and/or any other sector of the population, in terms of predetermined goals and indicators.

Rationale: To measure the intended and unintended effects of therapeutic interventions, in order to determine the value of a given intervention, a service, or treatment system to serve the expected treatment objectives.

57.2.1.4 Economic Evaluation of Treatment

Economic evaluations are a specific type of outcome evaluation. They measure the proportions of costs and benefits of an intervention, a service, or a treatment system. Costs and benefits are measured at the individual or at society level. In cost-effectiveness evaluation, effectiveness is expressed in terms of costs per unit of outcome. Cost-utility evaluation determines the gains in years and quality of life in relation to costs.

Rationale: To explore satisfaction with the results of investments made.

57.2.1.5 Meta-Evaluation

The growing number of evaluation studies and their unequal quality invited an effort to review evaluation studies, on the basis of rigorous method-

ological analysis, resulting in reliable information about "what works" and "what works for whom."

57.2.1.6 Comparable Terms

Other terms for process and outcome evaluation, especially in the educational field, are formative and summative evaluations. Formative evaluation is typically conducted during the development or improvement of a program or course. Summative evaluation involves making judgments about the efficacy of a program or course at its conclusion.

For other and partly overlapping definitions of terms, see the referenced evaluation guidelines of the World Health Organization [5] and the European Monitoring Centre for Drugs and Drug Addiction [7, 9].

57.2.2 Preparing for Monitoring and Evaluation

A detailed M & E project is the key to the feasibility of data collection, to the validity of data, and to the usefulness of results. The following issues and steps must be considered before starting a project. It is recommendable to set up an M & E project in collaboration with an expert.

57.2.2.1 Conceptual Issues

Treatment Objectives

The specific objectives of a given therapeutic method or of a given program determine the type of outcome data to be collected, in order to know how far outcome responds to the objectives. Objectives may be reduction of main substance use or any substance use, abstinence from main substance use or any substance use, health improvements, reduction or abstinence of illegal activities, social integration such as gainful employment or participating in a social network, or complete recovery [8].

Outcome Criteria

If no specific treatment objectives are in place, any M & E project has to determine which type of outcomes are to be measured. This may be those mentioned earlier, but also others such as the quality of life of patients/clients or the reduction of negative consequences of addiction at population level in terms of substance-related crime and nuisance or blood-borne infectious disease. The following is a catalog of the most frequently used outcome indicators (adapted from [9], Table 2) (Table 57.1):

Table 57.1 Outcome indicators

Retention rate	Measuring time in treatment
Status at discharge	Regular versus irregular discharge (drop-out, exclusion)
Addictive behavior	Consumption patterns of legal and illegal addictive substances
Risk-taking behavior	Injecting drugs, needle sharing, and unsafe sex
Health status	Changes in somatic and psychological health
Social reintegration	Changes in living arrangements, employment, social networking, and criminal activities
Quality of life	Subjective Well-being

The choice of outcome criteria should meet the interests of all stakeholders, including the mandating and/or funding bodies for the project.

Characteristics of the Target Population

Intermediate, short-term, and long-term outcomes of therapeutic interventions are diverse for different target populations. Age, gender, level of education, level of social integration and social support, religious affiliation, health factors such as comorbidity, etc. have a potential to influence how well a person responds to a therapeutic intervention or program. Data collection therefore must be tailored to the specificities of the target groups an intervention or service is meant to serve.

Understanding Addiction

Also, the kind of data to be collected for M & E depends on how addictive behavior is interpreted. Various paradigms apply here: the use of psychotropic substances can be understood as self-medication for symptom relief [18], as a special variation of self-manipulation, tailoring use to a desired state of mind, or as instrumental for self-enhancement, optimizing function and output [15]. Or else, substance use is understood as a lifestyle phenomenon, in the sense of "consumerism" or of an expression of subcultural identity.

On the other side, addiction is understood as a brain disease, following repetitive substance use, resulting in structural changes [20] or on a vulnerability-stress model focusing on the impact of genetic and environmental factors on the brain changes [34]. For each of these paradigms, specific contextual data and patient/client characteristics are of interest in order to explain the value of intervention outcomes.

Also, understanding addiction as a chronic relapsing disorder has consequences for the design and methodology of evaluation studies [22]. Or else, addiction is conceived in a synthetic theory as a pathology of the motivational system, resulting in a deficit of other satisfactory/pleasurable experience, restricting such experience to repetitive substance use [36].

57.2.2.2 Goals of Monitoring and Evaluation Projects

M & E projects are made for a variety of purposes (see also Ref. [9], Chap. 1). The purpose is relevant for the research questions to be answered by the project; the research questions are relevant for the design and methodology to be used as well as for the data which are necessary for answering the questions.

Measuring Program Implementation

A comparison is made between the intended standards of a therapeutic program or protocol and the de facto characteristics of its implementation. It includes structural and procedural aspects. Among the many issues of interest are the indication criteria, staff composition and qualifications, infrastructure and location of service, links with other services, etc. It may also include an estimation of how well the treatment needs in the regional/local population are covered.

Such projects are mainly of the process evaluation type. A recent example is part of the WHO collaborative study on substitution therapy of opioid dependence and human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) [19]. Continuous monitoring of the process has the advantage to document changes made over time in terms of program implementation.

Measuring Use of Resources

In an overall purpose to make best use of available human and financial resources, M & E projects can measure the overall utilization of the treatment capacity or the utilization by the intended target population. They can compare outcomes between services receiving similar investments and serving similar populations. More difficult and demanding are economic evaluations as mentioned earlier.

Measuring Efficacy and Effectiveness

Efficacy of therapeutic interventions is, as a rule, determined by clinical trials, using a randomized controlled design. These trials provide us with data showing the relative efficacy of a given intervention or medication in comparison to another intervention or medication, if the treatment is allocated at random and the sample characteristics are comparable.

In contrast, the effectiveness of an intervention or a treatment service is defined by how well an intervention or a service works in practice and produces the desired results. It is usually measured by cohort studies, including outcome evaluation with or without elements of process evaluation.

Efficacy and effectiveness studies contribute to a better knowledge on what treatment is best suitable, have the best chances for which patients/clients under which conditions, and thereby improve the indication criteria for patient/client placement.

Legitimation of Treatment

A frequent purpose of evaluation projects is demonstrating the value of a given intervention or service, in terms of desired outcomes, patient/client satisfaction, and positive economic balance of input and outcome. This can be done through a single-service follow-up study or a nonrandomized comparative study. The main issues why it is important to assure the legitimacy must be considered in the research questions and the study design.

Improvement of Services and Treatment Systems

M & E studies can provide data which allow to identify weaknesses, to initiate changes, and—in

a repetitive effort—to document the intended and unintended effects of such changes. Process evaluation and qualitative data are most helpful for improvement purposes [27].

57.2.2.3 Determining the Research Questions

The questions to be answered by an M & E project depend on the aims and must be made explicit, for an agreement between all stakeholders. The questions determine what kind of samples is needed, which data must be collected, and which study design is most appropriate.

Additional research questions may be included in order to address special interests by staff, funding agency, or other stakeholders. The inclusion of such questions has a potential to enhance cooperation and compliance with the main study.

The following types of research questions can be considered (see also WHO 2000, workbook 1 step 5, and [9], Chap. 3):

- *Descriptive questions* for precise information about observations made.
- *Normative questions* aiming at a comparison between observations and expectations (e.g., standards).
- *Impact questions* exploring the role of interventions or elements thereof for the observed outcomes.

57.2.2.4 Typology of Treatment Evaluation

There is no universally accepted typology. The following is mainly based on the types presented in the EMCDDA Guidelines [9] and in the WHO/United Nations Office on Drugs and Crime. (UNODC)/EMCDDA Evaluation workbooks [39].

Needs Assessment Evaluation

Needs assessment studies are used to determine and improve the coverage of treatment needs in a given population, in order to tailor treatment capacity, mix of services, and networking among services accordingly (WHO evaluation workbook 3).

Structure Evaluation

Evaluation of the appropriateness of infrastructure and other structural elements to facilitate the desired outcomes of treatment. This includes location, safety provisions, financial resources, staff composition and qualification, governance, and organization.

Process Evaluation

Process evaluation documents and analyzes how treatment is delivered. Assessment procedures, indication criteria, treatment planning, programming, qualification and attitudes of staff, continued training of staff, house rules, sanctions, etc. are some of the elements to be considered (WHO workbook 4, extensive list of available instruments for process evaluation on the EMCDDA instrument bank EIB).

Outcome Evaluation

The focus is on the consequences of treatment for patients/clients, their families, and the community. It provides information on which treatment modality has which consequences for which target groups under which conditions. It may consider the impact on other treatment approaches. It may become relevant for treatment motivation in the target population.

Outcome is measured against predefined behavior norms (normative evaluation), baseline pretreatment status (evaluation of change during treatment), or predefined treatment goals (goal-attainment evaluation). Outcome evaluation mainly uses quantitative methods (by randomized controlled trials (RCTs) or cohort studies), eventually a combination of quantitative and qualitative methods (WHO workbook 7, instruments on EIB of EMCDDA).

Patient/Client Satisfaction Evaluation

Patient/client satisfaction studies measure to what extent treatment provision and treatment results meet the expectations of patients/clients. They are a major source for service improvement, together with retention rates and drop-out rates (WHO workbook 6, instruments on EIB of EMCDDA).

Economic Evaluations

Various designs are used to describe and analyze economic factors in addiction treatment. Cost analysis measures the cost factors and overall

costs of treatment (e.g., per patient day, per treatment episode, per treatment modality, etc.). Cost-benefit evaluation determines the relation between costs and financial benefits (e.g., in terms of reduced health and social costs in a defined posttreatment period as compared to pretreatment values). Cost-effectiveness evaluation measures costs in relation to a specific unit of outcome (e.g., significant health improvement or significant reduction in addictive behavior). Cost-utility evaluation measures the utility of treatment for patients/clients, for example, in terms of disability-adjusted life years—DALYs [2] or as quality-adjusted life years—QALYs [25, 37]. For cost evaluations, see also WHO workbook 5; for economic evaluations, WHO workbook 8; and for instruments, see EIB of EMCDDA.

Formal Evaluation
This is an assessment of service compliance with professional, ethical, and legal standards.

Meta-Evaluation
Meta-evaluation is made on the basis of recognized procedures to combine quantitative results from several studies about the same or similar interventions, in order to establish composite outcome scores. This allows assessing the effectiveness of a given intervention with greater confidence than on the basis of a single study.

57.2.2.5 Evaluation by Whom?

External Evaluation
Outcome or/and process evaluation of treatment services or interventions by research professionals who are independent from the evaluated agency. This is the preferred modality because eventual bias in collecting client data is avoided, and the credibility of the study is enhanced. Disadvantages in comparison to internal evaluation may be the higher costs and resistance or noncompliance of treatment staff.

Internal Evaluation (Self-Evaluation)
This can be used as an internal learning process about the treatment program or in case of restricted funds for evaluation studies. However, internal evaluation is not recommended for outcome studies because credibility is lower in comparison to external evaluation. Collaboration with an external evaluation specialist is an advantage.

57.2.2.6 Evaluation Level and Timing

Evaluation Level
The target of M & E projects can be a specific type of intervention or therapeutic method. It can also be a specific service or setting for delivering treatment. In contrast to single intervention and service follow-up studies, a comparative evaluation focuses on the functioning and outcomes of a local, regional, or national treatment network of services or of the overall treatment system. Choosing the target implies the choice of an adequate type and design of the project.

One-Time and Repetitive Evaluation
One-time evaluation studies are frequently made for all purposes. More relevant are repeated studies or a continuous monitoring system, allowing for a documentation of specific changes in implementation and outcomes over time. However, such an approach has important cost implications. A possible compromise is the combination of a relatively simple monitoring of routine data with a more extensive evaluation study if indicated by changes in the monitoring data or after important program changes.

57.2.2.7 Resources

Estimations must be made on the amount of funds and type of manpower in order to conduct the planned M & E project, and the availability of these resources must be checked in advance, in order to avoid delays or restrictions during implementation. Also, the infrastructure for data storage and analysis must be made available.

In view of the difference in available resources between high-income and low−/middle-income countries, priority-oriented monitoring and evaluation research, as well as transnational collaboration, is recommendable.

Financial Resources
If an M & E study is mandated by an external agency (governmental or nongovernmental), the

budget available for the study must be identified, in order to design the study accordingly. Or else, the research group planning the study has to present a budget proposal and apply to a funding agency (Research council, Foundation, Health Authority, etc.).

If there are doubts about the feasibility of the study (e.g., access to services and patients/clients), a stepwise procedure may be preferred. In this case, a separate budget for the feasibility study is needed, and the results will determine the budget of the ensuing evaluation study.

Human Resources
Which staff is needed for carrying out a planned project? Various functions must be considered: expert support for setting up the research questions and protocol, for determining the appropriate methods and instruments, for training of interviewers, etc. Staff responsible for data collection, interviewers, staff for data control and entering into a master file, statistician for data analysis, etc. are needed. It is helpful to identify staff in advance, in order to avoid delays in implementation and in order to establish a realistic budget.

Infrastructure
Access to the necessary equipment for staff and for safe storage of data is to be ensured, as well as the disposition of the appropriate software for data handling and analysis.

57.2.2.8 Partners

Most M & E projects are a collaborative effort between various partners, especially in case of external evaluation of services and networks. Clear agreements on functions, responsibilities, temporal availability, and costs are recommended, eventually with written contracts.

Funding Partners
Agreements on the overall budget, bookkeeping, financial controls, timing of payments, and financial reports help to prevent misunderstandings and litigations. Such agreements should be made to protect the interests of all parties.

Therapeutic Partners
All projects on external evaluation are based on collaboration between researchers and treatment providers. Agreements are needed on the access to patient/client data and service data, access to patients/clients for external interviewers, responsible person in a given service for organizing and facilitating the research process, ownership of data, and arrangements for publishing the study results. Procedures in case of upcoming problems during project implementation should also be agreed upon in advance.

A special situation is created in case of a systematic evaluation at the system level, involving all or selected treatment providers.

Research Partners
In case multiple researchers or research groups are involved, a clear working arrangement should identify the functions, tasks, and responsibilities of the individual persons. If a service provider hires a researcher or research group for an internal or external evaluation, or monitoring system, there is also a need to identify the various functions, tasks, and responsibilities.

57.2.2.9 Expected Obstacles

Most problems occurring during project implementation are due to missing or incomplete preparation. However, even a carefully prepared project may meet some obstacles. Some of the frequent ones are mentioned here.

Compliance with Protocol
Staff involved in project implementation may disregard details of the research protocol and thereby weaken data reliability, even if well instructed. This may also happen in case of changes of staff. Tutoring staff activities over the entire duration of the project helps to avoid such failures. Also, efforts to make a strong evaluation culture at the system level acceptable will contribute essentially to overcome this type of obstacle.

Resistance from Patients/Clients
One of the most common problems is the refusal to participate in a randomized study, resulting in

an unacceptable degree of sample selectivity. This is especially to be expected if a control group with placebos or other forms of low therapeutic value are used or patients/clients are not confident that their data will be well protected against external parties, for example, in studies involving illicit substance use and/or drug-related criminal activities. Informed consent should cover not only aims and design of the study but also measures taken to guarantee data protection.

External Interference

It may so happen that family members of patients/client or other third parties raise opposition against an M & E project, on the basis of ethical concerns. It is advisable to have an explicit permission from an ethical committee, if not already prescribed by law.

57.2.3 Implementation of Monitoring and Evaluation

57.2.3.1 Available Guidelines and Instruments for Treatment Evaluation

International Guidelines for Treatment Evaluation

From the number of evaluation guidelines, a few are mentioned here, on the basis of their wide international applicability. It is highly recommendable to consult one or more guidelines before starting an M & E project.

WHO/UNODC/EMCDDA Evaluation of Psychoactive Substance Use Disorder Treatment Workbook Series (WHO 2000)

This publication consists of a series of workbooks intended to educate program planners, managers, staff, and other decision-makers about the evaluation of services and systems for the treatment of psychoactive substance use disorders. The objective of this series is to enhance their capacity for carrying out evaluation activities. The broader goal of the workbooks is to enhance treatment efficacy and cost-effectiveness, using the information that comes from these evaluation activities.

EMCDDA Guidelines for the Evaluation of Treatment in the Field of Problem Drug Use. A Manual for Researchers and Professionals [29, 9]

This publication provides basic information on the options, elements, and procedures of drug-related treatment evaluation. It also contains an overview of European and international evaluation and research networks.

Instruments for Treatment Evaluation

The EMCDDA evaluation instrument bank (EIB) covers a range of available instruments ready for data collection, including information on the target group specificity, the available languages (mostly English), copyrights, and eventual restrictions for use. Instruments are available for needs assessment and planning, for mediating and risk factors, for process and outcome evaluation, for patient/client satisfaction, and for staff knowledge and satisfaction.

The WHO/UNODC/EMCDDA evaluation workbooks present many instruments in the context of the various steps and approaches of treatment evaluation (WHO 2000).

A recent instrument for assessing and improving addiction treatment at the system level is the WHO Substance Abuse Instrument for Mapping Services (SAIMS) in high-income and middle–/low-income countries and disadvantaged regions [40].

57.2.3.2 Adaptation of Guidelines to Special Situations Recommendations

The recommendations made in guidelines do not always respond to the specificity of a given project. However, major deviations from recommendations should be highlighted and reasons should be given. Special situation may arise from restricted resources or ethical restrictions. While there is some research on how to adapt treatment guidelines to clinical practice [13], no such systematic effort is known for evaluation guidelines.

An innovative attempt is to be expected from the WHO SAIMS project [40].

57.2.3.3 Meta-Analysis and Reviews of Evaluation Studies

Two organizations have been established in order to review and analyze evaluation studies selected for their rigorous methodology: the Cochrane Collaboration and the Campbell Collaboration.

The Cochrane Collaboration (www.cochrane.org) has its focus on evaluation of medical treatments, while the Campbell collaboration (www.campbellcollaboration.org) has its focus on social interventions.

Both organizations make their reviews available in their respective online libraries (www.thecochranelibrary.com, www.campbellcollaboration.org/library.php). A growing number of reviews cover pharmacological and psychosocial treatments in addiction and their outcomes.

57.2.3.4 Study Designs and Protocols

The choice of the appropriate study design depends on the research questions and on the available resources. The most frequently used designs are presented in Table 57.2 (see also Ref. [9], Chap. 3, Table 1).

Cross-Sectional Studies

Cross-sectional studies are one-time studies to compare treatment services, treatment populations, and treatment outcomes at a given moment in time (e.g., intermediate outcomes during treatment or after terminating treatment). Cross-sectional studies cannot describe processes of change over time.

Table 57.2 Main types of study designs

Cross-sectional studies	Comparing interventions/services at a given point in time
Cohort studies	Comparing measurements of single interventions/services or several interventions/services at multiple points in time (baseline data, intermediate outcomes, outcomes at follow-up). Cohort studies are made prospectively or retrospectively (on the basis of past data files)
Randomized controlled studies RCT	
Quasi-experimental studies	
Comparing outcomes if interventions are assigned to patients/clients at random, not as in clinical practice (observational studies)	
RCT with special randomization procedures	

Cohort Studies

Cohort studies describe the course and outcomes of treatment populations, which receive their treatment as usual in practice, not allocated by randomization (observational or "naturalistic" studies). Cohort studies use retrospective or prospective data.

Longitudinal Retrospective Studies

Anamnestic data on pretreatment characteristics and outcomes of treatment populations are used to describe the therapeutic results of a given intervention/service alone or in comparison with other interventions/services. This type of study is more economic in comparison to prospective studies, which need multiple, at least two, measurement points in time; its usefulness, however, depends on the availability and quality of anamnestic data.

Longitudinal Prospective Studies

Collecting pretreatment, during-treatment, and posttreatment data at different time points allows a focused and detailed description of the treatment process and results. It avoids biased or missing baseline data and therefore provides for more reliable results of effectiveness. Prominent national studies comparing cohorts from different treatment settings are the DATOS study in the USA [28] and the National Treatment Outcome Research Study (NTORS) study in the UK [11].

Randomized Controlled Studies

Randomized controlled studies (RCT) are the "gold standard" for evaluating specific therapeutic modalities and medications in clinical research. Patients are allocated "at random" to an experimental group or to a control group, thereby minimizing selection factors between the two groups. As not all patients are willing to accept randomization, especially if not allocated to their preferred intervention, this design may suffer from refusal to participate or from elevated dropout rates. Randomized studies allow to identify the effectiveness of a modality or medication but

do not provide results of effectiveness due to their selectivity. An updated collection of RCTs on addiction treatment can be found in the Cochrane library.

Double-Blind Randomized

If assignment to the experimental or the control group is not revealed to patients and therapists, their preferences are better (although not completely) ruled out, and the study gets more reliable results about comparative treatment efficacy. This design is mainly used for a comparison of medications; psychosocial interventions cannot be "blinded."

Quasi-Experimental Designs

Instead of comparing two or more modalities, the effects of an experimental modality can be compared to the course while waiting to be accepted for that modality. In this case, the control group receives treatment as usual or no treatment while waiting.

In the Zelen design, informed consent is only asked after randomization and only from patients assigned to the experimental group, while those who are randomized to treatment as usual need not consent to participation in the study [31]. This design makes it easier for patients to participate because they do not have to consent to be randomized. Of course, blinding is not possible in this design.

Another design uses different sequences of treatment modalities, for example, A-B-A compared with B-A-B or B-B-A.

Role of Methodology for the Quality of Results

Grading of Evidence

Treatment evaluation searches for scientific evidence that can be used as a basis for therapeutic recommendations. However, there are grades of evidence, depending on the type of study design (see also Ref. [12]). The following is an adapted version (Table 57.3).

Standards for Consensus Building

Where evidence from quantitative studies is not available or feasible, recommendations for good practice are mainly based on expert opinion. In order to optimize the consensus-building process, rigorous rules have been established [1].

Table 57.3 Grading of evidence grade definition

A	Highest degree of evidence: Review from multiple randomized controlled studies (RCT) with convergent results
B	High degree of evidence; results from single RCT and controlled clinical studies
C	Moderate degree of evidence: Prospective comparative longitudinal studies (observational studies without control design)
D	Low degree of evidence: Single intervention/ service follow-up studies, case studies E very low degree of evidence: Nonsystematic observations
Z	Not known

57.2.3.5 Quantitative and Qualitative Methods

Quantitative Methods

Quantitative methods are used for outcome evaluation. They consist in collecting empirical data via standardized instruments (surveys, questionnaires, pre- and post-tests) for statistical analysis and mathematical modeling and in producing numerical results (statistics, percentages), which answer specific research questions. Data may come from existing databases (secondary data) or are collected directly from treatment samples (face to face, per telephone, or electronic media). Questionnaires may be self-administered or administered by trained interviewers. Sample size and homogeneity, reliability and validity of data, and appropriate statistical methods and models are essential for representative results.

Not all patients/clients who participate in a randomized evaluation study are compliant with the study protocol and available for follow-up data collection. Two concepts are therefore used for statistical analysis: the intention-to-treat (ITT) concept includes all participants who have been randomized, ignoring noncompliance and withdrawal, while the per-protocol concept includes only participants without any major protocol violations [14].

Qualitative Methods

Qualitative methods are mainly used for process evaluation. When indicating problem areas in the provision of treatments, they can also be useful for improvements and for generating new research questions. They provide information for the construction of questionnaires in process and outcome evaluation, and they can be used for the interpretation of quantitative findings [23].

The main methods are participant observation, semi-structured interviews, focus groups, and narrative research (see Ref. [9]). A standardized method for the selection of interview and focus group partners is the theoretical sampling model, allowing for the broadest possible spectrum of views and perspectives [10, 30].

57.2.3.6 Use of Results

It is advisable to determine at an early stage of an M & E project how the results will be communicated, by whom and how. This includes issues like data ownership and authorship in publications. In order to avoid later litigations, all agreements should be documented in written.

A first start to communicate evaluation results are intermediate and comprehensive final reports; for recommended components see [39] (workbook 2, step 4) and the EMCDDA Guidelines for treatment evaluation ([9], Chap. 6). Reports must at least be accessible to all stakeholders of an evaluation project. On the basis of the final results, a publication plan can help to make the best use of those. The scientific community is best reached by publications in peer-reviewed journals, and a wider audience eventually by open access journals, books, good practice documents (e.g., Ref. [33]), pamphlets, mass media articles, etc.

Once the results are known, what they mean and to whom they might be communicated should also be discussed in order to optimize their potential impact on treatments, on service planning and improvement, on treatment policy, etc.

57.2.3.7 Checklists for Assuring the Evaluation Process

All those involved in planning and implementation of a given project can profit from checklists which help to keep all elements of the project under control. The EMCDDA Guidelines for treatment evaluation present useful checklists for the preparation and implementation, as well as for the evaluation process ([9], Chap. 5).

57.2.4 Treatment Outcomes: Selected Evidence-Based Guidelines and Systematic Reviews

- Effectiveness of Therapeutic Communities: a systematic review [21].
- Principles of Drug Dependence Treatment. A Research Based Guide (NIDA [24]).
- Guidelines for the Psychosocially Assisted Pharmacological Treatment of Opioid Dependence [38].
- Contemporary Drug Abuse Treatment. A Review of the Evidence Base (UNODC [32]).
- Reviews for specific interventions:
- Calabria et al. [4]
- Humphreys and McLellan [17]
- Malivert et al. [21]
- Hertzler et al. [16]
- O'Donnell et al. [26]
- Werb et al. [35]
- Bomparis [3]

57.2.4.1 Cochrane Library (Selected Reviews)

- Psychological therapies for pathological and problem gambling (2011)
- Methadone for non-cancer pain in adults (2012)
- Psychosocial interventions to reduce alcohol consumption in concurrent problem alcohol and illicit drug users (2012)

- Nicotine replacement therapy for smoking cessation (2012)
- Mobile phone–based interventions for smoking cessation (2012)
- Combined pharmacotherapy and behavioral interventions for smoking cessation (2012)
- Psychosocial interventions for benzodiazepine harmful use, abuse, and dependence (2012)
- Effects of psychostimulant drugs on cocaine dependence (2010)
- Acamprosate for alcohol dependence (2010)
- Opioid antagonists for alcohol dependence (2010)
- Psychosocial interventions for reducing injection and sexual risk behavior for preventing HIV in drug users (2010)
- Psychosocial interventions for people with both mental illness and substance abuse (2010)
- Buprenorphine maintenance versus placebo or methadone maintenance for opioid dependence (2008)
- Psychosocial interventions for cocaine and psychostimulant amphetamines related disorders (2007)
- Alcoholics Anonymous and other 12-step programs for alcohol dependence (2006)
- Methadone maintenance at different dosages for opioid dependence (2003)

57.2.4.2 Campbell Library (Selected Reviews)

- Effects of early, brief, computerized interventions on Risky Alcohol and Cannabis Use Among Young People: A Systematic Review (2013)
- The Effectiveness of Incarceration-Based Drug Treatment on Criminal Behavior: A Systematic Review (2012)
- Brief Strategic Family Therapy for Young People in Treatment for Non-Opioid Drug Use (2012)
- Effects of drug substitution programs on offending among drug addicts (2009)
- Case management for persons with substance use disorders (2009)
- Motivational interviewing for substance abuse (2009)

Key Points

This chapter focuses on how treatment services and networks can be analyzed in regard to their functioning and usefulness, in a systematic long-term process, or in time-limited research projects. Essential elements are conceptual preparation of what should be learned (type of evidence), which patients and professional partners should be involved, what resources are needed and available, advantages and limitations of methods to be applied, and use of results in the interest of patients and all concerned.

Clinical Relevance

Treatment is about improving the symptoms of medical conditions, to learn about which interventions are effective for whom in the short and long term, and how to improve the patient's quality of life in caring for incurable conditions. This chapter helps clinicians to assess the patient situation beyond a formal diagnosis in all relevant aspects to develop and follow up an individual treatment plan and to learn about the effectiveness and side effects of their interventions.

Abstract

In the first edition of the International Society of Addicted Medicine (ISAM) textbook, specialized ways of training from The Netherlands, Canada, Norway and Indonesia were presented. In this chapter, an update of the training in these countries is presented. Contributions from India, Australia and the United States are new.

Although there are, of course, differences based on local settings and prevalence of substance-related disorders, there is a more or less consensus on the content of the educational courses. All contributions illustrate that it is not that difficult to reach consensus on a national level. What makes them all different is the adaptation to local educational and licensing requirements that govern the national practice of medicine.

A preliminary conclusion is that the process towards an Addiction Medicine (AM) specialty is universally incremental and currently in transition, creating unique challenges in implementation but also opportunities for international group support and collaboration.

Keywords

Addiction Medicine (AM) · Addiction Psychiatry · Educational courses · SWOT analysis · Medical speciality development International survey · Undergraduate curricula in AM · Postgraduate addiction-oriented courses

58.1 Introduction

Substance use disorders (SUD) affect every medical practice. It is a recent development that medical doctors specialize in the field of Addiction Medicine (AM). In the section on Education and Training in the first edition of the ISAM textbook, specialized ways of training in The Netherlands [6], Canada [5], Norway [19] and Indonesia [4] were presented. At the end of the introduction of the section, it was concluded that the initiatives described were uniformly recent ones and are at various stages of development [8]. It was hoped for that the section could promote more international collaboration and support. Concerning the training in different countries, it was also concluded that there is no 'one size model fitting all'.

A review paper summarized scientific publications that outlined the content of Addiction Medicine curricula and evaluated the evidence for efficacy for training in Addiction Medicine. One of the conclusions was that Addiction Medicine should get the same priority as other chronic diseases do and that it must be integrated into the core of medical curricula of under- and postgraduate training of medical doctors.

An international consultation on training in Addiction Medicine led to a global core set of knowledge, skills and attitudes and recommendations for the under- and postgraduate training of medical doctors. The need to tailor a curriculum to national settings and different specialities was recognized [2]. The journey towards specialty recognition must also adapt to local educational and licensing requirements that govern the national practice of medicine.

In this chapter, we will present an update of the training in Norway, The Netherlands, Canada and Indonesia. Initiatives from India, Australia and the United States are new in the chapter.

Some countries have adopted a focus on primary care; others have a focus on specialties, including psychiatry, internal medicine and community health, and most are adopting a multiple approach. In most paragraphs, the strengths, weaknesses, opportunities and threats are described, sometimes as a special subparagraph. A preliminary conclusion is that the process towards an AM specialty is universally incremental and currently in transition, creating unique challenges in implementation but also opportunities for international group support and collaboration.

58.2 The Netherlands

Between 2000 and 2005, it became clear for the medical directors in the Addiction Treatment facilities in the Netherlands that the quality of Addiction Medicine (AM) was problematic. This was due to shortage of medical doctors interested in AM, medical doctors in the field without

proper training, low perspective for career and being faced with the fact that the best doctors leave to specialize as psychiatrists, internists, neurologists or general physicians (GPs). In just two years, we managed to start a full-time, two-year professional training in AM in the Netherlands. In 2012, AM was approved as a medical subspecialty by the Royal Dutch Society of Medicine. The development of the Dutch Master in Addiction Medicine (MiAM) was described in detail in 2013(7).

The aim of this section is to describe the present status of the Dutch MiAM, to present an evaluation of the seven groups of medical doctors that graduated and to describe the process of re-registration of the doctors who were enrolled in the register from the start. First, some words will be spent on addiction psychiatry.

Addiction is not a special area of attention in the training for psychiatrists, and addiction psychiatry is not yet a super-specialty in the Netherlands. There are two structured ways to learn more on addiction as a graduated psychiatrist. The Radboud Center of Social Sciences of the Radboud University offers a 10-day course on addiction psychiatry for psychiatrists, focusing on the increase of knowledge and skills in individual psychiatrists. Multidisciplinary In-Company courses in addiction psychiatry for psychiatrists, psychologists and nursing specialists, focusing on increasing the quality of the integral care of the mental health institute for psychiatric patients with a co-occurring substance-related disorder, are developed and implemented by the first author (CDJ).

In the competency-based MiAM, theoretical courses are integrated with learning in clinical practice under guidance of an experienced clinical teacher: a dual education paradigm. The theoretical courses consist of evidence-based medicine, communication and basic psychotherapeutic skills, neurobiology of addiction, Addiction Medicine, addiction and psychiatry, clinical leadership and public health. The seven main competencies are concretized in 31 Entrustable Professional Activities (EPAs). EPAs are the units of a professional practice that constitute what clinicians do as daily work (8). They are integrated in a personal education plan (PEP) and are evaluated by different ways of examining and with a focus on stimulating self-reflection.

From the start of the MiAM in 2007 till 2019, a total of 139 medical doctors in 7 batches started the course, 65 women (47%) and 74 men (53%) with a mean age of 41.7 (SD 8.8) in a range of 26–59. Not all were native Dutch medical doctors, 39 (28%) came to the Netherlands and integrated as medical professionals after graduating as doctors again in the Netherlands. Many of them were refugees. Overall, 104 did graduate (75%) and 35 terminated the course prematurely (25%). The reasons for ending the course prematurely vary: severe physical illnesses, psychiatric or personality disorders, burnout, conflicts with management or a supervisor, inappropriate learning attitude or a combination of these.

In recent years, addiction doctors have gained a place within the medical community. Since the start of MiAM, the addiction doctor has become more professional and can therefore be designated as a treatment coordinator within the institutions for mental healthcare and addiction care. The programme is highly condensed, and 2 years is not enough to fully cover all aspects of AM. Although most graduates continue working in the addiction treatment centres, some of them wanted more and started psychiatry training to combine their clinical work as a PhD candidate.

Until the start of the MiAM in 2007, most doctors only worked in the specialized field of care for patients with SUD. In 2019, they also worked in general psychiatry, and there are opportunities for primary care, emergency care, liaison psychiatry, pain clinics and so on.

One of the challenges is to reassess the competences listed with the updated Canadian Medical Education Directives for Specialists (CanMEDS) competencies (9) and, above all, to integrate the educational milestones into clinical practice to illustrate how the competence of an addiction doctor progresses during his career—the journey from beginner to master.

In 2019, almost 200 medical doctors were included in the register of the Dutch Medical Society. In 2016–2017, there were almost 100 job offers. With an output of graduated doctors of 20 per 2 years from the MiAM, these job offers will never be fulfilled. The situation for the future is

even worse because it is expected that almost 40% of the registered will end their career within 10 years.

Postgraduates are registered as addiction specialists and have to re-register every 5 years. In order to keep the registration, one needs to meet certain criteria, for instance, for at least 16 h a week for the duration of 5 years, they need to have worked in patient care, attended training workshops and symposia, and participated in peer training meetings. The Dutch Society of Addiction Medicine developed the content and process of the individual evaluation programme that starts in 2020. Every Addiction Medicine Specialist will have to present a personal education plan, which will be evaluated every 5 years by a review committee. For former students of the MiAM, this will merely be a continuation of personalized learning. The older and mostly the self-taught group of experienced doctors face a new approach of lifelong learning.

58.3 Canada

Canadian medical practice, particularly in acute care settings, has needed to rapidly evolve to the opioid crisis, growing stimulant problems and the legalization of cannabis nationally. Substance use problems are cited as the third most important in order of competence for newly practising primary care physicians, ahead of ischaemic heart disease and diabetes [13]. Relatively small numbers of clinicians skilled in AM have been previously tied to a lack of available training in Canada, but that appears to be changing [13]. A number of initiatives nationally are underway to promote best practices and validate the special knowledge, skills and practices required for the practice of AM.

Initially, Canadian physicians sought specialty recognition through Certification and Board Diplomas of the American and International Societies of Addiction Medicine, which would be subsequently recognized by the Canadian Society of Addiction Medicine [7]. The strength of this was that it was accessible through a practice-eligible route, requiring less investment by practising physicians. But, while certification could ensure a certain knowledge base in AM, it may not ensure competence to practice AM or meaningfully structure training.

As medical training in Canada has shifted to being competency-based training [9], AM training initiatives have followed suit. The two primary licensing Colleges in Canada, the College of Family Physicians of Canada (CFPC) for primary care physicians and the Royal College of Physicians and Surgeons of Canada (RCPSC) for specialists, each approved added competencies for AM in 2016. The CFPC awards a Certificate of Added Competence (CAC), and the RCPSC awards a diploma in an Area of Focused Competence (AFC). They have slightly different but complementary approaches.

The CAC in AM approved by the CFPC in 2018 aims to determine competence at the advanced skills level for primary care providers. The CFPC has developed 13 priority topics specific to AM with key features to each. The priority topics were developed by a nominal group using an individual survey, followed by group discussion and consensus, as well as from a larger national survey of family practitioners. The priority topics include: (1) clinical boundaries; (2) AM screening, assessment and triage; (3) treatment planning and continuing care; (4) management of intoxication and withdrawal; (5) harm reduction within the continuum of care; (6) pharmacology; (7) psychotherapeutic techniques; (8) concurrent mental health disorders; (9) medical comorbidities; (10) pain and addiction; (11) special populations; (12) advocacy; and (13) provider health resilience. Each priority topic has key features to further specify and define them. Competence is indicated by consistent demonstration of most of the key features across a good sample of priority topics. Initial CACs will be awarded to family physicians who have previously acquired competence deemed worthy of recognition through practice experience, successful completion of a residency training programme and/or continuing professional development, and demonstrated leadership in the domain of the CAC. Thereafter, CACs are to be awarded based on the credentials and docu-

mented evidence as judged by a peer review committee process. It has led to the development of 1-year fellowships for primary care physicians in AM across Canada at multiple training sites. The strength of the CAC process is in its flexibility and accessibility to current primary care practitioners, as well as new graduates, so it is expected that there will be significant uptake of CACs and extend the specialty recognition of AM for those in primary care.

The AFC in AM approved by the RCPSC in 2019 applies to all medical specialties, so the development of the training requirements has been more complicated than that for the CAC. For residency training programmes to have an AFC programme in AM, they have to be accredited by the RSPSC, which can take 1–2 years to meet their requirements. To receive an AFC diploma in AM, trainees must be certified in their entry route discipline, in order to be eligible to submit a Royal College competency portfolio in AM to the AFC Program Committee at the accredited programme. Competencies are described in the CanMEDS roles [10] where diplomats are expected to function as a competent specialist in AM capable of enhanced practice within the scope of their discipline. The competency portfolio addresses eight goals, each having multiple milestones with standards of assessment and specific supporting documents that are required to be signed off upon by their supervisor. The eight goals include the responsibility for: (1) evaluation of patients for substance use or addiction(s) in urgent and elective settings; (2) acute stabilization and management of patients with addiction; (3) comprehensive ongoing management for patients with addiction; (4) health promotion practices for patients with addiction; (5) engaging and supporting individuals within a patient's social network; (6) acting as a resource for other health providers; (7) advocacy for patients with addiction, for addiction treatment or for addiction prevention and (8) advancement of the discipline of AM through teaching and scholarly activity. The AFC requirements are quite stringent, so it may be challenging for specialty residency training programmes beyond those in very large urban centres to be able to establish AFC accredited programmes and attract residents or fellows who are willing to commit further training time beyond the 5 years they already require for their specialty. Those who do the training, however, will be highly skilled and potentially greater advocates for the future of AM. By the standards being applicable to all specialties, it may also facilitate greater cross-pollenization in AM across specialties.

Specialty recognition of AM in Canada continues to expand through practice-eligible routes and formal residency training programmes, with there now being CACs and AFC diplomas for primary care and specialists, respectively. If the AFC diplomas are embraced by medical specialists, this may set the stage for the development of formal sub-specialties in AM in the future.

58.4 Norway

The development of the specialty in Norway was described in detail in 2015 [19]. The specialty and interim regulations were approved by the Ministry of Health in 2014, and the first AM Specialist was approved in 2015.

58.4.1 The Specialty Regulations and Other Requirements to Become a Specialist in Addiction Medicine

The specialty regulations are as follows: 5 years of internship in accredited institutions is required of which 42 months of internship in AM, including 12 months in a detoxification department, 6 months in inpatient/residential treatment, 12 months in outpatient treatment and, for the last 12 months, a range of services can be chosen. Twelve months of internship should be in psychiatry and a minimum of 6 months of these in an acute ward. The last 6 months of internship can be in other relevant areas of medicine, including somatic wards, pharmacology, psychiatry or general practice.

In addition, the candidate must have 270 h of national coursework during the 5 years and at

least 70 h of hospital coursework a year. The candidate must receive individual clinical supervision of at least 1 h per week throughout the clinical training and also group-based supervision. Further, the candidate must receive at least 30 h of specialized supervision in a specific therapeutic method.

58.4.2 The Status in June 2019

Overall, 129 doctors have been accredited full specialists in AM after interim regulations. Additionally, more than 100 medical doctors are in training across the country to become full specialists in AM. It is expected that approximately 20 of these candidates will be accredited full specialists in AM after the Specialty regulations in 2019.

Teaching hospitals have been established in all regions and at all larger hospitals in Norway. A total of 20 hospitals/institutions have been accredited as teaching hospitals.

A national coursework has been established. All candidates entering the structured education in AM will take part in a 4-week compulsory coursework over 2 years, covering a wide range of essential knowledge needed to be a specialist in AM. The third group of candidates in this compulsory coursework will finish the 4 weeks in the autumn of 2019, and a fourth group will be started the same autumn. Other coursework that have been established are courses of cognitive therapy, psychodynamic therapy and group therapy; pharmacology; treatment of attention deficit hyperactivity disorder (ADHD) for substance-dependent patients; as well as clinical toxicology. The candidate is also expected to use an online self-study portal and can, in this way, achieve competence in specific teaching goals.

58.4.3 National Conference in Addiction Medicine

Each year, a national conference for AM specialists, candidates and other medical doctors with interest in AM is arranged by the Norwegian Association of Addiction Medicine in order to further develop the new specialty and focus on new development and research in the addiction field. This conference is also an important meeting place for the new specialty.

58.4.4 Strengths, Weaknesses, Opportunities and Threats Analysis

The strengths of the full specialty in AM in Norway are several. We have successfully established the full specialty with accredited specialists and teaching hospitals in all regions of the country. The new specialty means that patients with substance use problems will receive specialist evaluation and treatment from well-qualified doctors in AM. The requirements for AM specialists are the same as for any other specialty in medicine, giving AM specialists a similar status as other medical specialists. The recruitment to the new specialty is very good because the medical doctors now have a possibility to make a career in AM. This means that the medical doctors will stay in the addiction field to a far greater extent than previously.

A weakness regarding the AM specialty is that not all the hospitals have enough specialists yet. However, as long as the recruitment into the specialty is very good, this is a situation which will improve with more medical doctors being accredited as specialists. Another possible weakness is that there is too little emphasis on somatic diseases in the specialist requirements.

Addiction research in Norway has developed a lot during the last 10–15 years and many PhD diplomas have been acquired both by medical doctors, psychologists and other professionals. Doctors in AM have good possibilities to finish a PhD as part of their specialist education or in addition to their specialty. Another opportunity is that having an AM specialty makes it easier to cooperate with regard to both treatment and research with somatic and psychiatric specialists, regarding acknowledging the many patients with co-occurring substance use problems and somatic and psychiatric diseases.

The establishment of the AM specialty has been viewed as a threat by some of the other professionals in the addiction field. The treatment of substance use disorders in Norway is a multiprofessional area, where social workers, psychologist, nurses, medical doctors and other professions work. It will be up to the AM specialists to prove that better educated medical doctors will be an asset, not only for the patients but also for the other professionals in the addiction field.

58.4.5 Conclusion

The full medical specialty in AM is well established in Norway. So far, 129 specialists in AM have been accredited. More than 100 specialist candidates are in structured training all over Norway to become full specialists in AM. There are enough medical doctors who want to start the structured training in AM. More than 20 teaching hospitals/institutions in AM across the country have been accredited. The national coursework for the candidates has been established and is well functioning. A yearly conference for AM has been established as an important meeting place for the thriving and developing specialty. A lot of work over a long time by many pioneering medical doctors in the addiction field has led to the successful establishment of a full specialty in AM in Norway. The Norwegian Medical Association views the establishment of the AM specialty as a success, in terms of how fast the specialty has developed and how well the AM specialists and training of the new candidates is spread around the hospitals in Norway during such a limited time period.

58.5 Indonesia

The development of a National Training Program on AM in Indonesia was described earlier [4]. Here, we describe the progress for the under- and postgraduate training. First, we like to globally describe the undergraduate AM Training (AMT). In 2019, the Atma Jaya Catholic University is the only medical school that provides AMT in a 5-week elective block for fourth-year medical students at the final semester of the pre-clinical level. After following the block, the participant is expected to have (1) increased knowledge and understanding of the basics of substance use and addiction (epidemiology, neurobiology, psychology, clinical, socio-cultural and medicolegal aspects) skills; (2) developed clinical skills (screening, diagnosis, early treatment), addiction counselling and public education; and (3) expressed positive attitudes towards patients with substance use and addiction.

The academic staff (Astri Parawita Ayu, Isadora Gracia and Kevin Kristian) that contributes to the AM block is mainly from the department of psychiatry. Atma Jaya has been organizing the AM block since 2009, and several evaluations have been performed. The AMT block improved students' attitude towards patients with addiction and changed their perceptions of addiction. Further development is threatened by the fact that human resources in the school of medicine are scarce. In 2019, the dean had requested the AMT team to propose topics that can be embedded in the medical curriculum and distributed throughout the pre-clinical and clinical training. Such a request is an opportunity to develop AMT in Atma Jaya further. To answer the dean, the academic staff and five students are running a training need assessment [15] among medical doctors who work in all primary healthcare facilities in Jakarta. Hopefully, other universities can collaborate, and replication of such an assessment by other universities will make the results eligible at the national level.

The Indonesian Standard Competency for Medical Doctors states that a general practitioner (GP) has to be competent in making a clinical diagnosis for a substance use disorder and providing initial treatment and referring a patient. However, there is no national curriculum for medical doctors in Indonesia yet. Each university has to develop its own excellency in one to three topics. Atma Jaya University is one of the universities that has a focus on addiction in the form of an elective block.

In Universitas Padjadjaran (UNPAD), another academic university, the focus is more on

postgraduate programmes [4], and the Indonesian Short Course on Addiction Medicine (ISCAN) was developed in 2010 [14]. After 2012, two batches of this 6-month course were conducted on the weekends for postgraduate medical doctors from all over Indonesia.

The first batch consists of 25 participants, most of them were recommended by municipal health departments in West Java as the requirements to be funded by UNPAD. The second batch were 30 participants, all of them were recommended and supported by national narcotics boards. We had evaluation on satisfaction to the topics and lecturers (Likert scale from 1–10). The average was an 8 for topics and lecturers in the first and second batch. We also have pre- and post-test for every module. It showed good improvement on knowledge. In general, the participants stated that the programme has been done well. They enjoyed the programme, although they had to spend their weekend to attend. The training would improve if behavioural addictions could also be tackled during the course, and if more workshops were integrated to improve their skills.

In 2017, the Department of Psychiatry of Medical Faculty-Universitas Indonesia/Cipto Mangunkusumo Hospital had started a training programme of subspecialty in addiction psychiatry in collaboration with the Kurihama Medical and Addiction Center, Japan, and Flinders University, Australia. Psychiatrists who want to become a consultant in addiction can enrol in this 2-year programme. By the end of the training, participants are expected to achieve academic and professional competence related to addiction psychiatry. In 2019, four addiction psychiatrists have graduated from such training. The training programme consists of a range of topics concerning drugs and behavioural addictions and characteristic psychiatric comorbidities. Participants are obliged to follow clinical rotation at hospitals, community services, prisons and the national rehabilitation centre. The academic activities include webinar lectures, case presentations, and, by the end of the training, participants should submit a research report.

A standard curriculum is needed for medical doctors, nurses, psychologists and pharmacists to develop interprofessional education modules. Specific training programmes for each professional to gain knowledge and develop special skills in providing addiction services from a positive attitude towards patients with substance-related disorders. For residents in psychiatry, a 3-month stage in the addiction division is obligatory. The continuity and development of those programmes face a lot of obstacles due to the willingness and leadership of the stakeholders, including lecturers, resources and budget.

The problem with the development of addiction curriculum in Indonesia is because there is no strong intention from stakeholders to provide standard services [3]. Several focus group discussions with stakeholders showed that addiction problems are increasing, and it was regarded as very important to provide standard competence for healthcare providers' work in the addiction field. However, there are no collaborating efforts to make AM curricula in Indonesia a priority yet.

Small and separate programmes have been developed in collaboration with the International Consortium of Universities for Drug Demand Reduction (ICUDDR), the Colombo Plan and the U.S. Bureau of International Narcotics and Law Enforcement Affairs (INL). Indonesian universities can use the whole or a part of the curriculum developed by ICUDDR.

Universities also work together with the national and provincial narcotic board and local governments to provide a 2-day addiction training for primary healthcare doctors. The problem is that they only offer little knowledge, and the training does not really improve the doctors' skills. Furthermore, there is no continuation of the training, and the rapid changes in the role of the primary health doctor limit the effects of the training. In this respect, national addiction curricula and standard competencies are needed.

The development of AMT in Indonesia has several strengths. The foundation of AM has been made, starting from a previous project Integrated Management of Prevention and Control & Treatment of hiv/aids (IMPACT). There are some psychiatrists and lecturers who are interested in AM, and collaboration with addiction experts in Indonesia and abroad has been established. However, there is not yet a strong leader to bring together all AMT programmes, there is lack of

support and budget from stakeholders such as faculty and government, and there is too limited time allocated for the development of an addiction curriculum due to overburden of the academic staff.

Although it is quite hard to develop AMT properly, there are opportunities for the future that are hopeful. Professional organizations acknowledge the need to improve skills of healthcare providers working in the addition field. There are new leaders and governmental regulations supporting addiction treatment, including training of professionals working in AM. Several non-governmental organizations are funding the development of AM curricula.

In our opinion, strong leadership and willingness to collaborate nationally and internationally are the keys to develop sustainable national addiction curricula.

58.6 India

In India, training in addiction has been ingrained in the 3-year postgraduate psychiatry course. Selection for the course is held generally through nationally competitive entrance examinations for medical graduates. The means and mechanisms for implementation of addiction training vary from institution to institution. Typically, case-based teaching is carried out as a part of the general psychiatric evaluations and mentoring from faculty members. Some of the institutions have dedicated clinics or centres where the postgraduate trainees are posted during their rotations, which last from weeks to up to 6 months. Seminars, case conferences and didactic lectures are the methods through which theoretical aspects of addiction psychiatry are discussed during the postgraduate general psychiatry training. The emphases on the addiction-related topics vary, but they form a part of the overall teaching curricula for the psychiatric trainees. Assessment is generally case-based and through written summative assessments, wherein addiction psychiatry may be an overall part of the psychiatric syllabus. There is heterogeneity and substantial variation in the manner in which teaching-learning of addiction psychiatry is carried out in different centres.

Overseeing the training programmes, a need has been felt for development of super-specialty courses in addiction psychiatry, on similar lines as super-specialty training in cardiology and neurosurgery after broad-based postgraduate training in medicine or surgery, respectively. Thus, the Doctorate in Medicine Addiction Psychiatry course has been launched, the first of such courses being instituted about 5 years back. Currently, at least four centres in India are running this course: All India Institute of Medical Sciences, New Delhi; Postgraduate Institute of Medical Education and Research, Chandigarh; National Institute of Mental Health and Neurosciences, Bengaluru; and All India Institute of Medical Sciences, Rishikesh. This 3-year super-specialty course is open to medical graduates who have completed a 3-year postgraduate degree in psychiatry, and selection is done through nationally open competitive examinations. The aim is to develop addiction psychiatry specialists who have wide clinical and research experience, deep theoretical knowledge and who are attuned to national realities in healthcare. They would be expected to provide better care for patients suffering from addictions and provide input for policy matters when required, apart from advancing the science related to AM.

Currently, the curricula vary across the centres offering the super-specialty course. The institutes have their own curricular structure, posting schedules, teaching-learning methods and assessment strategies. The variability enables utilization of the strengths and resources of each of the centre (e.g. research focus, clinical focus or public health engagement). The trainees have to engage in research or complete a dissertation under the guidance of a faculty member. Graduates from the super-specialty course in addiction psychiatry have been recruited in different teaching and clinical institutions.

The All India Institute of Medical Sciences, New Delhi, started the course in 2016 January. There are about five positions per year (highest in the country till date). Trainees have exposure to inpatient and outpatient clinical care, including outreach methadone and buprenorphine dispensing and engagement in community services. They are trained in laboratory services and psychother-

apy for patients with addictions. Consultation liaison addiction psychiatry services help them see referrals from other departments and the interface of addiction and multiple medical illnesses. The institute has a system of structured formative assessments as well, through written examination and case discussion. The trainees partake in teaching of other postgraduate students and indulge in peer-teaching as well. Many of them have undertaken additional research pursuits and have volunteered their time for organizing Continuing Medical Education (CME) and conferences in addiction psychiatry.

The strengths of a super-specialty in addiction psychiatry include deep focus on the various aspects of addiction, the availability of dedicated and experienced professionals and presence of a comparable accreditation framework as other super-specialty disciplines. The weaknesses include lack of wider and specific demand from patients and prospective employers, variations in the conduct and emphasis of the course across centres and the lack of an association dedicated specifically towards addiction psychiatry. The opportunities presented are the cross-institution dialogue for exchange of curricula and students, regularization into annual meeting and conferences, utilization of the super-specialty trainees to impart supervision and teaching to medical students and interns, changes in summative and formative assessment methods to reduce subjectivity, and greater exposure from humanistic and legal perspectives of addiction. The threats include failure to develop proper referral mechanisms so that the patients are able to reach the super-specialists, and inability to expand the number of centres offering the course due to dynamically changing healthcare priorities.

The number of positions for such super-specialty doctors have been limited (less than 20 psychiatry specialists who have completed the course), which is paltry compared to the large population of India (over a billion and counting). The overall number of medical health professionals and psychiatrists are limited in the country, and such super-specialty courses are nascent and niche. Yet, the keen interest shown by trainees has been encouraging. We hope that with time, the graduates of this super-specialty course would be able to provide leadership in the field of addiction psychiatry, by expanding clinical care, training other medical graduates, conducting relevant and ethical research, providing policy directions and advocating for the cause of those who have been suffering from addictive disorders.

58.7 Australia

The training in AM in Australia was described in detail in 2011 [11] and 2013 [12]. The Australian Medical and Professional Society on Alcohol and other Drugs (AMPSAD) began in 1981 and developed a short training course, but this was undertaken by very few medical practitioners.

The Chapter of AM (AChAM) formed in December 2001 within the Royal Australasian College of Physicians (RACP) [16], and the Australian government recognized AM as a medical specialty in November 2009. RACP is the largest specialist college in Australasia mainly comprising specialists in the various branches of internal medicine. AChAM has adopted a well-established and widely accepted training scheme. Specialist reimbursement item numbers commenced operating in November 2010 and were upgraded to match those of other RACP specialists in 2016. The number of trainees has been slowly growing, but there is still a significant shortage of AM specialists.

The Royal Australian and New Zealand College of Psychiatry (RANZCP) [17] established the Section of Addiction Psychiatry, initially, as a special interest group without formal training. Addiction psychiatry is now a recognized subspecialty of psychiatry with about 150 members and requires 2 years of clinical training (RANZCP). It leads to the Certificate of Advanced Training in Addiction Psychiatry and includes a formal education programme, case history and clinical skills development described as Entrustable Professional Activities (EPAs). This training is well structured and requires assessment of written assignments but without examination. There is healthy interest in this programme from trainees and a growing clinical workforce.

There is a special-interest network for general practitioners (GPs) interested in drugs and alcohol. This is one of the 29 of networks with a specific interest. As a part of GP training, candidates can do extended skills posts for 6–12 months, and AM is one of the options. There are no specific training requirements beyond this. A number of GPs have proceeded to AM specialist training as described in the next section.

58.7.1 Addiction Medicine Training Programme

Advanced training in AM follows a modification of the general Postgraduate Physician Training, which comprises 3 years of basic training in internal medicine post internship, followed by 3 years of advanced training in the chosen field. There is a written examination early during the third year of training, and successful candidates proceed to a difficult clinical examination in general internal medicine later that year. Once the clinical examination is passed, trainees may enter advanced training in AM or another field. Assessment is by assignments and supervisor reports on clinical work, but there is no examination. A key difference for AM is that the RACP clinical examination is not required for AM training. However, the title Fellow of RACP (FRACP) is not awarded unless the clinical examination is passed. Specialist physicians with FRACP have broader internal medicine training and clinical privileges compared to AM specialists (FAChAM). Remuneration is now the same.

Basic physician training is one pathway for entry, but it is only adopted by a minority of current AM trainees. Entry via other clinical training is accepted and provides flexibility (RACP).

Advanced training extends for 3 years of supervised clinical postings and structured learning activities (RACP). Core training requires at least 18 months in a clinical AM position. Of the total, at least 12 months must be spent in an ambulatory (community) assessment and/or detoxification service, in opioid agonist prescribing. Six months is required in a consultation-liaison term in a general hospital, in an in-patient unit and in a pain clinic. These attachments may be part-time and undertaken concurrently. Experience in Psychiatry is also required as part of AM rotation and/or as a separate rotation.

The curriculum for AM covers the broad themes of clinical assessment and management of alcohol and other substance use disorders in a broad range of settings, including consultation liaison in hospitals and other health services; public health and prevention of alcohol and other drug use–related harms; regulatory issues; and medicolegal and forensic aspects of the practice. The curriculum is supported by a number of online training modules accessible to accredited trainees via the RACP website. There is a weekly national training symposium that can be accessed face to face or by webinar.

Trainees work in accredited clinical sites for clinical training. Site accreditation for the AM training programme is the responsibility of Chapter Education Committee (ChEC) to ensure:

- An appropriate level of supervision by Fellows of the Chapter with Supervisor training.
- Exposure to a wide range of clinical presentations.
- Opportunities and support for continuing education and research.
- Suitable infrastructure for training–equipment, clinical and educational resources, quarantined training time.

Trainees are encouraged to nominate a mentor separate from their supervisor.

58.7.2 Outcomes to Date

Informal feedback has highlighted several strengths of the programme. Trainees appreciate rotation through different treatment services with exposure to diverse models of care and supervisors. In particular, the breadth of AM practice incorporating behavioural medicine, physical health and mental health is appealing to trainees. The focus on self-directed adult learning has been welcomed. The online training modules are popular, with standardized teaching that is accessible at any time. The public health work-

book and the research project were considered valuable learning activities.

The number of trainees has been slowly growing and while there were 30 trainees active in 2019, the number remains insufficient to meet workforce demands. In particular, most trainees are in the most populous state (New South Wales) with very few in other states.

58.8 United States

Health professions' academicians, under the leadership of David Lewis, MD, now the Donald G. Millar Emeritus Professor of Alcohol and Addiction Studies at Brown University, created the Association for Medical Education and Research in Substance Abuse (AMERSA) in 1976, an interdisciplinary professional society of faculty members in professional schools of medicine, nursing, psychology, social work and other disciplines. AMERSA (www.amersa.org) has been the most consistent driver of improvement in the curricula of professional schools so that all graduates are more knowledgeable about addiction, addiction treatment and the health impacts of unhealthy substance use. Sadly, the goals of AMERSA in this regard remain unfulfilled, as the incorporation of content about addiction and recovery into the curricula of professional schools remains spotty.

The American Society of AM (ASAM), the largest professional association of physicians (and, since 2013, other professionals) devoted to improving addiction treatment quality and access (www.asam.org), has long had a committee on medical education, but ASAM's most prominent success has been in offering continuing education courses to persons already in practice. The ASAM Annual Conference and State of the Art Conference attract attendees from dozens of nations worldwide. ASAM also had a fellowship committee in the 1990s, which collected information about AM fellowship programmes in existence at academic medical centres and located in treatment programmes; none of these were accredited at that time by the Accreditation Council on Graduate Medical Education (ACGME) [1].

In 1993, the field of psychiatry took the lead in developing ACGME accredited training for physicians [18]. These fellowship programmes in addiction psychiatry were open to psychiatrists who had completed general psychiatry training. There are currently 49 accredited fellowships in addiction psychiatry. Most of these programmes would admit a non-psychiatrist into training, but such graduates would not be eligible for certification in the field. Completion of a fellowship by a psychiatrist could lead to certification by the American Board of Medical Specialties (ABMS) and its member board, the American Board of Psychiatry and Neurology, in addiction psychiatry; physicians from internal medicine, family medicine or other disciplines completing an addiction psychiatry fellowship were not able to secure any certification recognized by the ABMS.

In 2007, ASAM decided that a necessary step in securing ABMS recognition of AM would be to have physician certification conferred not by a membership society such as ASAM, but by a free-standing certification board. Thus, ASAM assisted in the creation of the American Board of Addiction Medicine (ABAM), which began offering the national certification examination in 2010. ABAM created a sister organization named The ABAM Foundation renamed The Addiction Medicine Foundation, or TAMF, and on January 1, 2019, renamed the American College of Academic Addiction Medicine, ACAAM, www.acaam.org. The mission of ABAM was to certify individual physicians, via an examination, in the specialty of AM, while the mission of TAMF was to accredit fellowship training programmes in AM. The ABAM Foundation developed educational objectives for training programmes and accreditation guidelines for training programmes, and it did its best to have its processes mirror those of the ACGME in establishing educational objectives and a core curriculum for graduate medical education (GME) programmes. By 2018, ACAAM oversaw the development of 52 fellowship programmes which met the rigorous accreditation standards it had set. Around the time that the American Board of Preventive Medicine (ABPM), one of the 24 member boards of the ABMS, developed an application to the ABMS Board of Directors (with the assistance of ABAM

Directors and staff), TAMF approached the ACGME about taking over the accreditation of AM Fellowships. The ABMS approved the application of the ABPM in 2015, and a certification programme for physicians in the subspecialty of AM was established by ABPM under the auspices of the ABMS. The first examination offered by the ABPM was in 2017. The first training programmes accredited by the ACGME in 2018 were sponsored by various primary residency programmes and 1 year in duration. The ACGME will have accredited 54 AM Fellowships by June 2019 (ACGME). These are sponsored largely by academic departments in academic medical centres: 13 in Department of Internal Medicine, 25 in Department of Family Medicine, 27 in Department of Psychiatry, 1 in Department of Paediatrics and none in Department of Obstetrics and Gynaecology. Thus, graduate medical education at the fellowship level in the subspecialty of AM is now on a par with fellowship training in other medical disciplines. Of the total 74 ACGME and ACAAM accredited fellowships, 2 are in Puerto Rico and 3 are in Canada.

Undergraduate Medical Education (medical school training) in addiction continues to be far less robust than the scope of the public health problem of addiction and unhealthy substance use. The existence of ACGME accredited training programmes has gotten the attention of Deans of Schools of Medicine, and there is growing advocacy to expand and improve the education of all physicians in this area. ASAM continues to be interested in improvement in medical school curricula in addiction. A separate group, the Coalition on Physician Education (COPE) in Substance Use Disorders (https://www.copenow.org/), was created in the wake of a Leadership Conference on Medical Education in Substance Abuse co-sponsored by the ABAM Foundation and the White House Office on National Drug Control Policy in 2008. COPE continues to advocate for curriculum development in medical schools in addiction.

Parallel to medical education in allopathic medicine leading to a Doctor of Medicine (MD) degree is the education of physicians in osteopathic medicine. The American Osteopathic Association (AOA) accredits osteopathic medical schools akin to the way the American Association of Medical Colleges accredits allopathic medical schools, and the AOA also accredits osteopathic residency programmes akin to the way the ACGME accredits residencies. The AOA also offers certification programmes for individuals holding a Doctor of Osteopathy (DO) degree, and there is a subspecialty society for osteopathic physicians, the American Academy of Osteopathic Addiction Medicine (AAOAM). The AOA does not accredit any fellowships in Addiction Medicine, but physicians with DO degrees may enrol in ACGME accredited fellowship programmes in AM.

58.9 Conclusion

In this chapter, examples of the development of Addiction Medicine as a (sub)specialty are described. If we compare the situation in the countries that were described in 2015 with the current state of affairs, it appears that considerable progress has been made. Furthermore, we have the impression that the content of the training courses is not very different between the seven countries. All over the world, professionals in AM seem to share the same ideas about addiction and patients with substance-related disorders. Of course, the training courses are adapted, for instance, to prevalence of the use of certain psychoactive substances and their related disorders. To teach AM, they all adopted a framework of competencies similar to CanMEDS, but we are aware of different educational methods.

In general, it is encouraging that in a few countries, there is an AM specialty. In others, individual professionals or professional communities in the field are working on the establishment of AM as a specialty. In some countries, the focus is more on increasing the quality and quantity of training programmes in Addiction Psychiatry. We can confirm the statement that there is not ‘one size that fits all’ [8].

If we look in more detail to the line of development in the seven countries described, we notice, however, significant differences. Concerning the development and implementation of Addiction Medicine, the strengths, weak-

Table 58.1 Strengths, weaknesses, opportunities and threats during the development and implementation of Addiction Medicine as a specialty in seven countries

	Strengths	Weaknesses	Opportunities	Threats
The Netherlands	Recognized as specialty by the medical community. Dual educational system. Gained a place in medical community	Short (2 years) educational course and therefore different from other specialties. Still a small group of specialists.	Re-registration process guarantees quality. Emphasizes the existence of a specific group of specialists Destigmatization of patients with SUD	A lot of job offers and 40% leaving AM within 10 years Discussions and conflicts with other medical specialists on whose territory patients should be treated
Canada	The initiatives to improve the quality of Addiction Medicine are widely supported by the medical community	AM still part of other specialties	Growing interest in AM in several other specialties and acknowledgement of the importance by licensing authorities	Few AM specialists outside of major urban centres
Norway	Better educated doctors mean better treatment for patients. Recognized as specialty by the medical community. The requirements for AM specialists are the same as for any other specialty in medicine	Too little emphasis on somatic diseases in the specialist requirements	Chances for scientific research in the field of AM	It is up to the AM specialists to prove that better educated medical doctors will be an asset to the addiction field
Indonesia	In universities, there is a growing interest in and implementation of undergraduate education in AM and postgraduate Addiction Psychiatry. Well-appreciated short training in AM	No progress in establishing AM as a specialty	Professional organizations acknowledge the need to improve skills of healthcare providers working in the addition field International collaboration on AM	No strong leadership yet to convince the government of the importance of AM for public health. Limited resources and budget
India	Training in addiction has been ingrained in the three-year postgraduate psychiatry course.	No initiatives for an AM specialty, heterogeneity and substantial variation in teaching–learning of addiction psychiatry.	Development of super-specialty courses in addiction psychiatry	Failure to develop proper referral mechanisms for patients to reach the super-specialists, and inability to expand the number of centres offering the course
Australia	Addiction psychiatry is a recognized subspecialty of psychiatry, including a formal education programme. Dual-education system for advanced training in AM	There is still a significant shortage of AM specialists	Well-evaluated advanced training in AM and healthy interest in the Addiction Psychiatry programme from trainees	Too few specialists in less populated areas
United States	Accredited fellowships in Addiction Psychiatry. Fellowship level in the subspecialty of AM is now on a par with fellowship training in other medical disciplines	Addiction and recovery into the curricula of professional schools remains spotty	Formal agreement on AM as subspecialty by the medical communities	Undergraduate Medical Education in addiction continues to be far less robust than the scope of the public health problem of addiction

nesses, opportunities and threats are summarized in Table 58.1.

Working on the development of AM and setting up an AM specialty can certainly lead to AM being recognized as a successful specialty, as is clear in the Netherlands and Norway. However, the journey is not always that simple or successful. In the United States, it took a long time to get approval to establish AM as a specialty, and in Australia, it is quite difficult to attract enough trainees to meet the need for sufficient AM specialists. However, there is a stimulating message for the AM field: it is possible to set up an AM specialty. Even if it is not possible, the endeavour will still help the medical community to realize and to recognize that addiction is a chronic disease and thereby contributes to the destigmatization of patients.

Nevertheless, there is still a lot of work to do. The connection between the undergraduate curricula in AM and the postgraduate development or addiction-oriented courses in the training of other specialists is still lacunar in most countries. This also means that young doctors are usually unaware that it can be very interesting and beneficial to work with this group of patients. In case of a well-established AM speciality, the duration of the training is sometimes too short, and the content is not always properly attuned to, for example, the comorbidity of patients with a substance-related disorder. In large countries such as Canada, Indonesia, India and Australia, in particular, it is difficult to establish sufficient AM specialists outside of major urban centres or to create good training places there.

Although professional organizations acknowledge the need to improve knowledge and skills of healthcare providers working in the addiction field, inspiring leadership from the AM community is needed to make efforts in the development of training and teaching that matter. We have the impression that in our era social media stimulates international group support and that this should be encouraged in every possible way.

The increased interest in addiction and training in Addiction Medicine also stimulates scientific research in that field. After the recognition of AM as a specialty, it forces professional organizations to develop standards for the re-registration of AM specialists.

Finally, the recent progress in the development in AM should be stimulating for professionals in countries that are working in the field of AM and are struggling to take further steps; there is hope!

59 International Society of Addiction Medicine's International Certification of Addiction Medicine: The First 15 Years

Nady el-Guebaly and Claudio Violato

Contents

Abstract

This chapter reviews 15 years of effort by the International Society of Addiction Medicine to develop a multiple-choice test of knowledge and clinical judgment in the field. The process of establishing a pool of questions as well as criteria for eligibility to challenge such an examination is described.

Lessons derived from the repeated administration of the exam are reviewed. An international examination is possible, involving questions with good psychometric properties. The challenges of striving for an "a-cultural examination" as well as the necessities of cost accessibility, security, and sensitivity are reported.

Keywords

Certification · Multiple choice · Performance levels · Core competencies

59.1 Introduction

In 1999, the International Society of Addiction Medicine (ISAM) came into being. Its mission was to promote an international agenda, including advancing the knowledge about addiction seen as a treatable disease, advocating for the major role physicians play in its management as well as enhancing the credibility of their role, and, last, developing educational kits accessible to an international audience.

The need for improved medical education in the field is well recognized in both developed and developing countries and is detailed in other chapters of this textbook's section. The call for educating all physicians in playing their respective roles in the care of patients affected with the disorders of addiction has been made repeatedly [2, 3, 13]. An increasing number of generalists and specialist physicians are dedicating a major portion, if not all of their practice, to this significant public health issue. Enhancing their credibility and validating their practice through a formal process of certification became a goal of ISAM.

There is a growing international consensus about the core competencies required of every physician in treating abusing or addicted patients. They are screening, brief intervention, including motivational interviewing, and awareness of referral for treatment options, including mutual help. In the USA, these competencies are known by their acronym Screening, Brief Intervention, Referral to Treatment (SBIRT) [8]. By comparison, the boundaries of individual specialty competencies are understandably less defined. Based on core concepts from the basic sciences, evidence-based practices include, but are not limited to, prevention strategies; diagnosis, assessment, and early interventions; detoxification and craving; relapse prevention; psychotherapy, Cognitive Behavioral Therapy (CBT), 12-step, motivational enhancement, contingency management, and cue exposure; psychopharmacology, general and specific, including maintenance and medication interaction; physical and psychiatric concurrent disorders, primary or secondary disorders; ethical and legal issues around the workplace, including a physician's own impairment; chronic pain; forensic issues; cultural factors; age and gender issues; and behavioral addictions.

In the USA, the first medical association's certification examination in the field was held in 1983 by the California Society of Addiction Medicine, followed by the first national examination in 1986 under the auspices of the American Society of Addiction Medicine (ASAM). The American Academy of Addiction Psychiatry established the first subspecialty examination under the auspices of the American Boards in 1993. In 2009, the American Society of Addiction Medicine created an independent American Board of Addiction Medicine (ABAM), followed, in 2016, by admission to the American Boards as part of the American Board of Preventive Medicine (ABPN). Currently, those board certifications or diplomas are valid for 10 years. A commitment to maintenance of certification through documented lifelong learning and assessment of practice-based performance is also required. The criteria of eligibility for challenging these examinations limit the access to candidates mostly from within North America. Examples of other national efforts to validate the training of Addiction Medicine specialists are described in Chap. 59, Education: International Pathways.

59.2 The Certification Process

59.2.1 Chronological Development of an International Certification

Based on the US experience, in September 2003, in Amsterdam, the Board of the International Society of Addiction Medicine (ISAM) accepted to set up a valid and affordable international certification. An Editorial Board was formed composed of 10 senior clinician members of ISAM from 7 countries. An expert in medical education research, including examination psychometrics (C.V.), joined that Board.

ISAM initially recognized three English language multiauthored textbooks as a repository of current knowledge in the field through their successive editions [6, 11, 12]. The most current editions are Galanter, Kleber, and Brady 2015 [7] and Miller et al. 2018 [9]. These texts are backed by some 150 peer-reviewed journals in the field, ranging from basic science to clinical practice. An increasing number of research institutes are disseminating information across the world, including leading institutions such as, in the USA, the National Institute of Drug Abuse and the National Institute on Alcohol Abuse and Alcoholism.

To meet the criterion of affordability as well as reducing the differential access to the literature in different parts of the world, the knowledge basis of the examination was originally based on a primary reliance on the Principles of Addiction Medicine [11]. Since then, further changes have occurred: the nomenclatures of Diagnostic and Statistical Manual of Mental Disorders (fifth ed.; DSM-5; [1]) and International Statistical Classification of Diseases and Related Health Problems, 11th Revision (ICD 11) [16]. Since 2015, the main reference for the ISAM Certification has become the Textbook of Addiction Treatment: International Perspectives [4].

From the onset as part of the drafting of multiple-choice questions, a concerted effort was made to select as many "culture-neutral" questions as possible. Half of the Editorial Board were holders of ASAM certificates and aware of the preponderance of research data based on US populations in the textbooks that would be of lesser significance in other continents. This meant that the epidemiological database had to shift to the data collected by international bodies such as the World Health Organization (WHO) and the United Nations Office on Drugs and Crime (UNODC). Another implication was the exclusion of questions about national legislation replaced by questions about the International Conventions. At the end, from an initial pool of 450 questions, 200 multiple choice questions (MCQs) were selected at a 2-day meeting in September 2004 in Calgary. It was recommended that four options for each MCQ were sufficient (25% chance per option instead of five with 20% chance). From the very onset, it was clearly stated that the certification would be a test of knowledge with some vignettes assessing clinical judgment. The number of questions allocated to each content area was debated at length. It was eventually agreed that the proportion of content questions would reflect the extent of coverage of the topic in the selected textbooks. A subsequent update of the exam questions in 2015, using the Textbook of Addiction Treatment: International Perspectives, similarly reflects the major content areas (see Table 59.1).

Table 59.1 List of certification examination content areas and questions (2016)

Content area	Number of questions
I. Basic sciences and clinical foundations	20
II. Screening and early interventions	30
III. Drugs of abuse and pharmacotherapies for substance use disorders	35
IV. Behavioral approaches	20
V. Social therapies, treatment settings and systems approach to addiction treatment	20
VI. Behavioral addictions and management applications	20
VII. Medical disorders, complications of alcohol and drugs, pain and addiction	28
VIII. Psychiatric comorbidity complications of alcohol and other drugs	27
IX. Children, adolescents, young adults, and special populations	25
Total	225

59.2.2 The Minimum Performance Level Method

To fulfill their mandate of protecting the public, licensure and certification boards in the health professions need to determine which candidates are qualified to attain certification (pass the examinations) or not (fail). Many of these organizations use criterion-referenced testing with predetermined cutoff scores for pass/fail on licensing or certification examinations. There are many ways to set such cutoff scores, but most rely on expert judgment, employing empirical approaches such as the Nedelsky [10] procedure, based on the principle of minimum performance levels (MPLs). Accordingly, we employed a modified Nedelsky procedure for setting cutoff scores using MPLs.

In this criterion-referenced testing procedure, the total test score MPL is the sum of each item MPL [15]. The item writer, therefore, sets an MPL for each item. The MPL is the value ranging between 0.25 and 1.0, which reflects the probability that even a minimally competent candidate can answer this item correctly. An MPL of

0.25 indicates a very difficult item with an MPL of 1.0 reflecting an easy one.

59.2.2.1 Example Item from an ISAM Examination

An added formulation of buprenorphine designed to discourage intravenous use contains? (stem)

(a) Gabapentin (distracter)
(b) Nalmefene (distracter)
(c) Acetylcysteine (distracter)
(d) *Naloxone (keyed response)

A = 1.0 b = 0.75 c = 0.75 d*
MPL = 1/(4 – sum of p) = 1/(4–2:50) = 0:67

Each question having undergone a thorough and rigorous editing process receives an MPL. The construction and psychometric analysis of the exam is under the auspices of faculty from the Cumming School of Medicine at the University of Calgary as well as the University of Minnesota Medical School.

To renew the pool from September 2006, 25 "dummy" or experimental questions were added for psychometric testing and formed the basis of new yearly questions. This is a common practice in the testing industry to identify questions performing well enough to be retained for future test takers. More recently, feedback from the examination applicants also inform the need to upgrade specific questions for the next exam sitting.

The current exam is in two parts with an allowed duration of 2 h and 15 min each.

59.2.3 Psychometric Analysis

59.2.3.1 Item Analysis

A complete analysis of the test requires an item analysis. There are three essential features that constitute an item analysis: (1) difficulty of the item, (2) item discrimination, and (3) distracter effectiveness [5].

The difficulty of the item is the percentage or proportion of people who got the item correct. Item discrimination has to do with the extent to which an item distinguishes or "discriminates" between high test scorers and low test scorers. Distracter effectiveness refers to the ability of distracters in attracting responses. A distracter that attracts no response is not effective; it begins to become effective when it attracts some responses.

59.2.3.2 Reliability and Validity

The reliability of scores is assessed using the coefficient α. Coefficient α estimates the amount of variability in applicants' scores that is due to the difference in ability rather than random influences such as guessing. In the initial series of applicants, the reliabilities of all subtests ranged from adequate to good. In an 8-year study (2011–2018) of the overall test and subtests, alpha has ranged from 0.68 to 0.87, adequate to good. Validity of a test has to do with extent to which it measures whatever it is supposed to measure. As very careful attention is given to the development of the appropriate sampling of the subject matter and content (i.e., addiction medicine) of the ISAM test, it has adequate content validity. Empirical evidence of validity is sought by evaluating the correlations between the subscales of the test. Over the 8-year study period, subscale correlations have ranged from 0.25 to 0.78, providing evidence of both discriminant and convergent validity [14].

59.2.4 Criteria of Eligibility and Applicants' Countries of Practice

To enhance access to the examination by an international audience, the following eligibility criteria were recommended:

- Graduation from a medical school recognized by the WHO
- Valid license to practice medicine from a licensing jurisdiction (national, regional)
- Good standing in medical community, evidenced by at least three letters of recommendation, from physicians knowing the applicant for at least 2 years, including, if possible, one current ISAM member

- Completion of a formal university-based 1-year fellowship or equivalent in the addiction field
- Documented substantial portion of medical practice including evidence of continuing education (conferences, workshops, courses, etc.) over a 3-year period in the addiction field

The above criteria seem to be within the reach of all applicants, and no noticeable impediment to access of the required information has been recorded.

Fee

An international money order payable to the International Society of Addiction Medicine for US$800 (non-ISAM members), US$700 (ISAM members), and US$725 US (Affiliate Societies' members) is forwarded, along with the application.

From 2005 to 2018 inclusive, the examination has been held 23 times. Practitioners from Canada, Egypt, and Saudi Arabia have formed the bulk of the applicants so far. Candidates from Antigua, Hong Kong, Iceland, India, Iran, Jordan, Kuwait, Oman, Sudan, Turkey, UAE, the UK, Ukraine, the USA, and Vietnam have also challenged the examination. The overall pass rate has been a steady 78% so far.

59.2.5 Lessons Learned

In North America, the Canadian Society of Addiction Medicine recognizes both ASAM and ISAM certificates as equivalent. These qualifications are readily recognized to designate experts in courts and with independent medical examinations (IMEs) for a host of insurance and other agencies.

In Egypt, the ISAM certification is recognized by the Ministry of Health as a professional qualifier. The universities have agreed to use the examination as an end of training knowledge qualifier followed by a clinical skills examination.

A dialogue is ongoing, in several countries in Europe, to use the certification as adjunct to local diplomas. Setting a valid and reliable examination is a time- and resource-intensive exercise, and from our experience, the process of testing core knowledge does not need to be duplicated in every country. Potential addition of questions of national interest to the core questions is a possibility.

As the ISAM certification enters its 15th year, a review of the experience leads to the following conclusions:

1. An international certification examination is possible! While the experience so far focuses on Canada and the Middle East, the process is slowly gaining credibility, judging from the inquiries from other regions. The examination is also available to international fellows training in North America's leading institutions. Local leadership support to disseminate information and promote the value of a clinical knowledge qualifier is critical.
2. The questions show good discriminatory performance. Following the first exam set of 200, 9 questions were dropped and new ones added from the pool, and 36 others had their MPL readjusted, "raising the bar." To renew the pool, 25 "dummy" questions were added to be tested in each examination. The first major editorial update was conducted in 2010, resulting in the replacement of one-third of the questions by new ones and another third being modified. Only the references of the remaining third were updated. A second update occurred in 2015–2016, with the inclusion of the new reference source, The Textbook of Addiction Treatment: International Perspectives. The third cycle of editorial update will begin in 2020, coinciding with the publication of the second edition of the Textbook of Addiction Treatment: International Perspectives.
3. The careful development of the ISAM test has resulted in evidence for both validity (content, empirical) and reliability (internal consistency), and items that are carefully reviewed and evaluated for difficulty, discrimination, and distracter effectiveness.
4. The recommended curriculum should inform examination and vice versa. Topics where

the candidates are the weakest included pain and addiction; behavioral addictions; and diagnosis, assessment, and early intervention. In several countries, the field of addiction is limited to the management of substance misuse. Addition of "local" questions to the core examination has been proposed to accommodate the local legislative and possible cultural needs.

5. An "a-cultural" examination may be only a goal to strive for. Biological or laboratory tests may be largely culture-free, although epigenetic findings are showing a number of ethnic differences. Epidemiological data, psychological treatments, mutual help resources, and workplace guidelines are more influenced by the local culture. Many countries forbid the use of methadone maintenance, for example. Can a core examination be fair globally when the medical practices are subject to different cultural and economic constraints? Candidates appreciate the need to be aware of evidence-based treatment options available in other parts of the world and may promote their culturally sensitive adaptation in their own country.
6. The cost, integrity, and sensitivity of the examination are critical in all areas of the world but particularly in developing countries. Requests have been made to create a network of examination centers where the certification could be disseminated electronically. While this remains under consideration, there remains concerns about test security as well as a sustainable critical mass of applicants.
7. We have moved from a reliance on national textbooks to an internationally collaborated textbook, which is available in electronic version.
8. Each successful candidate receives a numbered certificate to avoid forgery. Displays of association membership certificates in practitioners' offices as evidence of competence have been reported. This increases the need for a recognized certificate, testing clinical knowledge through MCQs, and clinical vignettes.
9. The repeated experience of the examination in developing countries is that the pool of often university-based candidates readily achieves pass and higher scores. This pool is however finite. This observation calls for enhanced national efforts to increase the pool of justified candidates practicing evidence-based medicine across the nation.
10. Presenting standardized review courses and complementing the test of clinical knowledge with a standardized objective structural clinical exam (OSCE), administered locally, is the next frontier.

There is no doubt that language proficiency can be a barrier. Discussions have been underway to translate the examination into Spanish and Italian. Settings where a computerized version of the examination can be administered are being contemplated. The security of this process may be improving. The cost remains significant. The search for funding support is ongoing. Several examination sets are being administered by different academic institutions worldwide; must we reinvent the wheel time and time again?

Key Points

- An international examination is possible, involving questions with good psychometric properties.
- The eligibility criteria appear to be within reach of many countries with some English proficiency.
- The examination sections address a broad-based addiction medicine practice.
- The certification is a test of knowledge with some vignettes addressing clinical judgment.
- The ISAM Certification can be a useful adjunct to local diplomas.
- Cultural adaptation can be facilitated through evidence-based treatment options in the examination.

National Institute on Drug Abuse International Fellowships: Research Training for Addiction Specialists

60

Steven W. Gust

Contents

Abstract

Despite the widespread prevalence and increasing risk of disability or death associated with drug use disorders, access to evidence-based treatment is rare. The United Nations estimates that only one in six people who need drug treatment receive it, and cites the lack of research and training as barriers to expanding evidence-based treatment. Professional associations in the United States and the United Kingdom call for mentored research training to help health care professionals learn how to conduct research and understand and implement research findings in practice. Recent evaluations of research training programs found that physicians, service planners, and policymakers benefitted from mentored research training. Effective mentoring programs helped trainees conduct research, analyze data, publish findings, present at scientific meetings, collaborate with senior researchers, meet government officials, and continue networking after the conclusion of the fellowship. These components of effective research training programs are available through fellowships offered by the National Institute on Drug Abuse (NIDA) International Program. The NIDA fellowships for postdoctoral, mid-career, and senior addiction specialists are reviewed, including credential and citizenship requirements for applicants, and professional advantages are described. Former fellows head academic research centers and

nongovernmental organizations, provide addiction treatment, serve as government officials, and play key roles in international drug policy. NIDA fellows collaborate with international partners, receive grants from NIDA and other funders, publish articles, and present at conferences. They form a global network of drug abuse scientists working collaboratively to develop, validate, and implement evidence-based treatment and prevention programs around the world.

NIDA International · Addiction Research · Drug Abuse Fellowships

60.1 Introduction

Training an international cohort of health care professionals to research and treat drug use disorders is an increasingly urgent priority. The United Nations Office on Drugs and Crime (UNODC) estimated that 275 million people aged 16–64 used drugs in 2016 [1]. Of those individuals, 31 million were diagnosed with a substance use disorder. In 2015, drug use was associated with 450,000 deaths, an increase of 60% since 2000 [1]. The Global Burden of Disease research team reported that 31.8 million disability-adjusted life years (DALYs) in 2016 were attributable to drug use as a risk factor [2]. In 2017, drug use disorders were ranked 21 among the top sources of DALYs for men, an increase of 26.6% since 2007 [3]. Foreman and colleagues predict that by 2040, drug use disorders will be among the top 10 causes of years of life lost in Australasia, Eastern Europe, and high-income North America [4].

Despite the widespread prevalence and growing risk of disability or death associated with drug use disorders, access to evidence-based treatment remains limited. UNODC reports that only one in six individuals who need drug treatment have access to treatment services [1]. Barriers to evidence-based drug treatment include a lack of research, particularly in real-world health care settings, and a shortage of health care professionals trained in public health and medical models of drug treatment [5].

In the United States, the American Board of Medical Specialties formally recognized Addiction Medicine as a subspecialty in March 2016. Decades earlier, National Consensus Standards on postgraduate medical fellowship training in alcoholism and drug abuse called for a "meaningful, supervised research experience" ([6], p., 6). The Consensus Standard priorities included learning about research methods and how to design and interpret research studies. Conducting an independent research project was "desirable" ([6], p., 10). In 2018, the Association for Multidisciplinary Education and Research in Substance Use and Addiction (AMERSA) revised its standards for health care professional training. AMERSA recommends that physicians, nurses, pharmacists, social workers, and physician assistants who assess and treat patients who use alcohol and drugs should learn how to understand and implement research findings in treatment and participate in interdisciplinary activities, including research [7]. The United Kingdom General Medical Council essential capabilities for postgraduate medical curricula include "Research and Scholarship" among nine domains. The 2017 document describes requirements that doctors-in-training understand research methods and principles, learn to interpret public health epidemiology findings, and know how to translate research into practice [8].

Medical students who participate in mentored research programs develop positive opinions about both clinical care and academic research in substance abuse [9, 10]. Recent evaluations of research training programs conducted in both low- and high-income countries found that mentored research programs influenced fellows' research careers and success. This was especially true of programs that helped trainees develop and publish their own research and provided long-term networking after the conclusion of the fellowship [11–17]. For fellowships that focused on trainees from low-income countries, mentored research that prepared individuals for independent careers was enhanced by international col-

laboration with senior researchers, participation in workshops and scientific meetings, guidance in data analysis and scientific writing, and visits to the US National Institutes of Health (NIH) [18–20]. Treatment providers, service planners, and policymakers from low- and middle-income countries also benefitted from research training programs [14, 21].

60.2 Fellowships Supported by the National Institute on Drug Abuse International Program

Since 1990, the NIDA International Program has developed drug abuse research fellowships to facilitate an international network of scientists trained to investigate the causes, prevention, treatment, and consequences of drug use and addiction. NIDA's global network now includes scientists and drug abuse professionals from more than 110 countries who have completed more than 500 fellowships. Fellows work with NIDA grantees at US institutions and have conducted research in every aspect of the NIDA portfolio, including preclinical research and studies in epidemiology, prevention, treatment, and clinical trials.

NIDA currently supports four postdoctoral fellowship programs, a fellowship for mid-career drug abuse professionals from eligible low- and middle-income countries, and two professional development programs for senior scientists. NIDA International fellowship programs train substance use researchers from other countries in US research methods, help fellows enhance their understanding of the scientific basis of drug use and addiction, and promote research collaboration by introducing NIDA grantees to talented drug use researchers from other countries. The seven fellowship and scientific exchange programs expand the Institute's ability to build networks, mentor junior investigators, conduct needs assessments, and transfer knowledge. Table 60.1 summarizes the fellowship career levels, activities, eligibility requirements, and application deadlines. Additional details are available on the NIDA International Program website: https://www.drugabuse.gov/international/fellowships-landing.

The four INVEST fellowships combine postdoctoral research training in the United States with professional development activities such as preparing publications, poster or oral presentations at scientific meetings, and grant-writing guidance. The program is designed to enhance the ability of junior drug use scientists from other countries to conduct independent research upon return to their home country. Three fellowships are open to applicants from any other country—the INVEST Drug Abuse Research Fellowships, INVEST/Clinical Trials Network (CTN) Drug Abuse Research Fellowships, and the INVEST Drug Abuse Prevention Research Fellowship. The INVEST NIDA–Inserm Postdoctoral Drug Abuse Research Fellowship is restricted to US and French scientists, with US researchers working at Inserm laboratories in France and French researchers working with NIDA grantees in the United States. All fellows are invited to present their research at an appropriate scientific meeting, such as the NIDA International Forum satellite to the College on Problems of Drug Dependence, and meetings sponsored by the Society for Prevention Research or the Society for Neuroscience.

The NIDA Hubert H. Humphrey Drug Abuse Research Fellowships bring fellows from eligible low- and middle-income countries to study and work with colleagues in the United States. NIDA Humphrey Fellowships are part of a larger program coordinated by the US Department of State that provides mid-career experts with advanced leadership training that includes academic, practical, and cultural activities in the United States. NIDA Humphrey Fellows also receive training in addiction science and public health through specialized coursework, professional affiliations with US substance abuse experts, visits to NIH, and participation in the NIDA International Forum. The fellowships are particularly appropriate for treatment providers and policymakers who need to understand the science of addiction in order to adopt evidence-based treatment practice guidelines and government policies.

Table 60.1 NIDA International Program training opportunities for US and international scientists

Career level	Program name	Eligible audience	What fellowship includes	Application deadline
Postdoctoral training	INVEST Drug Abuse Research Fellowship	Non-US citizens, any topic	12-month training and professional development with a NIDA grantee at a US institution. May apply to renew once.	October 1
	INVEST/Clinical Trials Network (CTN) Drug Abuse Research Fellowship	Non-US citizens, topic of interest to CTN	12-month training and professional development with a NIDA grantee affiliated with a CTN Node at a US institution. May apply to renew once.	October 1
	INVEST Prevention Drug Abuse Research Fellowship	Non-US citizens or permanent residents conducting prevention research	12-month training and professional development with a NIDA-supported prevention researcher at a US institution. May apply to renew once.	October 1
	INVEST NIDA–Inserm Postdoctoral Drug Abuse Research Fellowship	French citizens work with a NIDA grantee at a US institution US citizens work at an Inserm lab in France	6- to 12-month training and professional development. May apply to renew once.	Applications may be submitted at any time
Mid-career training	NIDA Hubert H. Humphrey Drug Abuse Research Fellowship	US State Department identifies eligible countries and reviews applications	10-month academic study and professional development activities	Deadlines vary Apply through US Embassy or Fulbright Commission in eligible countries
Senior researcher exchanges	Distinguished International Scientist Collaboration Award (DISCA) and USDISCA	DISCA: Non-US citizens visit NIDA grantees in US USDISCA: US citizens and permanent residents visit research partners in other countries	Research exchange visits of at least 1 month to finalize a specific task that could not be completed without face-to-face consultation	December 1

The competitive Distinguished International Scientist Collaboration Awards (DISCA) and the companion Distinguished International Scientist Collaboration Awards for US Citizens and Permanent Residents (USDISCA) programs support brief research exchange visits between senior researchers from other countries and NIDA grantees. The research team must propose a specific task that could not be completed without face-to-face consultation.

60.3 Professional Advantages of the National Institute on Drug Abuse International Program Fellowships

Former NIDA International Program Fellows advance scientific knowledge on drug use and addiction through their research and professional careers. Former fellows head academic research centers and nongovernmental organizations,

provide addiction treatment, serve as government officials, and play key roles in international drug policy through international organizations such as the Colombo Plan Drug Advisory Programme, European Union, Inter-American Drug Abuse Control Commission (CICAD) at the Organization of American States, United Nations, and the World Health Organization (WHO). For example, former NIDA International Program fellows played key roles in developing WHO and UNODC guidelines for substance use treatment and prevention, pharmacological and psychosocial approaches to treating opioid dependence, community efforts to address opioid overdose, treating substance use disorders in pregnant women and people involved in the criminal justice system, and the effects of nonmedical cannabis use. Former NIDA Fellows also contributed to the joint European Monitoring Centre for Drugs and Drug Addiction/Organization of American States handbook on building a national drug observatory, and have led the Drug Advisory Programme at the Colombo Plan.

Fellows conduct and publish peer-reviewed research. An analysis of fellows' publications during 2016 and 2017 identified 561 unique articles published in peer-reviewed publications indexed by the NIH PubMed database. More than half (52.4%) of former NIDA International Program postdoctoral fellows and more than one-fourth (25.8%) of all former fellows published articles during that time frame [22].

An evaluation of the Virginia Commonwealth University host campus for the NIDA Humphrey Fellowship program found that former fellows reported collaborating with international partners, receiving grants, publishing articles, presenting at conferences, and obtaining new credentials since completing their fellowships. Of the 108 former fellows from 52 countries, 34.7% had collaborated with a US partner, 24.3% had collaborated with other former fellows, and 19% had received grant support. Nearly one-third (30%) had published a manuscript, 49% had presented at a conference, and 46% had conducted research. About one-fourth had received a license or certification (26%), and 21% had enrolled in an academic program since completing their fellowship [23].

The NIDA International Program helps fellows build on their research training through the annual NIDA International Forum. About 200 researchers participate, nearly half from the United States and other high-income countries. Former fellows and other participants make oral or poster presentations, network with former mentors and other fellows, and establish new research partnerships. Between 2012 and 2017, more than 30 NIDA grants were associated with the Forum; the foreign principal investigator on 23 of those grants was a former NIDA International Program fellow [22].

60.4 The Way Forward

Although the NIDA International Program fellowships are unique, a few other NIH research training programs are available for addiction specialists who are not US citizens or permanent residents. The Visiting Program supports NIDA Intramural Research Program (IRP) fellowships for non-US postdoctoral researchers and temporary full-time research positions for international scientists. NIDA IRP also offers limited predoctoral research opportunities for international students. The NIDA IRP training opportunities are online at https://irp.drugabuse.gov/training/. Information about other NIH Institutes that participate in the NIH Visiting Program is available at https://www.ors.od.nih.gov/pes/dis/VisitingScientists/Pages/default.aspx. The NIH Fogarty International Center (https://fic.nih.gov) supports a number of training programs for scientists and clinicians from low- and middle-income countries, and NIDA participates in the Fogarty D43 institutional training grant for Chronic, Non-Communicable Diseases and Disorders Across the Lifespan.

NIDA promotes international collaborative research through a dedicated funding opportunity (PA-18-773, International Collaborative Research on Drug Abuse and Addiction Research) that requires a partnership between a US scientist and their partners in another country. Many other NIH funding opportunities are open to participation by non-US researchers. Each funding opportunity announcement includes an eligibility

section that will specify what types of foreign participation are permitted for that announcement. Currently, about 8% of the NIDA research portfolio is allocated for international research, primarily through grants to US domestic organizations with foreign partners. All international research must meet special requirements, such as providing access to unusual talent, resources, populations, or environmental conditions not available domestically, demonstrating how the international research will significantly advance US health sciences, and documenting relevance to the NIDA mission.

NIDA works closely with international organizations devoted to improving drug addiction research and treatment, such as CICAD, Colombo Plan, European Monitoring Centre for Drugs and Drug Addiction, International Consortium of Universities for Drug Demand Reduction (ICUDDR), International Society of Substance Use Professionals, UNODC, and WHO. Most of these training programs are designed for the global health care workforce, but few offer mentored research training. ICUDDR members are developing undergraduate, graduate, and postdoctoral training programs within their own universities, and international research training opportunities will expand as these programs mature.

60.5 Conclusions

The need for evidence-based drug use and addiction treatment is increasing, along with the need for addiction specialists who understand the principles of research and know how to implement findings into practice. Organizations such as AMERSA and the UK General Medical Council call research training essential for qualified addiction specialists. Practitioners who participate in effective research training programs report improved job satisfaction and professional success in both clinical and research careers. Effective research training programs include components such as conducting research, analyzing data, publishing findings, presenting at scientific meetings, collaborating with senior researchers, meeting government officials, and networking after the conclusion of the fellowship. Since their creation in 1990, the NIDA International Program drug abuse research fellowships have provided effective mentoring and networking for addiction specialists from other countries. The NIDA fellows' successful clinical and research careers document the professional advantages mentored research training can offer.

NIDA will continue to support its international drug abuse research fellowships, adapting and expanding the program as funding permits to meet the growing demand for mentored addiction research opportunities. The current NIDA–Inserm fellowship provides a model for addiction research training partnerships with similar institutions in other countries: NIDA supports French researchers who train in the United States, and Inserm supports US researchers who train in France. We invite current and new partners interested in addiction research training to join NIDA in meeting this critical need.

Key Points

- Professional associations such as the American Board of Medical Specialties and credentialing bodies such as the UK General Medical Council recommend research training to help addiction specialists evaluate and implement research findings in practice.
- Since 1990, NIDA has supported more than 500 research training fellowships for postdoctoral researchers, mid-career professionals, and senior scientists from 110 countries.
- These NIDA International Fellowships include components proven to be effective, such as conducting research, analyzing data, publishing findings, presenting at scientific meetings, collaborating with senior researchers, meeting government officials, and networking after the conclusion of the fellowship.

- NIDA International Fellowships contribute to former Fellows' successful careers and advance scientific knowledge about drug abuse:
  - Former fellows head academic research centers and nongovernmental organizations, provide addiction treatment, serve as government officials, and play key roles in international drug policy through roles at international organizations.
  - Between 2012 and 2017, more than 30 NIDA grants were associated with the NIDA International Forum; the foreign principal investigator on 23 of those grants was a former NIDA International Program fellow.
  - In 2016–2017, former NIDA fellows published 521 unique research articles indexed by PubMed.

Clinical Relevance

Clinicians are better prepared to adopt evidence-based treatments if they have research experience and can integrate published research findings into practice.

Undergraduate Medical Training in Substance Misuse

61

Contents

Abstract

Whilst addiction psychiatry is a recognised subspecialty in the UK, research into UK medical schools during the 1990s showed very low levels of exposure of future doctors to teaching on drug and alcohol misuse issues. Substance misuse is prevalent in almost all branches of medicine. As a result, there are extensive opportunities to teach and learn about it. However, this also leads to the risk that the topic may be fragmented, poorly coordinated and spread too thinly, so that it is often ultimately barely visible to students. In the UK, a 'Substance Misuse in the Undergraduate Medical Curriculum Project' was funded with the aim of improving the teaching of substance misuse to medical undergraduates so as to enhance medical education in addictions and improve treatment services in the future.

Medical education · Undergraduate · Addiction · Curriculum Substance Misuse

61.1 Introduction

This chapter focuses on the need for training and education on substance-related disorders for undergraduate medical students and describes initiatives undertaken in the UK. It provides a brief historical and contextual introduction, describes work undertaken and explores issues of sustainability within a constant changing health landscape.

61.2 Historical and Contextual

Substance misuse has been a national and international public health challenge for many years. The use and misuse of alcohol, drugs (licit and illicit), prescribed and over-the-counter medications, and tobacco impacts individual patients, their families and communities. Doctors and other health professionals across all medical specialities are highly likely to encounter individuals with substance-related health problems, given the extent of these problems. All health professionals have a key role in improving not only the health of their individual patients but also the nation's public health. This was recognised by both the World Health Organization [25] and the United Nations [18, 19] who have recommended to governments that substance misuse should be included in medical teaching.

UK statistics show that, in 2016, there were estimated to be 77,900 deaths attributable to smoking amongst adults aged 35 and over based on the original cause of death. Hospital admissions estimated to be attributable to

smoking indicates that 22% of all admissions were for respiratory diseases, 15% for circulatory diseases and 9% for cancers. Of the admissions for cancers, 47% were caused by smoking, with 40% of admissions for respiratory diseases that can be caused by smoking, were estimated to be attributable to smoking [20, 21]. The total cost to society (in England) is approximately £12.9 billion a year and includes the cost to the NHS of treating diseases caused by smoking and lost productivity due to premature deaths, smoking breaks and absenteeism [1].

In 2017–2018, there were 338,000 estimated admissions to hospitals that were attributable to alcohol, and, in England, in 2017, there were 5,843 alcohol-specific deaths with alcoholic liver disease accounting for 80% of the deaths, and 9% were from mental and behavioural disorders due to the use of alcohol [23]. Alcohol is estimated to cost the NHS around £3.5 billion per year [14].

About 3 million adults aged 16–59 in England and Wales in 2017–2018 had used illicit drugs, with Class A drug use (typically opioids and cocaine) increasing since 2011–2012. In 2017–2018, there were 7258 hospital admissions for drug-related mental and behavioural disorders, and 2503 deaths were related to poisoning by drug misuse. In the same period, 268,390 individuals were in contact with drug and alcohol services during 2017–2018 with those in treatment for opiate dependence making up the largest proportion of the total numbers in treatment (53% or 141,189) [20–22].

In 2014, the National Treatment Agency estimated that the overall annual cost of drug misuse was around £15.4 billion. A total of £13.9 billion was due to drug-related crime, while around £0.5 billion was NHS costs for treating drug misuse [2].

Research, including surveys into the undergraduate medical UK curricula between the late 1980s and 2004, found that substance misuse was generally very poorly represented in the training of future doctors, and the number of hours allocated to formal teaching about substance misuse was small. It was taught mainly within the disciplines of psychiatry and pharmacology, thus reinforcing the false notion that substance misuse is a niche specialty topic [3, 4, 7, 12]. Whilst it was found that there were numerous initiatives in North America, some establishing a core curriculum and others developing teaching and learning

innovations, very little innovation was taking place in the UK. The lessons were clear: substance misuse has to be integrated into the curriculum of medical students, and it has to be a topic introduced from the very beginning of the course—not least for students' own health and professional behaviour.

Previous initiatives undertaken by St George's, University of London, and the World Health Organization (WHO) on substance misuse education for doctors, pharmacists and nurses resulted in the WHO recommending to governments that substance misuse should be included in the medical curricula [6, 11, 25].

Proposals were submitted to the Department of Health to develop a consensus approach to the enhancement of substance misuse training in medical and nursing schools in the UK. Funding was awarded in 2005 to improve the education of doctors in substance misuse and to develop a consensus approach to substance misuse training in medical schools, and a national project, 'Substance Misuse in the Undergraduate Curriculum', was established and led by Professor Hamid Ghodse, Director of the then International Centre for Drug Policy at St George's Medical School.

61.3 Description of the Project

This project has comprised three phases. In Phase 1, during 2005–2007, a UK corporate guidance document was developed that set out core aims and learning outcomes for substance misuse teaching and learning in the undergraduate medical curricula. Phase 2, during 2008–2011, focused on implementing the guidance through the appointment of curriculum coordinators in English medical schools to identify what substance misuse teaching was being undertaken, and to recommend changes to ensure that substance misuse issues were fully covered. Phase 3, from 2012 onwards, concentrated on developing and extensively revising a set of factsheets, initially written in Phase 2, and which covered substance misuse relevant to a range of clinical conditions, groups of patients, specialities and settings.

61.3.1 Phase 1

Building on the research done in the late 1980s and 1990s, during Phase 1, the project further reviewed the ways in which substance misuse problems was being taught in all UK medical schools [3, 6, 7, 12, 13]. It sought to establish the reasons for ineffectiveness and to make proposals for improvement in medical schools throughout the country. The project aimed to understand the reasons why medical education was not preparing doctors appropriately in this respect; to identify initiatives that different medical schools could take to improve matters; and make recommendations for further action.

A survey was undertaken in 2005 which provided an overview of the state of substance misuse education in all UK medical schools. The aim of the survey was to gather information about substance misuse teaching and learning, including strategies medical schools used for embedding the topic in the curriculum, and to collect examples of good quality learning materials. Responses were obtained from each of the 32 UK medical schools.

The survey findings included the following:

- There was no commonality of approach in what was taught about substance misuse: learning outcomes differed hugely in style, level of detail and emphasis.
- Many schools covered a lot about alcohol, but relatively few covered teaching about drugs—with this aspect frequently being left to psychiatrists only.
- Only two schools planned and coordinated their substance misuse curriculum as a whole. Mostly, the teaching was concentrated in the specialty niches.
- Assessment of substance misuse within curricula was rarely planned. As 'blueprinting' against curriculum outcomes was being increasingly introduced, more formal planning in this area was expected.
- About half the schools had some provision of optional learning about substance misuse through 'student-selected components' (SSCs).

The main outcome of Phase 1 of the project was the production of a UK-wide consensus guidance document on substance misuse in the undergraduate medical curriculum and agreed by all medical schools. The document, 'Substance misuse in the undergraduate medical curriculum' set out core aims and learning outcomes for undergraduate curricula [15].

This guidance document, endorsed by the Chief Medical Officer (England) and the General Medical Council, was a milestone in medical education on substance misuse, setting out three core aims for undergraduate medical education in substance misuse that are still relevant today.

1. Students should be able to recognise, assess and understand the management of substance misuse and associated health and social problems, and contribute to the prevention of addiction.
2. Students should be aware of the effects of substance misuse on their own behaviour and health and on their professional practice and conduct.
3. Students' education and training should challenge the stigma and discrimination that are often experienced by people with addiction problems.

61.4 Substance Misuse Core Curriculum Aims and Learning Outcomes

It is acknowledged that one of the difficulties in mapping and tracking the teaching of substance misuse is that topics associated with substance misuse permeate the whole curriculum and are not simply confined to certain clinical specialties or basic science subject disciplines. In order to aid curriculum planning and integration of substance misuse topics into appropriate course areas, the outcomes have been grouped under six key areas:

1. Bio-psychosocial models of addiction
2. Professionalism and self-care
3. Clinical assessment of patients
4. Treatment interventions
5. Epidemiology, public health and society
6. Specific disease and specialty topics

The outcomes are presented as high-level outcomes, so as to make them as flexible as possible in comparing them with and applying them to the diversity of UK curricula. Each area is mapped on to the outcomes prescribed by the General Medical Council (GMC) in Tomorrow's Doctors 2003 (paragraphs 4–10), the relevant sections of which are summarised under each of the areas. Keywords are highlighted in italics within each of the learning outcomes so as to help curriculum mapping.

61.4.1 Core Topics and Learning Outcomes

1. Bio-psychosocial Models of Addiction

On graduation, students should be able to:

- Define *substance misuse*, mechanisms of dependence (both physical and psychological), tolerance, withdrawal and addictive behaviour
- Demonstrate awareness of the range of substances that can be misused; the different *types and classes of licit, illicit and over-the-counter (OTC) substances*; and other colloquial names and their effects
- Demonstrate awareness of the psychological, social and biological aspects of *dependence*; the interactions between such factors in the individual; and the different *models* used to describe addiction
- Describe the *mechanisms of tolerance, dependence and withdrawal* of different drugs and the involvement of different neurotransmitter systems

Meets GMC outcome:

– *4b – Know about, understand and be able to apply and integrate the clinical, basic, behavioural and social sciences on which medical practice is based*

2. Professionalism, Fitness to Practise and Students' Own Health

On graduation, students should be able to:

- Describe the *principles of rational prescribing* and the use of psychoactive medication
- Demonstrate *professional behaviour* towards individuals with problems of addiction, which incorporates a non-judgemental compassionate approach and respect for a patient's autonomy
- Describe the *ethical and legal issues* associated with dealing with cases of substance misuse
- Explain and outline the problems of *iatrogenic addiction*
- Describe the *risk factors* for substance misuse in medical students and in health professionals
- Describe how substance misuse problems may affect a *health professional's* judgement, performance and care of their patients
- Describe the need to balance due concern for the health of a colleague with responsibilities for the *safety and welfare of patients*
- Outline the role of the medical schools and the GMC in ensuring students and doctors' *fitness to practise*
- Describe the *sources of help* for students and doctors with drug and alcohol-related problems

Meets GMC outcomes:

– 4a (i) – *Know and understand our guidance on the principles of good medical practice and the standards of competence, care and conduct expected of doctors in the UK.*
– 4d – *Recognise personal and professional limits and be willing to ask for help where necessary and recognise the duty to protect patients and others by taking action if a colleague's health, performance or conduct is putting patients at risk.*
– 5c – *Be willing to respond constructively to the outcome of appraisal, performance review and assessment.*
– 10 – *Graduates must be aware of the health hazards of medical practice, the importance of their own health and the effect that their health has on their ability to practise safely and effectively as a doctor.*

3. Clinical Assessment of Patients

On graduation, students should be able to:

- Describe the major *clinical features* of alcohol abuse, drug dependence and tobacco use
- Describe the possible *outcomes of different treatment regimens for substance misuse* and discuss the prognosis and management
- Take a focused drug and alcohol *history*
- Elicit signs of misuse of alcohol, tobacco and illicit or over-the-counter (OTC) drugs through *physical and mental state examinations* and identify and prioritise medical and psychosocial problems associated with substance misuse
- Demonstrate appropriate skills for communicating sensitively with patients about substance misuse issues and know how to *deal with challenging, aggressive or intoxicated patients*, balancing

assessment need with their own safety and that of others
- Appropriately order and interpret *urine, blood and other appropriate tests* for drugs of addiction; use standardised *screening and assessment instruments* to detect alcohol and drug levels; and describe other special investigations and how to interpret results
- Carry out a *psychological assessment* of a patient's readiness to implement change

Meets GMC outcomes:

– 4a(iii) – *Know about and understand how errors can happen in practice and the principles of managing risks*
– 4c – *Be able to perform clinical and practical skills safely*
– 6b – *Be able to communicate effectively with individuals and groups*
– 6c – *Understand the principles of audit and the importance of using the results of audit to improve practice*

4. Treatment Interventions
On graduation, students should be able to:

- Describe the *common treatment regimens* for various types of addictions and withdrawal states
- Describe the basis of *commonly used therapies* for addiction
- Describe the variety of UK agencies to which patients with addiction problems can be referred, and how and where to make appropriate *referrals for treatment*
- Demonstrate awareness of risk related to *needle use and disposal* for healthcare workers and patients and risk prevention
- Advise a patient appropriately on *reducing or abstaining from drinking and smoking* and list appropriate agencies or individuals to which patients can be referred to create a treatment plan
- Advise women on the effect of substance use and the impact on *foetal and maternal health*
- Demonstrate awareness of the need to assess patients' *capacity to consent* to treatment
- Describe the impact of substance misuse on *drug interactions* and a patient's compliance with treatment

Meets GMC outcomes:

– *4b – Know about, understand and be able to apply and integrate the clinical, basic, behavioural and social sciences on which medical practice is based*
– *7a – Know about, understand and respect the roles and expertise of other health and social care professionals*

5. Epidemiology, Public Health and Society
On graduation, students should be able to:

- Outline *UK policies* on misuse of drugs, drug prescribing and dispensing, and on alcohol and smoking
- Outline *UK legislation* controlling drugs, alcohol and tobacco, including the legal alcohol limits for driving
- Explain *hazardous and harmful levels of alcohol consumption*, and the *recommended limits for alcohol consumption*
- Outline UK *strategies for the prevention and treatment of drug misuse*
- Outline *international policies and strategies* to limit drug supply and demand
- Describe the *epidemiology* of alcohol consumption, smoking, drug misuse in the general population, vulnerable groups and specifically in doctors and other health care professionals

- Describe the problems associated with *self-medication*
- Demonstrate awareness of the risks in different *work environments* and the need for employers to have *drug and alcohol policies*
- Describe the *effects of addiction* on individuals, their families, friends and colleagues in a range of age-groups; from children and adolescents to older people
- Describe the long-term *physical, psychological and social consequences* of various types of addiction and substance misuse, including the economic consequences and the links between crime and substance misuse
- Describe the risks to the children of addicted parents, including *child protection policies* and a doctor's duty to implement these

Meets GMC outcomes:

- *4a(ii) – Know about and understand the environment in which medicine is practised in the UK*
- *4a(iii) – Know about and understand how errors can happen in practice and the principles of managing risks*
- *4b – Know about, understand and be able to apply and integrate the clinical, basic, behavioural and social sciences on which medical practice is based*
- *6c – Understand the principles of audit and the importance of using the results of audit to improve practice*

6. Specific Disease and Speciality Topics
On graduation, students should be able to:

- Recognise *life-threatening complications* of substance misuse, including septicaemia, pulmonary emboli and overdose and be able to carry out appropriate interventions
- Describe and explain the links between substance misuse and:
  - Accidents and violence (including sexual assault and sexually transmitted diseases—STDs)
  - Lung disease, specifically tobacco, 'crack' cocaine and cannabis
  - Anxiety, depression, dementia, schizophrenia
  - Acute psychotic episodes
  - Self-harm and suicide
  - Heart disease, hypertension and myocardial infarct and cocaine use
  - Liver disease, pancreatitis and gastritis
  - Infectious diseases, including human immunodeficiency virus (HIV) and hepatitis B and C virus infections

From International Centre for Drug Policy [17] *Substance Misuse in the Undergraduate Curriculum Project Report, Appendix 1.*

61.4.2 Phase 2

The second phase (2008–2011) provided a time-limited period of intensive support for the development and implementation of the new curriculum guidance into the teaching and learning opportunities of the medical schools at a local level, and into their local curriculum planning processes; promoted a self-sustaining network of all English medical schools involved in changing their curricula; and developed and validated a toolkit [16] of guidance for the effective implementation/development of substance misuse training in the undergraduate medical curriculum. A series of fact sheets, written by clinicians with in-depth knowledge of substance misuse, were produced to provide concise, relevant and up-to-date information on specific areas of substance misuse teaching. They were found to be

very valuable resource since they provided a framework for developing current teaching material as well as being used as stand-alone teaching resources.

Each medical school was required to identify a local academic champion whose role was to motivate change and to supervise the work of the appointed local curriculum coordinator to implement the integration of substance misuse teaching and assessment in the undergraduate curriculum. Specifically, the role of the local curriculum development coordinators was to manage the implementation of the substance misuse Toolkit across the medical school for undergraduate education; to map and review the current curriculum compared to the guidance recommendations; and to make recommendations for implementation. These roles were supported by a national coordinator whose key task was to oversee the management of the implementation phase and work with the participating schools.

In the UK, medical education is regulated by the General Medical Council, with all school curricula being bound by the structures and demands of the key policy documents 'Tomorrow's Doctors' [8, 9]. Undergraduate medical training in the UK was comprehensively reformed, following the recommendations of 'Tomorrow's Doctors' [8, 9] and the subsequent Outcomes for Graduates [10]. Although curricula are structured differently across the participating medical schools, they all share the aims of providing high-quality medical education for students and of producing well trained and competent doctors [24].

Within the participating medical schools, a range of teaching and learning methods and corresponding range of assessment methods are used. Curricula set around a pre-clinical phase of learning (typically for 2 years), followed by a clinical phase, moving away from purely academic and theoretical studies towards more applied work. Intensive patient contact and clinical experience are used by some of the schools, whilst others use the approach of learning through a problem/case-based learning (PBL/CBL). This approach typically uses patient 'cases' or particular medical 'problems' to exemplify the learning required of students throughout the course. These cases are likely to link to a spiral curriculum, where layers of learning, for example, around physiology, anatomy or basic science, are revisited repeatedly in increasing detail. PBL or CBL course structures are more likely to include clinical placements right from the start of the course.

In each participating medical school, the current teaching and learning of substance misuse within the undergraduate medical curriculum was identified. Coordinators undertook a mapping exercise that enabled them to construct a comprehensive overview of substance misuse teaching within their respective school, and for their findings to be aligned to the substance misuse learning outcomes from the core curriculum guidance. This process identified what was covered, not covered and what could be added to within substance misuse teaching, including areas of commonality across the schools.

Broad areas that were identified as needing more development through this process included professionalism (e.g. attitudes, values, judgement, coping with substance misuse on placements); iatrogenic addiction; fitness to practise issues; self-care; child-related issues (e.g. parenting, potential neglect, foetal and maternal health); drug policies and work environment; strategies and policies on drug use; treatments for addicts (e.g. engagement, motivation, referrals, risk-reduction strategies); sources of help for students/doctors who misuse substances; specific clinical issues (e.g. needle use, outcomes of addiction, prescribing, neurological issues, complications, drug use/types); and communication issues (including capacity to consent). It was encouraging to note that such a key topic for future public health as 'advising a patient appropriately on reducing or abstaining from drinking and smoking and implementing a treatment plan with the patient' was one of the most widely covered topics. Concurrently, student views and experiences of substance misuse teaching were gathered through surveys and focus groups in some of the participating schools. The findings from each survey were compiled, and in summary, the views of students were that they perceived substance misuse to be an important

aspect of undergraduate medical education, with the teaching being comprehensive and sufficient. Overall, the bio-psychosocial aspects of addiction were covered well in teaching sessions, but more could be done regarding the clinical assessment of patients. Most of the teaching and learning was perceived to occur through independent study or via formal sessions, such as lectures or intercalation degrees.

Students perceived the teaching of alcohol, smoking and illicit drug use to be well covered; however, they felt that they could be taught more about over-the-counter drugs and prescription drug misuse. Students also recommended more teaching on how to manage addicts and about the effects of different substances when used on their own or combined. Students varied in their confidence of performing different skills with patients who misuse substances and did not feel particularly confident in taking an illicit drug history, discussing options for patients to cut down to stop alcohol or illicit drug use, and in recommending appropriate organisations which could help patients stop misusing substances.

The work during this phase enabled the changes to their curricula made by the coordinators to be delivered over a rapid timescale, and brought about important changes to the teaching and learning opportunities for future doctors. These changes addressed key recommendations that were made to improve substance misuse learning. In addition to modifying the learning outcomes, the coordinators, supported by the academic champions, introduced a range of initiatives, including new lectures and special study module components, and provided additional substance misuse resources for students to use, which supported the taught sessions. Initiatives were undertaken to raise awareness of substance misuse issues, including workshops, quizzes and working with external organisations. The toolkit and fast fact sheets that were developed across the two phases of the project were also important in providing useful materials for use in a wide variety of settings, disciplines and learning opportunities, and for integration across all years of training. These fact sheets have continued to be updated and the number of titles expanded to reflect changes such as the development of e-cigarettes, and emerging issues like gambling, and novel psychoactive substances. (https://www.addiction-ssa.org/hot-topic/factsheets/).

61.5 Opportunities and Threats

Major changes or re-structuring of curricula poses both opportunities and pitfalls for substance misuse teaching. New recommendations made during a re-structuring may build on developments to date, potentially with additional substance misuse learning opportunities, but positive changes can also fall by the wayside, especially if local enthusiasm and championing of the issue falter.

Taking new opportunities as they arise may enable sustainability. Making use of those areas of teaching which are currently ‘hot topics’ could be helpful, such as the question of professionalism, substance misuse by older people, teaching about emerging drugs such as novel psychoactive drugs, e-cigarettes and training in prescribing for medical cannabis. Similarly, a focus on issues of public concern, such as addiction to prescribed drugs, drug deaths, from both illicit and licit substances, might help maintain and highlight the need for substance misuse teaching to be clearly evident in the curriculum.

61.6 Evaluation

Although there was no formal evaluation of the project as it was not part of the funding, the National Steering Group for the Project decided to incorporate it within the timescale of the project as it was felt that this is an integral part of any training programme or initiative. In 2010, a small working group was established to evaluate the development, implementation and short-term outcome of the substance misuse undergraduate medical curriculum project. The views of both curriculum coordinators and academic champions were collected through interviews, questionnaires and a focus group.

The evaluation component of the project produced several recommendations concerning resources, training and sustainability:

- A core expert group/advisory panel should continue to meet on a biannual or annual basis for 2–3 years to ensure that substance misuse teaching objectives remain embedded within undergraduate curricula so that the following recommendations are actioned
- To develop a generic 1-day curriculum mapping/review training course that could be accessed online or rolled out as a package for others working on similar projects. This would be delivered on commencement of the curriculum development post
- To develop a database/resource of all SSCs and SSMs currently offered by medical schools in the area of substance misuse
- To develop a resource-sharing portal where all project resources can be collated and accessed for teaching purposes, including a core list of recommended addiction teaching and learning resources.
- To maintain and update the fact sheets
- To develop guidance on topics and questions for assessment and to provide questions for the Medical Schools Council Assessment Alliance (MSCAA) common assessment ban of questions
- To identify a 'link person' for substance misuse teaching should be identified in each participating school
- To develop specifically designed tools, such as Google desktop or Google box to assist the process of curriculum mapping. Such software might potentially be used to create a database with ability to rate content
- To ensure continuity of undergraduate substance misuse–related learning outcomes through to postgraduate education and with appropriate professional postgraduate medical education initiatives
- Relationships with Third Sector providers and other partners should be built to ensure that teaching via placements continues.
- In the light of ongoing changes to drug and alcohol service provision, medical schools should actively seek recognition of time and resources for teaching undergraduate medical students to be included within commissioning tender documents and service specifications [17].

We are well aware that the changes in the treatment policy landscape in the UK has also resulted in a reduction in addiction psychiatry services over the past decade. This has very serious implications for training since the number of specialist addiction psychiatrists, who often contribute to teaching medical students as described earlier and also provide clinical placements, has been halved [5].

A key question now, some years on from the conclusion of the major phases of the project, is how best to sustain the positive changes implemented in the teaching of substance misuse to future doctors, so that future graduating medical students continue to be better equipped to deal with substance misuse? This undoubtedly requires a group of passionate and compassionate addiction specialists who can act as lecturers, trainers, mentors, supervisors and advisors for medical students, as well as for generalist or specialist doctors and their teams. The range of medical specialties to which substance misusers present.

How will different models of learning be implemented and compared? How can substance misuse education be 'normalised' within curricula so this is not perceived as an optional extra, rather than an essential component? Who will ensure that the new emerging issues described earlier, for example, the training needed for prescription of medical cannabis, the recognition of substance use in older people, the rising numbers of alcohol- and drug-related admissions and deaths, are highlighted in the undergraduate and postgraduate medical curricula. How will post-qualification postgraduate training and continuing professional development be organised? And what about other professional groups who play a major role in the detection and treatment of addiction problems?

61.7 Conclusions

This model comprising national guidance on core curriculum content, a toolkit to aid the implementation process and which is supported with teaching resources, has the potential to be adapted and implemented in many different settings and professional disciplines such as nursing, pharmacy and psychology. It can be extended to provide in-depth specialist professional training as well as continuing professional development for general practitioners, psychiatrists and medical specialists such as physicians, obstetricians and surgeons, as well as dentists. It is eminently suitable for undergraduate, postgraduate and continuing professional training for those professional groups allied to the medical profession, including nurses, occupational therapists, social workers, psychologists and pharmacists. This model and the curriculum content provide a core learning resource for any organisation that is considering the development and implementation of a programme on substance misuse. While some components are universally applicable, some may need to be developed with the particular programme in mind. However, this gives the opportunity for some initiatives to take account of their own special circumstances and expand the resources in line with their needs.

It still seems paradoxical that given the nature and extent of addiction problems in almost every branch of medicine, it is not accepted, and therefore acceptable, that addiction training is considered a 'must have' like cancer, heart disease and diabetes rather than a possible optional extra for which a case still has to be made.

A national strategy which has direction and funding from government and coordinated support from diverse stakeholders is a valuable start. Educators with the range of clinical skills and up-to-date knowledge base are an essential element for the introduction and continuation of integration of substance misuse education into the undergraduate medical school curriculum, specialist programmes and continuing development.

61.7.1 Clinical Relevance

As substances are ubiquitous, substance problems resonate throughout virtually every medical speciality. Patients will be misusing combinations of tobacco, alcohol, prescribed and over-the-counter medications, as well as illicit drugs. Thus, they will present with overt and covert clinical symptoms and syndromes related to substance use, misuse and dependence. Without a detailed understanding of the complex interrelationships, patient care will be compromised. Hence, it is essential that medical students have a systematic knowledge of the effects, side effects, consequences and causes of substance misuse, in order that they can undertake a thorough assessment. Training in detailed history taking will lead to more accurate diagnosis, which can inform better targeted treatment. Since there are a range of effective psychological and pharmacological treatments available for the management of substance-related conditions, students need to have the opportunity to develop the skills to administer these interventions. Doctors also need to understand how the medical profession interacts with other colleagues, for example, nurses, psychologists, pharmacists, in the provision of comprehensive services for patients. Furthermore, exposure of students to collaborative working and integration of medical, social and psychological approaches within a multidisciplinary team structure can demonstrate how patients can be adequately supported to achieve the best possible outcomes. Finally, there are exciting new developments in neuroscience, and it is important that tomorrow's doctors gain a deeper appreciation of the biological basis of addiction, while not detracting from the contribution of psychosocial treatment and the role of a public health approach.

In conclusion, it is important to bring out some key points that should be taken into account:

- The use and misuse of alcohol, illicit drugs, tobacco, prescribed and over-the-counter medications are a major public health challenge facing society today. It impacts not only

patients but also their families and their communities in general.

- Those who suffer physical, psychological and social harms as a result of misuse of substances will almost certainly be seen by doctors and their teams at some stage. Therefore, the medical profession has a vital role to play in the recognition, assessment and management of problems associated with substance misuse.
- However, the changes in commissioning addiction treatment services to organisations which are not part of the National Health Service, as well as the significant reduction in funding for treatment facilities, have implications far beyond the implementation of interventions. It threatens the provision of appropriate high-quality teaching and training for future medical students and trainee doctors in the numerous specialties to which patients with substance problems present.
- If health professionals are to succeed in dealing with the problem of substance abuse, they require a systematic training so that they have better understanding of the nature and complexity of the problems associated with substance misuse as well as the interventions which are available.
- They need to be continually updated as new scientific developments emerge and debate some controversial issues, which have recently surfaced, such as the use of medical cannabis, vaping cigarettes and other substances, and the misuse of prescribed medication, for example, gabapentinoids.
- Thus, a sustainable strategy, which sees as its core aim for medical education that medical students have the skills and knowledge to effectively manage substance misuse when they meet it, needs to be outlined and realised.
- Ensuring financial assistance for qualified staff to support implementation of the new curriculum at a local level has contributed to improvements in the extent and quality of teaching on substance misuse issues. This depends on high-level support within medical schools and at governmental level so that the programme can be initiated, maintained and evaluated so it becomes a salient component of the undergraduate medical course.

Behavioural Addictions & Management Implications

Nady el-Guebaly and Henrietta Bowden-Jones

62 Behavioral Addictions and Management Applications: An Introduction

Nady el-Guebaly and Henrietta Bowden-Jones

This section is dedicated to the increasing recognition of the behavioral addictions as a significant component of our field of practice and windows into human nature without the effect of substances. The inclusion of gambling disorder under the DSM-5 diagnostic code of substance-related and addictive disorders as well as the recent recognition of Internet gaming disorder in the ICD11 are but examples of the awareness of an expanding empirical basis. At the same time, the increasing range of behaviors susceptible to develop from an excessive engagement to a habitual or compulsive pattern behooves us to seek for common as well as distinct features.

Two overview chapters investigate the empirical "state of the science." Drs. Yau, Leeman and Potenza review the "Biological Underpinnings of Behavioral Addictions" including frontostriatal brain imaging findings, the implication of neurotransmitters and genetic heritability, as well as their potential in management (Chap. 65). Drs. Kim and Hodgins present an overview of "Transdiagnostic Mechanisms" among behavioral and substance addictions as well as potential empirically supported interventions that target these similarly (Chap. 66).

The next seven chapters address common and distinct features of currently recognized clinically significant behaviors.

Drs. Echeburúa and Amor's chapter (Chap. 67), "Psychological Management of Gambling Disorder with or without Comorbidities" details the current psychological treatment options including inpatient and outpatient treatments, individual and group cognitive-behavioral therapies, motivational enhancement therapies, Gamblers Anonymous, and relapse prevention. Various pharmacotherapies may reinforce psychological therapy along with incremental benefits with comorbid disorders.

Further information is required about the specific features of gambling by women. Drs. Bowden-Jones, Zendle and Althaus chapter (Chap. 68), "Gambling and Gaming Addictions in Women," covers the gender specifications, similarities and differences in epidemiology, courses, comorbidities and treatment.

The next two chapters detail the intertwined investigations of the current highlighted interests in "Problematic Internet Use" (Chap. 69) and "Internet Gaming Disorder" (Chap. 70).

Drs. Kiraly and Demetrovics discuss the concept of Internet addiction and its criticisms, the development of diagnostic criteria as well as prevalence estimates and the main treatment approaches. Drs. Kaye, Kuss and Rumpf provide a related overview of the current conceptual and methodological challenges in gaming disorder from the ICD 11 as well as DSM-5 appendix perspectives.

The last three chapters are an intriguing exploration of three "required" behavioral needs, that is, shopping, sex, and food, and the determinants of their evaluation into disorders. Drs. Filomensky and Tavares review the epidemiological challenge, assessment scales, comorbidities, clinical manifestation and determinants of "Compulsive Buying Disorders" (Chap. 71). The existing pilot treatment trials are identified with the best evidence favoring cognitive behavioral models.

Drs. Hertzsprung and Amadala provide a sensitive review of the evolution of excessive and maladaptive sexual behaviors into the diagnostic syndrome of "Sex Addiction" (Chap. 72). Available screening and assessment instruments are described as well as a synopsis of etiological determinants and comorbidities. The prevailing psycho-social approaches and a laudable search to validate staff training are outlined as well as the current pharmacological trials.

Dr. Yarnell-MacGrory et al.'s concluding chapter is an insightful description of the common elements between "Binge Eating, Obesity, and Addiction" (Chap. 73). This interaction has come to prominence as a result of the public concern over the pandemic of obesity rising worldwide and the identification of addictive features in the development of binge eating. Intriguing common neurobiological and psychosocial features are identified as well as a brand-new field of investigation into the phenomenon of food addiction and its optimal management.

This section hopefully conveys the potential for insights of behavioral addictions as windows on human nature without the effect of substances. Each new behavior contributes its own perspectives, but we should beware of the public concern over pathologizing an ever-expanding list of behaviors. The section merely makes reference to exercise and work as other candidate behaviors; there are others. Recommendations for the addition of new behaviors tend to emphasize the presence of inclusive criteria. The identification of exclusion criteria will also be necessary for the credibility of the diagnostic process.

A comprehensive biopsychosociocultural conceptualization of these disorders is critical, and the relative significance of each of these components is yet to be determined. In sum, current or potential candidates for a behavioral addiction have to present solid evidence of the involvement of the brain reward circuitry as the basis for a shared psychopathology involving a decision-making bias and inhibitory control deficits.

Besides the recognition of gambling disorder as an addiction, the new nosologies also acknowledge the prominence of craving in the addiction process. As we approach a better model of addiction, we shall be able to depend less and less on a model based on negative consequences and avoid the perils of a circular logic, that is, it is an addiction because it is harmful and it is harmful because it is an addiction. Along with craving, the careful reader will notice that the two other implicit concepts crosscutting the chapters from this section are loss of control and compulsion (defined as repetitively performing a behavior as a strategy to deal with an emotional imbalance). Starting with this triad, we may get closer to an evidence-based phenomenological model of addiction, while distancing from a harm-based model, which may be unduly vulnerable to ever-changing cultural values and judgment calls (take, e.g., the recent evolution of the gambling perspective from frowned upon behavior to government-embraced leisure activity).

That is not to deny the obvious impact of sociocultural factors especially in the determination of new behavioral addictions such as Internet and video gaming. Even in the case of essential behaviors such as sex, eating, and shopping, never before in history have individuals and communities had a wider access to services, products, and credit. Our "information" society suffuses

people with news about novel and potentially gratifying behaviors, shortening the time to adequately ponder and decide.

Finally, besides perfecting and broadening the contours of the addiction model, behavioral addictions may challenge previous widely accepted treatment goals such as abstinence. Popular goal posts promoted by 12-step-based programs such as "avoid the first drink" or "avoid the first dose" become unrealistic when expanded to "avoid the first log-on," "avoid the first purchase" and "avoid intercourse," and in the case of compulsive eaters, "avoid the first bite" is an utterly impossible goal! Compulsive eaters anonymous meetings discuss "avoiding the first compulsive bite," which relates to eating when under the influence of an emotional turmoil in an unconscious attempt to deal with it, which will likely lead to loss of control. Clusters of components/symptoms must be identified for each of these behaviors in order to build tailored preventive and treatment strategies more effectively than current broader behavior-focused approaches.

Abstract

Neurobiological and clinical data indicate that maladaptive engagement in certain behaviors warrants consideration as "behavioral" or non-substance addictions. This chapter reviews existing neurobiological and genetic/family history evidence for behavioral addictions involving gambling, internet use, video-gaming, sex, eating, and shopping. At a neurochemical level, behavioral addictions may involve dysregulation of serotoninergic, dopaminergic, noradrenergic, and opioidergic systems. At a neurocircuitry level, findings suggest dysfunction in subcortical and frontal areas; disruption in these regions and related circuits could lead to disadvantageous decision making, impaired inhibition, and increased cue-induced craving. While a genetic understanding is at an early stage, genetics/family-history data support heritability for behavioral addictions and suggest genetic overlap with other psychopathologies. As this represents an emerging area of research, data remain sparse in multiple domains. An improved understanding of behavioral addictions will help in establishing appropriate nomenclature and enhance the ability to recognize, prevent, and treat these disorders more effectively.

63.1 Introduction

While the term addiction has traditionally been associated with excessive alcohol and drug use, the Latin word (*addicere*) from which it is derived was not initially linked to substance use. Addiction professionals and the public are recognizing that certain behaviors bear resemblance to alcohol and drug dependence, and data have been forwarded that these behaviors warrant consideration as non-substance or "behavioral" addictions. Excessive engagement in such behaviors as gambling, internet use, video-game play, sex, eating, and shopping may represent addictions, with a minority of individuals displaying such habitual or compulsive engagement. Shaffer et al. [61] proposed that addiction should be considered as a syndrome with multiple opportunistic expressions (e.g., substance abuse, pathological gambling, food addictions). Aided by data from neurobiological studies, this view has gained momentum in the past decade and, importantly, has led to the category of "Substance Use and Addictive Disorders" to replace "Substance-related Disorders" in the *DSM-5* [2]. Although gambling disorder is presently the only condition included in this category, other conditions were considered. Notably, internet gaming disorder has been included in the DSM-5 as a condition requiring further study. Along similar lines, gambling disorder and gaming disorder have been included in the 11th edition of the *International Classification of Diseases* (ICD-

11) as "Disorders Due to Addictive Behaviours" [70]. Establishing nomenclature and criteria for behavioral addictions may enhance our capacity to recognize and define their presence.

Biochemical, functional neuroimaging, genetic, and pharmacological research in substance addiction has implicated several neurobiological processes. Multiple neurotransmitters (e.g., serotonergic, dopaminergic, noradrenergic, opioidergic) may contribute to the pathophysiologies of addictions [58]. For example, dysregulated dopamine systems, which are involved with learning, motivation, and salience of stimuli and rewards, and serotonin (5-HT) systems, implicated in behavioral control, may significantly contribute to addictive disorders. Prolonged engagement in an addictive behavior may lead to a reduction of sensitivity to biological rewards and decrease an individual's perceived control over seeking and eventual engagement in the behavior. At the neurocircuitry level, the mesolimbic dopaminergic pathway (linking the ventral tegmental area to the nucleus accumbens and frontal areas) may contribute to decision-making circuitry in risk-reward assessment. Preclinical and clinical work suggest that disruptions in these regions could lead to disadvantageous decision making (e.g., choosing immediate gains versus long-term consequences), impaired ability or willingness to inhibit response to drugs/addictive behaviors when exposed to them, and increased drug- and cue-induced craving [72].

Research also indicates genetic effects on the use and misuse of substances [39]. Several putative risk genes have been identified. Examples include the A1 allele of the Taq1A polymorphism of the dopamine D2-receptor (*DRD2*) gene, associated with measures of impulsivity and behavioral inhibition, and the low transcribing short-allele of the serotonin transport gene (*5HTTLPR*), implicated in moderating the impact of stressful life events on risk of psychiatric conditions such as depression and anxiety [72]. These genes have shown associations with addictions in some but not all studies.

Behavioral addictions frequently co-occur and appear to share important elements with substance-related addictions [72]. In terms of phenomenology, both behavioral and substance addictions may be thematically categorized along four domains: craving, compulsion, diminished control, and persistence of behaviors despite negative consequences [61]. Moreover, both have been characterized as disorders of motivation, reward and decision making [58, 72]. Growing evidence, particularly in pathological gambling, indicates that behavioral addictions share overlapping neurobiological mechanisms and genetic contributions with substance addictions. However, differences have also been observed, and the extent to which findings from substance addictions extend to individual behavioral addictions may differ.

This chapter reviews existing neurobiological and genetic/family history evidence pertaining to behavioral addictions in an attempt to shed light on these emerging mental health problems from a neuroscientific perspective. Specifically, the following sections discuss the neural systems, neurotransmitters, and genetics/family history findings relating to gambling disorder, internet addiction, internet gaming disorder, compulsive sexual behavior disorder, food addiction, and compulsive shopping or buying. As this is an emerging area of research, data are sparse in some domains. Similarities and differences with substance-addition findings are highlighted. Epidemiologies are addressed briefly, and more detailed descriptions of clinical features and treatment methods can be found in other chapters. An overview of the neural systems, neurochemistry, and genetic results can be found in Tables 63.1, 63.2, and 63.3, respectively.

Table 63.1 Overview of neural system results for selected behavioral addictions, with a focus on fronto-striatal findings

Behavioral addiction	Key results	Similarities and differences with key results in substance use disorders
Gambling disorder	*Frontal areas:* *Cognitive tasks:* Most findings suggest reduced activity in multiple frontal regions in GD, but also findings suggest increased activity and negative findings *Cue-induction studies:* Suggest differences in activity, but the precise nature of differences warrants additional study	Between-group differences are observed in SUD and control comparison subjects with many tasks indicating reduced frontal activity, but precise nature of differences warrants additional study
	Striatal areas: *Cognitive tasks:* Reduced ventral striatal activity to monetary reward anticipation *Cue-induction studies:* Mixed with some studies showing reduced striatal activity in GD compared to controls *Others:* Ventral striatal activity inversely correlated with impulsivity measures and problem-gambling severity	Many findings suggest reduced ventral striatal activity during monetary reward anticipation in individuals with SUDs compared to controls
	White and gray matter: Poorer white matter integrity in multiple regions; some volumetric differences in gray matter and white matter differences between GD and controls, some of which overlap with SUDs; gray matter reduction observed in frontal regions, independent of SUDs comorbidity	Poorer white matter integrity and decreased gray matter volumes in SUDs
Internet addiction disorder	*Frontal areas:* *Cognitive tasks:* EEG studies indicate diminished efficiency of response inhibition; differential ACC activity to decision conflicts between IAD and controls *Resting state:* Differences in regional homogeneity in multiple frontal regions, but the precise nature of differences warrants additional study	Underactive feedback valence in individuals with SUDs Preliminary studies suggest reduced regional homogeneity in SUDs
	White and gray matter: Lower gray matter density in multiple regions including dlPFC, ACC, and insula; differences in white matter integrity between IAD and controls involving the internal capsule, but effects may be potentially widespread	Poorer white matter integrity and decreased gray matter volumes in SUDs
Internet gaming disorder	*Frontal areas:* *Cognitive tasks:* Diminished functional connectivity within executive networks linked to poorer cognitive control *Cue-induction studies:* Greater activation of multiple frontal areas including the OFC and dlPFC; findings linked to transitions and treatment outcomes	Between-group differences are observed in SUD and control comparison subjects, but precise nature of differences warrants additional study
	Striatal areas: *Cognitive tasks:* Diminished activation of ventral striatum during reward processing *Cue-induction studies:* Increased activity in the ventral striatum compared to control subjects *Resting state:* Reduced fronto-striatal connectivity linked to cognitive control deficits in IGD	Reduced ventral striatal activity typically reported; however, findings may differ per task
	Gray matter: Relatively reduced gray matter volumes in cortical regions including ACC and vmPFC	Decreased striatal and cortical gray matter volume (including ACC and vmPFC) in SUDs

Table 63.1 (continued)

Behavioral addiction	Key results	Similarities and differences with key results in substance use disorders
Compulsive sexual behavior disorder	*Fronto-striatal areas:* *Cue-induction studies:* Activation of emotion and reward regions and networks, as well as thalamic activity	Cue reactivity to drug cues activates emotion and reward regions and networks among SUD subjects
	White matter: Higher integrity of lower superior frontal region	Poorer white matter integrity in SUDs
Food addiction	*Frontal areas:* Increased OFC activation in response to food cues but decreased activity upon ingestion of food among individuals with high food addiction scores	Between-group differences are observed in SUD and control comparison subjects, but precise nature of differences warrants additional study
	Other regions: Increased ACC and amygdala activation in response to food cues among individuals with high food addiction scores	Evidence for ACC activity in risky decision making in SUDs; amygdala activity associated with trait craving in SUDs
Compulsive shopping disorder	*Striatal areas:* Increased activity in ventral striatum upon product presentation	Reduced ventral striatal activity typically reported; however, findings may differ by task
	Other regions: Reduced activity in insula and ACC during price presentation	Insula activity in response to substance cues; evidence for ACC activity in risky decision making in SUDs

GD gambling disorder, *SUDs* substance use disorders, *IAD* internet addiction disorder, *IGD* internet gaming disorder, *EEG* electroencephalography, *dlPFC* dorsolateral prefrontal cortex, *ACC* anterior cingulate cortex, *OFC* orbitofrontal cortex, *vmPFC* ventromedial prefrontal cortex

Table 63.2 Overview of neurochemistry results for selected behavioral addictions

Behavioral addiction	Key results	Similarities and differences with key results in substance use disorders
Gambling disorder	*Dopamine:* Mixed reports of dopamine involvement; negative between-group findings for between-group differences in D2-like receptor availability at rest; dopamine antagonist administration may promote gambling motivations in GD and medications not efficacious, although efficacy may be influenced by individual differences; dopamine release and function may contribute to impulsivity and decision making	Dopamine release has been related to substance use; reduced D2-like receptor availability in SUDs typically reported for stimulant and alcohol SUDs; mixed clinical findings with dopamine antagonists; individual differences in dopamine release and function may contribute to variability in impulsivity and risky decision making in SUDs
	Serotonin: Mixed results with SSRIs; possible individual differences in serotonin function	Evidence suggest between-group differences in serotonergic function; mixed clinical results with SSRIs suggest possible individual differences
	Opioids: Positive clinical findings with opioid antagonists, with some evidence of lasting effect, although findings mixed	Multiple positive clinical findings suggest role for opioid systems, particularly for opiate and alcohol dependence
	Other neurotransmitters: Noradrenergic levels elevated among GD; preliminary positive clinical findings with glutamate antagonist suggest glutamate may contribute to impulsive and compulsive behaviors	Findings suggest elevated noradrenergic levels in some SUDs; positive clinical findings suggest role for glutamatergic systems

(continued)

Table 63.2 (continued)

Behavioral addiction	Key results	Similarities and differences with key results in substance use disorders
Internet addiction disorder	*Dopamine:* Decreased striatal dopamine transporter expression in preliminary IAD studies; limited findings suggest differential D2-like receptor availability in the striatum – however results may differ between subdivisions	Mixed findings regarding levels of dopamine expression in striatum; reduced D2-like receptor availability in some SUDs typically reported
Problematic video-game playing	*Dopamine:* Limited and preliminary findings suggest increased dopamine release in ventral striatum during video-game play; dopamine dysregulation in striatum may relate to duration of IGD	Dopamine release has been related to substance use and studies indicate between-group differences in dopaminergic activity in some SUDs
Compulsive sexual behavior disorder	*Serotonin:* Positive results from clinical trials with SSRIs, but may treat comorbid psychiatric disorders which in turn helps address CSBs	Mixed clinical results with SSRIs, with some positive and others negative
	Opioids: Initial positive findings for high doses of opioid receptor antagonist; however, positive results not long last	Multiple positive clinical findings suggest a role for opioid systems in SUDs
Food addiction	*Dopamine:* Dopamine release related to food and food cues; reduced D2-like receptor availability in very obese humans and mice; animal models of food addiction suggest consumption of hyperpalatable foods decreased dopamine release and receptor expression following withdrawal; pro-dopaminergic stimulant lisdexamfetamine approved for treatment of BED; the role of dopaminergic activity in food addiction has not been directly investigated in humans	Dopamine release has been related to SUDs and studies indicate between-group differences in dopaminergic activity in some SUDs; decreased dopamine release and receptor expression follow substance use withdrawal, particularly in striatal regions, for some SUDs
	Serotonin: Positive findings in open-label and double-blind studies with SSRIs for BED but not food addiction *per se*	Mixed clinical results with SSRIs, with some positive and others negative
	Opioids: Positive findings for high doses of opiate antagonist in rodents, but the precise nature is unclear; different nutrients may have different effects on the opioid system	Multiple positive clinical findings suggest a role for opioid systems in SUDs
Compulsive shopping disorder	*Serotonin:* Some positive results from clinical trials with SSRIs, while controlled results for others have been typically negative	Mixed clinical results with SSRIs, with some positive and others negative

GD gambling disorder, *SUDs* substance use disorders, *IAD* internet addiction disorder, *PVG* problematic video-game playing, *CSB* compulsive sexual behavior disorder, *SSRIs* selective serotonin reuptake inhibitors, *BED* binge-eating disorder

Table 63.3 Overview of selected genetic results for selected behavioral addictions

Behavioral addiction	Key results	Similarities and differences with key results in substance use disorders
Gambling disorder	*Family history:* GD highly heritable; twin studies indicate genetic factors may share similar magnitudes with or contribute more than environmental factors to overall risk for developing GD	SUDs highly heritable; twin studies indicate genetic and environmental factors share similar magnitudes of influence on overall risk for developing a drug use disorder
	Molecular genetics: Preliminary findings suggest genetic polymorphisms related to dopamine (*DRD2*) and serotonin transmission (*5HTTLPR, MAO-A*); genome-wide association studies have not identified single nucleotide polymorphisms that significantly contribute to GD	Associations with polymorphisms related to dopamine and serotonin transmission; genome-wide associations indicate different contributions to individual SUDs

Table 63.3 (continued)

Behavioral addiction	Key results	Similarities and differences with key results in substance use disorders
Internet addiction disorder	*Molecular genetics*: Preliminary findings suggest over-expression of ss *5HTTLPR* genotype in males with IAD	Associations with serotonin transporter gene polymorphisms
Problematic video-game playing	*Molecular genetics:* Preliminary findings suggest the presence of Taq1A polymorphism of *DRD2* receptor gene and low activity *COMT* alleles more likely in males with online PVG	Links between SUDs and Taq1A polymorphisms, but not universally replicated; low activity *COMT* variant linked to various SUDs (e.g., nicotine, methamphetamine, and alcohol)
Compulsive sexual behavior disorder	*Family history:* More likely to have parent with hypersexual disorder; more likely to have first-degree relative with SUDs	Individuals with SUDs more likely to have first-degree relative with various SUDs and psychopathology
Food addiction	*Family history:* Obesity ten-fold more likely in people with an obese first-degree relative	Individuals with SUDs more likely to have first-degree relative with various SUDs and psychopathology
	Molecular genetics: Obese individuals with BED, compared to non-BED, had lower frequencies of the *Taq1A1* polymorphism of *DRD2* receptor gene and higher frequencies of the G118 polymorphism of the mu-opioid receptor gene (*OPRM1*); over-expression of ss *5HTTLPR* genotype in overweight adolescent; *FTO* linked to BMI and enhanced neural response to food cues	Associations with polymorphisms related to dopamine and serotonin transmission; *OPRM1* polymorphisms may mediate reward effects of drugs of abuse (e.g., opiates, alcohol, heroin) – however results in clinical populations have been mixed; *FTO* gene linked to alcohol dependence
Compulsive shopping disorder	*Family history*: Relationship to parental history of compulsive shopping disorder and first-degree relative with SUDs	Individuals with SUDs more likely to have first-degree relative with various SUDs and psychopathology
	Molecular: Negative findings for *5HTTLPR* polymorphisms	Associations with serotonin transporter gene polymorphisms

GD gambling disorder, *SUDs* substance use disorders, *IAD* internet addiction disorder, *PVG* problematic video-game playing, *DRD2* D2 dopamine receptor gene, *5HTTLPR* serotonin transporter-linked polymorphic region, *MAO-A* monoamine oxidase A gene, *COMT* catechol-O-methyltransferase gene, *OPRM1* mu-1 opioid receptor gene, *BMI* body mass index

63.2 Gambling Disorder

In the last decade, pathological gambling or gambling disorder (GD) has developed a strong research base in the wake of worldwide legalized gambling and concerns over gambling's possible health and social impacts. In the *DSM-5,* pathological gambling was renamed as GD and recategorized to the newly expanded "Substance-Related and Addictive Disorders" category. With this move, GD became the first recognized non-substance behavioral addiction, implying many shared features between GD and substance use disorders (SUDs). GD can include preoccupations with gambling, gambling with greater amounts of money to receive the same level of desired experience (tolerance), repeated unsuccessful efforts to control or stop gambling (impaired control), restlessness/irritability when trying to stop gambling (withdrawal), and interferences in major areas of life functioning. High comorbidity rates for GD and substance addictions have been observed, with a meta-analysis suggesting a mean co-occurrence of 57.5% [48].

63.2.1 Neural Systems

The basis of GD is likely multifactorial. Changes in processing of gambling cues and gambling

decisions, including those relating risk/reward decision making, reward processing, and impulse control, are likely contributing factors [72]. Research on GD that coincided with the *DSM-5* reclassification included neuroimaging studies that have typically investigated frontal and striatal circuits, although several lines of evidence also suggest the involvement of other regions [58].

Neuropsychological findings in GD have indicated impaired decision making and deficits in executive functions compared to controls [72]. Functional magnetic resonance imaging (fMRI) studies during cognitive tasks have implicated frontal areas. In particular, multiple investigations have observed differences in ventromedial prefrontal cortex (vmPFC) function in GD. For example, GD (versus control) subjects have exhibited relatively diminished vmPFC activation during presentation of incongruent stimuli in the Stroop color-word interference task, during anticipation of gains and losses in the monetary incentive delay (MID) task, and during a simulated gambling task [58]. However, seemingly contradictory findings have also been reported. During high-risk gambling decisions in the IGT, fMRI findings demonstrated that GD individuals exhibited relatively greater frontal lobe and basal ganglia activation, particularly in the vmPFC, caudate, and amygdala [59]. Across individuals with and without GD, performance on the IGT correlated largely with ventral striatal activity during a prospect phase of reward and loss processing on the MID task [8]. Differences in findings across studies may relate to the specific tasks used [45], populations studied or other factors. Cue-induction studies have also reported both relatively decreased and increased vmPFC activity for problematic gambling/GD (versus control) in response to gambling stimuli [58]. Taken together, dysfunction in frontal areas responsible for decisional processes appears to contribute to GD, although the precise nature of the dysfunction is unclear.

Dysfunction in the striatum may also contribute to GD. A recent meta-analysis indicates striatal hypoactivation during reward anticipation in individuals with GD or SUDs compared to controls [49]. The GD and SUD groups diverged during reward outcome: while individuals with SUDs showed increased ventral striatum activation, individuals with GD showed decreased activation in the dorsal striatum. In gambling cue-exposure tasks, GD exhibited decreased activation in the ventral [56] and dorsal [15] striatum compared to control subjects. In both GD and alcohol dependence, ventral striatal activation during reward anticipation was inversely correlated with impulsivity measures [6].

Aside from frontal and striatal circuits, other brain regions have also been implicated. GD (versus controls) displayed significantly greater activity in regions involved in sensory encoding (e.g., parahippocampal gyrus and occipital cortex) to video presentation of gambling cues [58]. Among GD subjects, subjective intensities of gambling urges following viewing of gambling videos correlated positively with activation in brain regions implicated in the retrieval and processing of emotion including the bilateral temporal poles, medial temporal gyrus, and medial occipital gyrus and inversely with activation in the left dorsal medial frontal cortex, an area involved in performance monitoring. Control participants did not show gambling-urge-related correlations at the same threshold [7]. Relatively diminished insula activation in GD during reward processing has also been noted [6]. Insula involvement in craving responses have also been noted [58].

Neuroanatomical alterations may also exist in GD. Diffusion tensor imaging has been largely consistent in indicating disrupted white matter integrity, as indexed by fractional anisotropy values, although findings are diffuse [58]. Multiple regression analyses suggest that this reduction may be predicted by GD status, as well as age and past alcohol abuse/dependence [58]. Microstructural white matter differences may similarly impact GD and cocaine-use disorder [73]. Using voxel-based morphometry (VBM) to assess gray and white matter differences revealed a lack of structural differences in individuals with GD compared to control subjects [58]. In one large structural MRI study ($N = 205$), Zois et al. [81] found significant gray matter reduction in frontal regions in GD, independent of SUDs comorbidity, compared to healthy controls.

Another large study found altered sulcogyral patterns in the orbitofrontal cortex linked to GD [46].

63.2.2 Neurochemistry

Dopaminergic findings in GD present a complicated picture and questions have been raised regarding how central dopamine may be in GD, especially given the lack of replicability of findings [57]. Using positron emission tomography (PET) with the tracer [^{11}C]raclopride, one small study reported that GD individuals performed worse on the IGT than control subjects, and among GD subjects, dopamine release in the ventral striatum was positively associated with excitement levels [47]. Another tracer, [^{18}F]fluorodopa, for dopamine precursor indicated increased dopamine synthesis in GD [65], though negative findings have also been reported [50]. In another small study, D2/D3 receptor availability has also been shown to negatively correlate with mood-related impulsivity ("urgency") within the striatum [14] and positively correlate with problem-gambling severity within the dorsal striatum [12] among GD. While there were no differences in the magnitude of dopamine release between GD and control subjects during a slot machine gambling task, among GD, dopamine release correlated positively with problem-gambling severity [30]. However, unlike findings in substance addictions, especially to stimulants [66], no significant difference in D2/D3 receptor availability at resting state was observed between GD and control subjects [58]. These findings and others have led investigators to question the role for dopamine in addictions [55]. Dopamine agonists have been associated with impulse control disorders in Parkinson's disease [58]. Further, oral administration of a D2-like receptor antagonist, haloperidol, increased gambling motivations among GD subjects while no such effect was observed among control subjects [58], although individual differences may be important [58]. Individual differences or other factors (e.g., placebo responses) may explain with the lack of efficacy of D2-like antagonist drugs (e.g., olanzapine) in the treatment of GD [72]. Taken together, these data raise questions regarding a precise role for dopamine in GD.

Pharmacological studies also implicate serotonin in GD. Selective serotonin receptor inhibitors (SSRIs) have had mixed results for GD and substance addictions [58]. For example, some randomized control trials have found fluvoxamine and paroxetine to be superior to placebo in treatment of GD, while others have reported negative findings [72]. Heterogeneity in treatment response may result from individual differences, with some data suggesting that individuals with co-occurring anxiety disorders may respond well to SSRIs [58].

Other neurotransmitter systems may also contribute to GD. Dysregulated hypothalamic-pituitary-adrenal (HPA) axis and increased noradrenergic levels have been observed in GD [58]. Opioid antagonists (e.g., naltrexone and nalmefene) have demonstrated superiority over placebo in multiple randomized clinical trials [58]. Following a 6-month open-label naltrexone treatment, the majority of GD patients did not relapse during a 6-month medication-free follow-up [58]. Thus, opioid antagonist treatment may have lasting effects, although controlled trials with longer-term follow-up are needed to examine this possibility. Lithium and the glutamatergic nutraceutical n-acetyl cysteine have also shown promise in small controlled trials [58]. Topiramate in conjunction with behavioral therapy has also shown promise [58]. Memantine, an N-methyl-D-aspartate (NMDA) type glutamate receptor antagonist, reduced both the number of hours spent gambling per week and money spent gambling in GD after 10 weeks of medication; in addition, GD subjects reported improved cognitive flexibility post-treatment, suggesting that glutamate may contribute to impulsive and compulsive behaviors [58].

63.2.3 Genetics/Family History

Data from the Vietnam Era Twin Registry estimate the heritability of GD to be 50–60% [58]. This estimate is similar to those from substance addictions [39]. Twin studies suggest that genetic

factors may contribute more than environmental factors to the overall variance of risk for developing of GD [58]. Shared genetic contributions between GD and SUDs have been identified [58].

Genetic polymorphisms related to dopamine transmission (e.g., *DRD2* and Taq1A1) and serotonin transmission (e.g., *5HTTLPR* and *MAO-A*) have been associated with GD, albeit not in a consistent fashion, and may have additive effects [72]. Genetic studies are best considered preliminary given the small sample sizes and absence of stratification by demographics. Replication of candidate gene studies using alternate designs is needed. Towards this end, genome-wide association studies to date of GD have not identified single nucleotide polymorphisms (SNPs) reaching genome-wide significance [58].

63.2.4 Conclusion

GD has been the most frequently studied behavioral addiction. Although the neurobiology of GD is incompletely understood, recent neuroimaging, neurocognitive, neurochemical, and genetic work indicate similarities with SUDs.

63.3 Internet Addiction Disorder

The internet is integrated firmly into modern society and has substantially changed the way we conduct our daily lives. Its popularity, particularly among youth, has raised concern over its potential harms. While moderate internet use may enhance one's quality of life by widening social circles and enhancing psychological well-being [72], diminished control over internet use may impact negatively on daily function, family relationships, physical and mental health, and may lead to incarceration and legal troubles [72]. No formal diagnostic criteria for "internet addiction disorder" (IAD) or problematic internet use currently exist in the DSM-5 or ICD-11 as the groups considering internet use behaviors have seen the internet as a delivery system that permits certain behaviors like gaming or gambling, and gaming and gambling disorders have online and offline specifiers in ICD-11 [70]. Definitions of IAD are often based on *DSM-IV-TR* criteria for pathological gambling [75] with some, such as Young's Internet Addiction Scale, having demonstrated sufficient reliability [72]. In terms of comorbidity, IAD may frequently co-occur with not only SUDs, but also various psychiatric conditions including mood, impulse-control, and personality disorders [72].

63.3.1 Neural Systems

Electrophysiological studies indicate diminished efficiency of response inhibition in IAD. Electroencephalography recordings of the P3 amplitude, an event-related potential associated with response evaluation and inhibitory processing, was found to be higher and have longer peak latency among IAD versus control subjects during a Go/No Go task [72]. These findings suggest IAD individuals may need to engage more cognitive resources to inhibit behavior and are less efficient in information processing. Another study by the same research group found that for incongruent conditions during the Stroop task, IAD versus control subjects showed reduced medial frontal negativity, suggesting impaired cognitive control [72].

Anterior cingulate cortex (ACC), a region implicated in decision conflicts, has been associated with IAD. Compared to controls, IAD subjects demonstrated greater ACC activation for incongruent conditions during the Stroop task and more severe scores on Young's Internet Addiction scale [72]. In a guessing task with monetary gain and losses, increased activation of the orbitofrontal cortex to gain trials and decreased ACC in loss trials was observed in IAD compared to control subjects, suggesting sensitization to reward and desensitization to loss [72]. Resting-state differences in IAD subjects have also been detected with increased regional homogeneity observed in the right frontal region, left superior frontal gyrus, right cingulate gyrus, bilateral parahippocampus, and other regions [72]. Increased regional homogeneity may reflect enhancement of synchronization among these

regions which may consequently enhance sensitivity to rewards.

Evidence also indicates potential structural differences. Using MRI, lower gray matter density in regions tied to emotion regulation including the ACC, posterior cingulate cortex, insula, and lingual gyrus has been found [72]. Moreover, gray matter volumes of the right dorsolateral prefrontal cortex (dlPFC), left ACC, the right supplementary motor area, and white matter fractional anisotropy measures in the posterior limb of the internal capsule have been negatively correlated with the duration of IAD [76].

In the same study, Yuan et al. [76] also reported increased fractional anisotropy within the region of the left internal capsule accompanied by decreased fractional anisotropy within the right parahippocampal gyrus among IAD adolescents. Others have reported widespread reduction of fractional anisotropy beyond the parahippocampal gyrus in major white matter pathways and abnormal white matter structure in IAD adolescents [72].

63.3.2 Neurochemistry

Several small studies have explored dopaminergic functioning in IAD. A recent study using single-photon emission computed tomography (SPECT) scans reported decreased striatal dopamine transporter expression among male IAD subjects compared to age-matched controls [72]. In addition, the authors reported significantly decreased volume of the bilateral corpus striatum among IAD subjects. Another study using [^{11}C] raclopride (PET) scanning reported that adult males with IAD (versus male control subjects) had reduced dopamine D2-like receptor availability in subdivisions of the striatum including the bilateral dorsal caudate and left dorsal putamen compared to controls; moreover, receptor availability was negatively correlated with IAD severity [33]. Interestingly, dopamine receptor availability in the ventral striatum did not differ between the control and IAD groups [33], contrasting results from SUDs [72]. Further studies are needed regarding the role of dopamine in IAD, particularly given the small sample sizes in studies to date.

63.3.3 Genetics/Family History

Few studies have investigated the genetics underlying IAD. Homozygosity of the short allelic variant of the *5HTTLPR* (*SS-5HTTLPR)* gene may be more frequent among male IAD adolescents. IAD subjects expressing *SS-5HTTLPR* showed higher harm avoidance and scored higher on Young's Internet Addiction Scale than IAD individuals who expressed other variants of the gene [43, 72]. The nicotinic acetylcholine receptor subunit alpha 4 (CHRNA4) gene may also contribute to IAD. The T-variant (CC genotype) of the rs1044396 polymorphism on the CHRNA4 gene occurred more frequently among IAD (versus control) subjects; further analyses revealed that this finding was driven by females, suggesting sex-specific genetic effects [72].

63.3.4 Conclusion

IAD may be increasingly prevalent concurrent with increased internet availability, accessibility, and popularity. It is important to note that many studies have involved adolescent males and have been performed in Asia; therefore, results may not be generalizable to other populations.

63.4 Internet Gaming Disorder

There has been debate whether problematic video-game playing warranted consideration as a unique mental disorder. While the DSM-5 workgroup concluded that there was insufficient evidence to include "internet gaming disorder" (IGD) as a behavioral addiction in its main text, the World Health Organization included "gaming disorder" in ICD-11 [70]. Some have argued that IGD is a subtype of IAD and both should be considered under the umbrella term pathological technology use [72]. However, it is important to consider the two conditions individually, as each

may be associated with different clinical and health-related correlates [72]. IGD may be both similar to and distinct from other behavioral addictions such as GD and IAD in terms of availability and use of visual and auditory rewards, – and such differences may contribute to IGD's unique features [72]. Unfortunately, research on IGD often does not differentiate between online and off-line games, making it difficult to separate IGD from IAD findings.

63.4.1 Neural Systems

Electrophysiological data indicate reduced frontal-central error-related negativity amplitudes among IGD (versus controls) in response to incorrect trials relative to correct trials in the Go/NoGo task, suggesting compromised error processing among IGD subjects [72]. In addition, frontal-central error-related negativity amplitude was negatively correlated with weekly gaming hours [72], suggesting potential desensitization to negative consequences.

Changes in reward processing and reward sensitivity are considered crucially important for addiction. In one study, Kühn et al. [42] conducted MRI scans on 154 14-year-olds and found both functional and structural differences between frequent (≥9 hours/ week) and infrequent (<9 hours/week) video-game players. In the MID task, frequent players showed greater activation of the ventral striatum during loss feedback compared with no loss. Moreover, higher left striatal gray matter volume was observed among frequent compared to infrequent players, and this volumetric difference was found to negatively correlate with deliberation time on the Cambridge Gambling Task (CGT). Striatal differences have also been noted in cue-induction studies. Post-cue changes indicative of increased activity have been found in the right ventral striatum and caudate nucleus among male adults playing >30 hours/ week on the "World of Warcraft" game compared to "non-heavy" gamers playing <2 hours/week [34].

In addition to striatal findings, Ko et al. [34] also reported greater activation in the right orbitofrontal cortex, bilateral ACC, medial frontal cortex, and right dlPFC in heavy (versus non-heavy) players following cue presentation. Activation of these areas was positively correlated with self-reported gaming urge and recall of gaming experience provoked by "World of Warcraft" pictures [34]. Similar findings have been reported in subsequent studies examining individuals with current IGD [72] and those in remission from online IGD [72]. Moreover, reduced fronto-striatal in resting state functional connectivity was linked to cognitive control deficits in IGD [77]. Taken together, this suggests deficient modulation of reward-driven behavior may be associated with dysfunctions in the frontal cortex.

More recent studies have additionally implicated fronto-cortical mechanisms in IGD [64]. For example, resting state differences in executive control networks have been found, with weaker strength among IGD relative to non-IGD subjects in a manner that was linked to cognitive control [17]. Additionally, relative blunted ventral striatal activation has been observed during reward processing in IGD [16], as has been reported in GD and SUDs [49].

Findings have also linked brain mechanisms to transitions in IGD and its treatment. For example, cue-related activation of the lentiform nucleus has been linked to emergence of IGD, [20] and relatively decreased engagement of the dlPFC and increased engagement of the insula may be linked to persistence of IGD [18]. Treatment studies have implicated activation and connectivity patterns to outcome measures, implicating regions like the insula and precuneus [78] as well as orbitofrontal cortex, hippocampal, and supplementary motor regions [79]. These findings suggest that treatment may operate to change regional connectivity patterns underlying cue-responsivity and learned associations linked to gaming behaviors. Gender-related differences are also important to consider and may provide insight into why males may be more vulnerable to developing IGD [19, 21].

White matter and gray matter studies have been conducted with some evidence suggesting better white matter integrity in IGD [22]. A meta-analysis

has shown reduced gray matter volumes in IGD in regions including the vmPFC and ACC [71], as has been seen in substance addictions [74].

63.4.2 Neurochemistry

In an early neurobiological study of video-game playing using [^{11}C]raclopride (PET) scanning, increased release of dopamine to D2-like receptors in the ventral striatum was observed following 50 minute of video-game playing in eight healthy adult males [72]. A more recent study using SPECT similarly suggested increased dopamine release in the caudate during a motorbike racing computer game, compared to baseline measures among healthy adult males [72]. Video-game playing appears to induce dopamine release that may be comparable to the effects of psychoactive substances [72]. However, the relevance to IGD remains to be studied, although preliminary studies suggest that dysregulation of D2-like receptors in the striatum may be linked to duration of IGD [63].

Following a 6-week trial of bupropion (a drug with influences on dopaminergic and other neurotransmitter systems), individuals with IGD (>30 hour StarCraft/week) demonstrated decreased craving for video-game play, reduced total gameplay time, and less cue-induced brain activity in the dlPFC compared to pre-treatment [72].

63.4.3 Genetics/Family History

Genetic studies for IGD are limited. Han et al. [27] reported that the presence of the Taq1A1 allele of *DRD2* and the low-activity Val158Met variant of COMT genes was more prevalent among online PVG adolescent males than controls. Genome-wide association studies are needed.

63.4.4 Conclusion

With public attention, IGD is actively being studied. Preliminary studies suggest neurobiological similarities with substance addictions. The decision to include gaming disorder in the ICD-11 should further promote research efforts and attention of health professionals to this disorder.

63.5 Hypersexual Disorder or Compulsive Sexual Behavior Disorder

"Hypersexual disorder," "sexual addiction," or "compulsive sexual behavior disorder" may be defined as recurrent or repetitive sexual behavior that interferes in areas of life functioning. Hypersexual disorder, conceptualized as a nonparaphilic sexual desire disorder with impulsivity and/or compulsivity components [31], was considered for inclusion in DSM-5 but was excluded [2]. However, the ICD-11 has included criteria for compulsive sexual behavior disorder (CSBD) as an impulse control disorder [70], and as such we use this term in this chapter. However, as most research has not employed the recently developed diagnostic criteria, we will also refer to CSBs, as appropriate. Some individuals who suffer from CSBD may display clinical features that resemble addictive disorders including craving prior to behavioral engagement, impaired control over behavioral engagement and behavioral engagement despite adverse consequences [35].

63.5.1 Neural Systems

Early neuroimaging studies often focused on cue-induced reactivity. A recent meta-analysis of functional neuroimaging studies suggest overlapping as well as distinct neural substrates of cue reactivity to drug, gambling, food, and sex rewards [54]. Much like drug cues, cue reactivity to sexual stimuli may involve networks that process rewards, emotions, and habits (including cingulate gyrus, insula, head of the caudate, frontal gyrus, and cerebellum). However, sexual reward cues may induce unique activation of the pulvinar in thalamus. Structurally, gray matter volume of the right caudate has been found to be negatively associated with reported pornography

hours per week [41]. Taken together, these findings suggest that exposure to sexual stimuli may relate to fronto-striatal pathways.

Early neuroimaging studies of CSBs used varying approaches. Using diffusion tensor imaging, Miner et al. [52] found that although mean diffusivity in the inferior frontal region was negatively correlated with impulsivity, fractional anisotropy and mean diffusivity measures of this area did not differ between individuals with and without CSBs. These data suggest possible differences from GD and some other behavioral addictions in which associations with inferior frontal white matter disorganization have been reported (i.e., low fractional anisotropy and high mean diffusivity), albeit not always in inferior frontal regions [72].

Men with CSBs as compared to those without have shown greater activation of the ACC, ventral striatum, and amygdala in response to sexual cues, and functional connectivity of these regions was associated with sexual desire more strongly in men with CSBs [68]. Men with problematic pornography use as compared to those without have shown greater ventral striatal activation to cues predicting the possible receipt of viewing sexual/erotic images, with the degree of neural activation correlating with task response times and out-of-the-magnet measures of sexual addiction, pornography viewing, and masturbation [26]. These and other findings suggest links between CSBs and formally defined addictions [37, 62].

Animal research suggests that the medial prefrontal cortex (mPFC) contributes to sexual behaviors. Lesions of the mPFC in rats may block the acquisition of sex-aversion condition and impair the suppression of seeking of sexual rewards in the face of aversive consequences [72]. How the mPFC may contribute to CSBD requires further study.

63.5.2 Neurochemistry

Our current understanding of the neurochemistry of CSBD is predominantly derived from pharmacological studies. In a double-blind, placebo-controlled study of CSBD in homosexual and bisexual men, the selective serotonin reuptake inhibitor (SSRI) citalopram was found to reduce sexual desire without lessening sexual satisfaction [72]. Another SSRI, fluoxetine, was found to be effective in reducing symptoms in men with either paraphilia or paraphilia-related disorders [72]. In addition, better results were obtained when methylphenidate was used in conjunction with fluoxetine, suggesting an additive effect and implicating possible involvement of dopamine and norepinephrine [72]. A case series of men with problematic pornography use being treated with paroxetine suggested possible efficacy with respect to reducing anxiety and pornography use but was also associated with the emergence of other problematic sexual behaviors [25].

Naltrexone, an opioid receptor antagonist, appears effective in treating hypersexual disorder. Administration of high doses (100–200 mg/day) has been reported to successfully reduce hypersexual disorder symptoms, sexual urges, sexual fantasies, and masturbation in two case report studies [72]. These features, however, recurred following naltrexone discontinuation. Naltrexone has also been reported to reduce urges in problematic pornography use in a man receiving cognitive behavioral therapy [38].

Other investigators have suggested that medications (such as SSRIs and lithium) may not specifically manage sexually addictive behaviors but rather treat comorbid psychiatric disorders, which may, in turn, help patients address CSBs [72]. Controlled trials and systematic studies are needed to examine efficacy and tolerability of medications for CSBD.

63.5.3 Genetics/Family History

Individuals with CSBD appear more likely to have parents with a similar condition and were more likely to have a first-degree relative with SUDs [72]. Carnes [13] reported that 87% of CSBD patients come from families with addiction problems.

63.5.4 Conclusion

CSBD is a clinical condition that may have substantial negative impacts. Neurobiological research in CSBD is emerging, and the inclusion of defined criteria in the ICD-11 should help promote consistency across studies.

63.6 Food Addiction

Food addiction has been discussed in the popular media and has received considerable research attention. Addictive processes have been suggested to underlie obesity [72]. Emerging neurobiological research suggests both substance use and eating behaviors may engage similar neurocircuitry and have consequently led to the conceptualization of "foods as drugs." However, the concept of food addiction remains debated with some investigators arguing that existing research has yielded conflicting results [80] and others arguing that this construct may be particularly relevant to certain subgroups of obese individuals, such as those with binge-eating disorder (BED) [72]. Although not labeled as such, several core features of BED share similarities with those for substance dependence including strong food cravings and diminished control over eating [72]. Over a quarter of clinicians report often or always using addiction-based therapies for BED [72], further suggesting clinical and phenomenological similarities. It is important to note that for some individuals, overeating is a relatively passive event that takes the form of liberal snacking, eating large portions, and physical inactivity [3], and the extent to which these behaviors may constitute an addiction has been debated.

63.6.1 Neural Systems

With regard to cognitive control circuits, imaging studies in obese (versus lean) subjects have documented increased frontal activation of the vmPFC, dlPFC, and cingulate gyrus upon exposure to food-related stimuli and have been implicated in feeding motivations [72]. Obese versus lean individuals have also shown enhanced corticolimbic-striatal activation to favorite food cues and stress cues in a guided imagery fMRI task [29]. In the same study, measures of insulin resistance correlated positively with regional brain activations to favorite-food, stress, and neutral-relaxing cues in obese but not lean individuals and regional brain activations (particularly in the thalamus) mediated the relationships between insulin resistance and favorite-food-cue-induced craving in obese but not lean individuals. These data suggest that obese individuals may be hyper-responsive to food cues (particularly those of high-caloric value), and that metabolic measures may relate to these brain activations differently in obese and lean individuals.

Obesity is a heterogeneous construct and data suggest that certain subgroups, such as those with BED, may exhibit food-addiction features more so than others. Individuals with BED compared to body mass index (BMI)-matched non-BED obese and lean individuals showed relatively diminished activity in the vmPFC, inferior frontal gyrus, and insula during the Stroop task [9]. The same research group found that during a MID task, BED obese individuals showed relatively diminished ventral striatal activity during anticipatory phases relative to non-BED obese individuals, whereas non-BED obese individuals showed heightened ventral striatal and vmPFC responses compared to lean individuals [9]. Further, preliminary data link relatively diminished ventral striatal activation to poorer treatment outcome in BED [5]. Taken together, these results suggest that neural differences exist between obesity subgroups.

Neuroimaging studies have directly assessed food addiction. Gearhardt et al. [24] found that activation in the ACC, medial orbitofrontal cortex, and amygdala in response to anticipated receipt of food was positively correlated with food addiction scores among lean and obese young females. Furthermore, females with high food addiction scores, compared to those with low scores, showed decreased activation in the orbitofrontal cortex during food intake. No significant correlation was observed between food addiction score and BMI, suggesting that food

addiction and related neural functioning may occur among individuals with a range of body weights. In another study, Feldstein Ewing et al. [23] found greater response across the orbitofrontal cortex, ventral striatum, and additional frontoparietal and temporal regions among overweight/obese individuals in an fMRI gustatory cue exposure task when comparing task-related response after consumption of a high-calorie versus low-calorie drink. These neural responses were, however, not related to food addiction scores.

63.6.2 Neurochemistry

Dopamine release has been related to food and food cues [72]. Overconsumption of energy-rich foods may condition dopaminergic responses to food cues and concurrently down-regulate dopamine responses to other incentives [67]. Administration of dopamine antagonists may abolish responding for food in rats [72]. Development of addiction-like reward deficits and onset of compulsive-like food-seeking may be accelerated by lentivirus-mediated knockdown of striatal D2-like receptors in rats with extended access to palatable, high-fat food [72]. Studies using [^{11}C]raclopride (PET) scanning have demonstrated that D2-like receptor availability is reduced in obese individuals and mice [72]. Moreover, among obese individuals, D2-like receptor availability correlated negatively with BMI scores [72].

Data from animal models suggest ingestion of foods of different palatability and energy density may produce different effects in dopaminergic systems. Rats classified as prone to binge-eating consumed significantly more highly palatable and energy-dense (high-fat, high-sugar) food and tolerated higher levels of foot-shock for such foods than binge-eating-resistant rats [72]. Regular consumption of energy-dense food may have lasting consequences on the brain. Using a diet-induced model of obesity, rats fed a high-sugar diet compared to those on an unrestricted diet showed decreased dopamine release in the nucleus accumbens following 36 hours of food deprivation [72]. Similarly, Alsiö et al. [1] found that rats fed a high-fat (versus unrestricted) diet showed decreased expression of D1 and D2 receptors in the ventral tegmental area, nucleus accumbens and prefrontal cortex (PFC) following a 18-day withdrawal. Furthermore, obesity-prone rats showed increased craving and anxiety compared to obesity-resistant rats during the second withdrawal week following discontinuation of the energy-dense diet [72]. Future studies are needed to examine whether these dietary findings may extend to human subjects.

The only medication with a formal indication in the treatment of BED is lisdexamfetamine [51]. Lisdexamfetamine is a stimulant pro-drug whose product (dextroamphetamine) promotes dopaminergic and noradrenergic effects by blocking their reuptake and increasing their concentrations in the synaptic cleft, and as such models of BED consider roles for dopaminergic and noradrenergic systems [28, 32].

The serotonin and norepinephrine reuptake inhibitor sibutramine and SSRI fluoxetine have shown some efficacy in treating eating disorders and were approved by the Food and Drug Administration for treatment of obesity and bulimia nervosa, respectively, although the former has been recalled in the United States for cardiovascular safety concerns [51]. SSRIs in general may be effective in targeting binge-eating, psychiatric and weight symptoms [60], although the effectiveness and duration of these medications remain under debate. Open-label studies report initial SSRI (citalopram and fluoxetine) administration reduced binge-eating and weight loss in BED patients; at a 6-month follow-up, these beneficial effects were maintained with continuation of SSRI treatment [44] though there has been conflicting evidence on their long-lasting effects [72]. In a randomized, double-blind, 12-week study of escitalopram for the treatment of individuals with co-occurring BED and obesity, individuals receiving high-dose escitalopram treatment had significantly greater reductions in weight, BMI, frequency of binge episodes, and global severity of illness scores than those receiving placebo treatment [72].

Opioids are implicated in eating behaviors [72], although the precise nature of their influences are unclear. High doses of the opiate antagonist, naloxone, increased sugar consumption, and opiate-like withdrawal symptoms including elevated plus-maze anxiety, teeth chattering and head shakes in sugar-binging rats following a period of abstinence [72]. These findings may, however, be unique to sugar binging. Bocarsly et al. [11] reported that rats on high-fat diets did not show signs of opiate-like withdrawal when exposed to naloxone. Taken together, these findings suggest that the brain opioid system may be differently affected by the overeating of different nutrients.

63.6.3 Genetics/Family History

Obesity is ten-fold more likely in people with an obese first-degree relative [72]. When pregnant rats maintained a highly palatable and energy-dense (high fat, high sugar) diet, their offspring showed an increased preference for sugar and fat in comparison to those with mothers on a control diet [69]. Additionally, dopamine and opioid receptor expression was increased in reward-related brain regions including the ventral striatum, PFC and hypothalamus [69].

In humans, obese individuals with BED, in contrast to non-BED obese controls, had lower frequencies of the Taq1A1 allele of the *DRD2* gene and higher frequencies of the G118 allele of the mu-opioid receptor gene (*OPRM1*) [72]. Non-obese individuals with a variant of the fat mass and obesity-associated (*FTO*) gene – a gene linked to the regulation of the activity of dopaminergic midbrain areas and whose polymorphisms have been linked to BMI – demonstrated enhanced neural response to food cues [40]. Taken together, genetic data suggest dopamine and opioid receptor genotypes be involved in obesity and different patterns of eating. Genetic polymorphism of the *5HTTLPR* has also been implicated, with S allele carriers showing higher BMI scores than homozygous LL carriers and being more frequent among overweight adolescents [72].

63.6.4 Conclusion

Eating behaviors have been tested extensively using animal models, and a considerable amount of neurobiological research has been generated, although less is known about food addiction per se. Data suggest that animal results may be transferable to human populations, although further research is needed. Certain subgroups of people with obesity (e.g., those with BED) and certain diets (e.g., highly palatable, energy-dense) may share more neurobiological similarities with SUDs. Such findings have important implications, and the extent to which a food-addiction model applies to individuals with obesity and its subgroups merits further investigation.

63.7 Compulsive Shopping or Buying

Classically referred to as "oniomania," compulsive shopping or buying has had a long-standing history (in comparison to more recent phenomena such as IAD and IGD) and was clinically described a century ago. Interest in compulsive shopping or buying has rekindled in recent years (see review: [10]). However, compulsive shopping or buying is not included as disorder in the DSM-5 or ICD-11 [53].

63.7.1 Neural Systems

An fMRI study found stronger ventral striatal activity among individuals with compulsive shopping or buying (versus control subjects) during the initial product presentation phase of a multi-phase purchasing task [72]. During a subsequent price presentation phase, individuals with compulsive shopping or buying showed reduced activation of the insula and ACC. ACC activity was also higher among individuals with compulsive shopping or buying during the concluding decision phase.

63.7.2 Neurochemistry

Beneficial results of citalopram, an SSRI, have been reported in a small 12-week open-label trial, and in a 6-month follow-up, individuals with compulsive shopping or buying continuing citalopram were less likely to relapse than those who discontinued the medication [72]. A subsequent study found those assigned to placebo were more likely to relapse compared to those randomized to continue taking citalopram in a 9-week double-blind, placebo-controlled administration following a 7-week open-label trial [72].

Findings from other SSRIs have been negative. Another study by Koran et al. [36] found no difference between escitalopram and placebo conditions. Double-blind comparisons of fluvoxamine and placebo similarly found no difference in compulsive shopping or buying symptom reduction [10]. As such, data supporting SSRIs in the treatment of individuals with compulsive shopping or buying are mixed, and currently no medication has a formal indication for compulsive shopping or buying.

63.7.3 Genetics/Family History

Compulsive shopping or buying may run in families. Of 18 individuals with compulsive shopping or buying, 3 had one or more first-degree relative with compulsive shopping or buying and 11 had relatives with a SUD [72]. Negative findings have been reported for *5HTTLPR* polymorphisms [72].

63.7.4 Conclusion

Our current knowledge of the neurobiology and genetics of compulsive shopping or buying is limited, but preliminary research suggests altered neurofunctional responses to shopping stimuli. Further research is needed to determine the role of various neurotransmitters, the efficacies of specific medications, and the underlying biology.

63.8 Conclusion

Research in behavioral addictions is challenging due to the heterogeneity of the behaviors, with certain subgroups arguably fitting better in an addiction framework than others [72]. Further complications stem from the arguably normative nature of these behaviors, which has led to debates among researchers as to what constitutes an addiction [4, 72]. Uniformly agreed upon diagnostic criteria and assessment tools will not only facilitate comparisons across studies, but may help to ensure that cut-off points are appropriately generated. Additional research in the domains of neuroimaging, neurochemistry, genetics, and treatment is needed to increase knowledge of behavioral addictions to the level of that for substance addictions. In particular, future studies investigating often underrepresented female populations (especially for IAD and IGD) and studies conducted longitudinally would provide valuable information and more comprehensive understanding.

Keeping these limitations in mind, existing research suggests parallels between behavioral addictions and SUDs. Data are most extensive for GD, and these data led to reclassification of GD as a behavioral addiction in DSM-5 and ICD-11. Although many gaps in knowledge remain, research in IAD, IGD, CSBD, food addiction, and compulsive shopping or buying has accelerated in recent years, with such work yielding important insights.

Neuroscientific approaches to addiction have traditionally been based on the premise that addiction is a process that results from brain changes associated with chronic intake of physical substances. Although the neurobiologies of behavioral addictions remain less well understood than those of SUDs, recent research suggests that similar biological features may lead to the development of behavioral and substance addictions. Given the considerable co-occurrences of behavioral and substance addictions, an improved understanding of their relationships has important implications for not only furthering our understanding of the neurobiologies of these disorders, but also improving prevention and treatment strategies.

Key Points

- Which disorders constitute behavioral addictions remains debated
- Gambling disorder and gaming disorder are recognized by the World Health Organization as disorders due to addictive behaviors
- Similarities and differences exist between individual behavioral addictions
- Similarities and differences exist between behavioral and substance addictions

The Transdiagnostic Mechanisms of Behavioral Addictions and Their Treatment

64

Hyoun S. Kim and David C. Hodgins

Contents

Abstract

Behavioral addictions such as gambling, video games, shopping, and compulsive sexual behaviors share considerable similarities to substance use disorders. These similarities were officially recognized in the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) with the inclusion of gambling disorder in the Substance Use and Related Disorders, the first behavioral addiction to be recognized as such. While our knowledge of behavioral addictions has grown exponentially in the past several decades, evidence-based treatments of behavioral addictions are lacking. Given the similarities between substance and behavioral addictions, we argue that it is possible to develop a treatment for behavioral and substance addictions that targets their underlying similarities (i.e., transdiagnostic mechanisms). In this chapter, we provide an overview of the transdiagnostic mechanisms of behavioral (and substance) addictions as well as the empirically supported intervention possibilities that target them. Specifically, we identify six transdiagnostic mechanisms: deficits in motivation, urgency, deficits in self-control, maladaptive expectancies and motives, deficits in social support, and compulsivity. We conclude with

a discussion on transdiagnostic treatments (i.e., treatments that apply the same underlying intervention principles to a class of disorders) and propose a recently developed pragmatic transdiagnostic treatment of addiction called the Component Model of Addiction Treatment (CMAT; Kim, Hodgins (Front Psych 9, 2018)). The CMAT may have several benefits over disorder-specific treatments, including providing treatment for emerging behavioral addictions (e.g., gaming, shopping, compulsive sexual behaviors). Clinical applications of the CMAT are discussed.

64.1 Introduction

Traditionally, the concept of addictive disorders was limited to psychoactive substances. However, with the publication of the 5th edition of the Diagnostics and Statistical Manual of Mental Disorders (DSM-5) [2] and the 11th edition of the World Health Organization's International Classification of Diseases (ICD-11) [23], the concept of addiction was expanded to include non-substance-related addictive behaviors. Specifically, gambling disorder was included in the Substance Use and Related Disorders section of the DSM-5, and as a disorder due to addictive behaviors in the ICD-11. Gaming disorder was also recognized as an addiction in the ICD-11 with its inclusion alongside gambling disorder in the disorders due to addictive behaviors section. Gaming was also included in the DSM-5 appendix as requiring further investigation (i.e., Internet gaming disorder). In other words, the DSM-5 and ICD-11 recognize the existence of behavioral addictions. It is anticipated that additional behavioral addictions will be added in the future as research evidence accumulates supporting their validity [63]. For example, while compulsive buying and sex addiction were not included in the DSM-5 or ICD-11, with more empirical evidence, these behavioral addictions may also warrant inclusion in future editions [43, 55].

The past several decades have seen remarkable growth in the empirical investigations of behavioral addictions. While fewer than 300 studies were published on this topic in 1990, this number increased over eightfold with over 2500 articles published in 2013. These articles examine a wide array of issues related to behavioral addictions, including their risk factors and correlates with other psychiatric disorders [8]. What can be concluded from the extant literature is that there is a considerable overlap across addictive behaviors, including both substance and behavioral addictions in etiological (e.g., onset, natural course), phenomenological (e.g., cravings, preoccupations), and clinical (e.g., treatment strategies, comorbidities) factors [24].

Despite the increased empirical interest, our knowledge regarding the optimal treatment of behavioral addictions remains sparse. Indeed, gambling disorder is the only behavioral addiction that currently has validated evidence-based treatments. For example, both motivational interviewing (MI)/enhancement therapy and cognitive behavioral therapy have demonstrated efficacy as evidence-based psychological treatments for gambling disorder [74]. In contrast, the evidence base for the treatment of other behavioral addictions, including Internet gaming disorder, is less developed [63]. This is an important gap as behavioral addictions are relatively common psychiatric disorders with prevalence rates of up to 22% ([63]).

We have recently argued that a potentially limiting factor in the development of behavioral addiction treatment is the tendency to create disorder-specific protocols [38]. For example, there now exists separate treatment protocols for gambling disorder, gaming disorder, and compulsive sexual behaviors, to name only a few. Unfortunately, the creation of disorder-specific protocols is problematic on several grounds. The

first and foremost limitation is that there are dozens of behaviors that have been purported to be behavioral addictions [35]. Thus, a disorder-specific treatment approach would necessitate the creation of dozens of treatment protocols for each "unique" disorder, with significant overlap in treatment content of each. It would also necessitate clinicians to learn and become competent in dozens of treatment protocols, which may not be feasible due to time and costs. The creation of disorder-specific protocols also further perpetuates the notion that each potential behavioral addiction is a new psychiatric disorder when the empirical evidence suggests considerable similarities across behavioral addictions. These similarities may warrant conceptualization of behavioral addictions as a group of disorders that represent a common underlying pathology rather than as unique disorders.

The similarities between addictive disorders have been noted since the 1980s with the general theory of addictions [34], and they have been expanded upon in subsequent years (e.g., [25, 61, 68, 75]). For example, Shaffer et al. [68] posited in their syndrome model of addiction that addictive disorders can be thought of as a syndrome of shared signs and symptoms that reflect common underlying risk factors. Orford [61] outlined a set of primary and secondary psychological processes, occurring within a sociocultural context, that lead to a strong attachment to "appetitive" activities (e.g., drinking, gambling, exercise) with impairments of self-control. Griffiths [25] also posited that all addictions can be conceptualized by their similarities rather than their differences. Specifically, according to Griffiths [25], all addictions share six core characteristics: (1) salience, (2) mood modification, (3) tolerance, (4) withdrawal, (5) conflict, and (6) relapse. More recently, seven constructs were derived from expert consensus to be important in understanding the neuropsychological dysfunctions underlying addictions. These include aspects of the positive valence system (reward valuation, reward expectancy, action selection, reward learning, habit), the cognitive control system (response selection/inhibition), and impairment of control (compulsivity) [75]. Given the considerable overlap across addictive disorders, we contend that it is possible to develop a unified treatment model that can be applied across not only behavioral addictions but also substance addictions that target their underlying similarities (i.e., transdiagnostic mechanisms).

Indeed, treatments that target shared mechanisms are not novel and have been developed for anxiety disorders [4] and eating disorders [18]. These treatments target core etiological and maintaining factors shared by a group of disorders, such as avoidance and high neuroticism seen in anxiety disorders and preoccupation of body weight and shape seen in eating disorders. Herein, we suggest that it is also possible to develop a treatment that capitalizes on the underlying similarities between behavioral and substance addictions. In the following section, we provide an overview of the transdiagnostic mechanisms of behavioral and substance addictions along with their intervention possibilities: deficits in motivation, urgency, deficits in self-control, maladaptive expectancies and motives, deficits in social support, and compulsivity (Table 64.1).

The following transdiagnostic mechanisms were identified based on our review of the literature. Specifically, the transdiagnostic mechanisms were selected if they were important etiological and maintaining factors across behavioral and substance addictions, and there existed empirically supported interventions to modify them. It is important to note that other transdiagnostic mechanisms may be identified in the future based on empirical support for their importance across addictive behaviors as well as support that they are amiable to change.

Table 64.1 Transdiagnostic mechanisms of addictions and their interventions

Transdiagnostic mechanism	Intervention	Technique/Skills
Deficits in motivation	Motivational interviewing	Decisional balance Asking about the future Asking about the time before the addiction Asking about values Confidence and importance ratings Query extremes
Urgency	Mindfulness-based interventions	Mindful breathing Body scan meditation Urge surfing
Deficits in self-control	Problem-solving Working memory interventions	5 steps to problem-solving Cognitive training
Maladaptive expectancies and motives	Cognitive-behavioral interventions Coping skills interventions	Thought records Increasing Pleasant activities
Deficits in social support	Self-help programs Assertiveness training	12 step groups/SMART Recovery Expressing negative emotions Asking for support Refusal skills
Compulsivity and maladaptive perseveration of behavior	Stimulus control Cue exposure intervention	Identifying high-risk situations Cue exposure training

64.2 Transdiagnostic Mechanism of Behavioral and Substance Addictions and Their Intervention Possibilities

64.2.1 Deficits in Motivation

The first transdiagnostic mechanism is motivation to change. At least a modicum of motivation is necessary for clients to engage in treatment, even if the motivation is externally derived, reflecting pressure due to family, friends, or more formal influences such as legal mandate. It is increasingly recognized that the first step in treatment is addressing motivation. Furthermore, addressing motivation as needed throughout treatment leads to better engagement, lower attrition, and better outcomes [56]. Motivational interviewing (MI) is a style of interacting with clients that helps them engage in the treatment process, focus on refining their change goals, and identify personal motivations to change and resolve any ambivalence about their decisions. A recent "review of reviews" showed that evidence for the efficacy of MI is strong across a range of addictive behaviors [15].

A related and important issue in treatment is the issue of treatment goal. Treatment goal, whether abstinence or harm reduction, will likely depend on multiple factors, including client preference. MI helps clients to identify and refine their change goals, without imposing any specific goal, which may help enhance motivation. An important consideration in the treatment of behavioral addictions is that the strict focus on abstinence that traditionally is found in substance use disorder treatment is not necessarily applicable for behavioral addictions. Take gambling, for example, does abstinence from gambling preclude any type of gambling, including the purchase of an occasional raffle ticket, or only cessation of the problematic types for the client? Evidence suggests that certain types of gambling can continue non-problematically after a person "quits gambling" [39]. For other behaviors, specifically everyday behaviors such as shopping, work, sex, and eating, cessation may not be feasible at all. Moreover, it is clear that clients with both behavioral and substance addictions shift their goals over time, often not sharing their goal with the treatment provider [69]. At the same time, there is some evidence

that with greater problem severity, adoption of an abstinence goal is associated with better outcomes [69]. A common clinical stance, consistent with MI, is to help the client identify their personal goal in specific terms and to support the client in striving toward that goal but also encouraging revisiting the feasibility of the goal as treatment proceeds.

Miller and Rollnick [52] emphasized that although a range of MI therapeutic techniques are available, the spirit in which MI is offered is an essential ingredient. MI is a client-centered, collaborative interaction in which the client is encouraged to identify and describe reasons, needs, and desires to change their behavior and to talk about their ability and commitment to take action. These verbalizations are termed "change talk," and recent process research shows that the amount of change talk generated in MI is linked with subsequent successful change [46]. Therapists strategically reflect the change talk that they hear to encourage clients to provide examples, elaborate, and expand on their reasons, desires, and need for change. Clients are also invited to describe their ambivalence toward change, including reasons that they would prefer to continue their problematic behaviors and reasons that change would be difficult. This discussion is labeled as "sustain talk," and a greater proportion of change talk versus sustain talk is also linked with successful change [46].

Keeping in mind that the collaborative and client-centered spirit of MI is central, a variety of exercises are available for use in individual therapy and in groups to have clients generate change talk and explore their ambivalence [52]. The Decisional Balance exercise is a frequently used method for helping the client engage in this discussion. It involves using a 2 × 2 grid to capture and summarize the clients' discussion of the benefits and disadvantages of changing and not changing (i.e., pros and cons). The goal is to use the grid as a clinical tool to engage clients in clarifying their goals and generating change talk. The therapist reflects what is said and asks for more detail and examples, which serve to increase the amount of change talk even more. (Table 64.2 lists this technique and other common MI exercises.) Some exercises elicit change talk and some help resolve ambivalence by underscoring the discrepancy between the clients' addictive behavior and their goals and values. In individual therapy, the goal is to continue the discussion until the client is subtly or overtly expressing a

Table 64.2 Exercises to enhance motivation

Exercise	Brief description	Key questions
Decisional balance exercise	Client describes their reasons for changing and not changing using a 2 × 2 grid (pros and cons of changing and pros and cons of not changing)	What are the good things about your involvement with… And the not so good things? What would not be good about changing? And good about changing?
Asking about the future	Clients describe a discrepancy between their current behavior and future goals	Where do you see yourself going in 5 years?
Asking about the time before the addiction	Clients describe a discrepancy between their current behavior and desired goals	What was life like before you began to…?
Asking about values	Clients describe a discrepancy between their current behavior and values	What is important to you? When you make a decision, what values do you consider?
Confidence and importance ratings	Clients are asked to rate the importance of change and their level of confidence in being able to change if they wanted to, using a 0 to 10-point scale.	In terms of importance, you rated…. This is (above a zero, moderate, high). Why not lower? What would need to happen to make it higher? In terms of your confidence, it is (higher/lower) than your importance. Why is it …?
Query extremes	Clients are asked about the worst- and best-case scenarios if they overcome or do not overcome their addiction.	What is the worst thing that might happen if you continue to…? And the best is you do not?

desire to move to actively tackling the problem. For example, in a subtle shift, the change talk might shift to discussion of steps already taken to change ("I googled to see how to cancel my online account") or envisioning what change might look like ("Friday nights might be difficult to fill. I think I will need to join a sports team"). More overtly, the client may ask what the possibilities are for change. In the group context, the therapist must observe the group as a whole to determine when to shift into the next more action-oriented topic.

64.2.2 Urgency

Urgency is a facet of impulsivity that is characterized as the tendency to act rashly during intense emotional experiences [13]. People may act rashly under intense positive emotions (i.e., positive urgency) and/or during intense negative emotions (i.e., negative urgency). For a significant proportion of individuals, the function of engaging in addictions is to alleviate negative affect. Indeed, the ability of both behavioral and substance addictions to regulate affect has been suggested to be an important component of all addictive behaviors [25, 61]. There is empirical evidence to support the notion that negative urgency may be an important transdiagnostic mechanism across addictive disorders. Negative urgency has been found to be a robust predictor of both behavioral and substance addictions (see [38]) and is elevated among people with comorbid behavioral and substance addictions [19]. Negative urgency has also been found to have important treatment implications. Although negative urgency increases the risk of relapse, it is a facet of impulsivity that can be modified during treatment [26]. As such, negative urgency may constitute an important transdiagnostic mechanism that may need to be addressed in treatment.

Mindfulness-based strategies effectively target negative urgency. Mindfulness is generally defined as the ability to pay attention to the present moment purposefully and non-judgmentally [3], and it has been conceptualized as being both a trait and a state [37]. Importantly, there is evidence to suggest that mindfulness-based interventions can increase trait levels of mindfulness, even when people are not engaging in mindful practice (see [21]). In recent years, mindfulness-based interventions have gained empirical support in the treatment of a variety of psychiatric disorders, including addictive disorders [12]. For example, mindfulness-based approaches have been applied to a wide array of behavioral and substance addiction with preliminary support for their efficacy [66]. Mindfulness-based interventions provide skills to help clients cope with difficult emotions in the present moment rather than reacting to their internal states. By staying in the present moment, the intensity and duration of negative emotions are lessened, which reduces the likelihood of turning to an addictive behavior as a maladaptive coping mechanism. Indeed, a potential mechanism for the treatment effects of mindfulness is a reduction in behavioral reactivity and improving emotion regulation skills (i.e., negative urgency; [33]).

As previously mentioned, mindfulness can be cultivated through mindful practice. Formal practices of mindfulness include mindful breathing [11], in which clients purposefully focus their attention on their breath and observe their breath without trying to change it. It is common for clients to shift their attention to thoughts that may arise during mindful breathing practice, especially when they are newly developing mindfulness skills. When clients notice that their attention has wandered from focusing on their breath, they are encouraged to acknowledge their thoughts and gently and non-judgmentally shift their attention back to their breath. The mindfulness breathing exercises are typically 10 minutes in duration and can be guided or unguided. Body scan mediation is another common mindfulness-based practice. In this practice, clients bring their focused attention to physical sensations (e.g., tingling, tightness, pulsing) that they may be experiencing in their body. This can be done systematically, by beginning to examine sensations starting from the head and moving purposefully down to the toe, or simply noticing a physical sensation that may arise. Similar to the mindful breathing exercise, it is common for cli-

ents to experience their mind wandering, and when this occurs, they are encouraged to purposefully reorient their attention to bodily sensations. With continued practice, clients are able to purposefully attend to their breath and physical sensations for longer periods of time. Importantly, clients also develop the skills to purposefully shift their attention to different aspects of their affective and physical states in their day-to-day lives, thus lessening behavioral and emotional reactivity. Mindfulness training is typically done as weekly or twice-a-week sessions and can be conducted in both individual and group settings. It is helpful to debrief with clients regarding their experiences, including whether they noticed any thoughts that arose during the practice, the process of reorienting their attention to their breath, and whether they found the practice easy or difficult. Additionally, clients are often assigned to practice 10 minutes of mindfulness practice daily as homework.

Mindfulness-based interventions may particularly be beneficial in helping clients manage their urges and cravings. Urges and cravings are robustly associated with addiction and are a risk factor of relapse [67]. Mindfulness-based strategies are effective in reducing cravings, which may be a potential mechanism that leads to the overall treatment outcomes for addictions [66]. The experience of urges and cravings can be broken down into thoughts, physical sensations, and behaviors [50]. Through the practice of "urge surfing," clients develop the skills to tolerate their urges and cravings rather than reacting to them by engaging in the addictive behavior. Specifically, clients first acknowledge that they are experiencing an urge or craving. Thereafter, clients use the same skills developed in the mindful breathing and body scan exercises to purposefully shift their attention and observe their urges and cravings as they are experienced. With focused breathing, clients are able to release the tension associated with their urges and cravings, thereby reducing their emotional and behavioral reactivity. This cycle of focusing on the experience of urges and cravings combined with focused breathing is repeated until the intensity of the urge and cravings subside.

64.2.3 Deficits in Self-Control

Self-control is the ability to direct ones' actions toward a goal [5], both in the shorter term and in the longer term. Poor self-control is a component of impulsivity, and in addicted individuals, it is reflected in delay discounting, shortened time horizons, and self-control resource depletion [38]. In addition, deficits in self-control are associated with executive functioning deficits commonly seen in addiction [24]. Executive functioning is the ability to organize, plan, problem-solve, and coordinate thoughts and actions toward goal-directed behavior, thus facilitating self-control [9]. As such, executive functioning involves top-down cognitive processes such as inhibitory control and working memory [14].

A variety of treatment techniques are available to address deficits in the capacity to self-regulate. A well-established treatment intervention is training in problem-solving [57]. Generally, problem-solving consists of five structured steps [53]. The first step is to adopt a problem-solving orientation to situations that cause distress. Rather than catastrophizing or focusing on the hopelessness or unfairness of the situation and reacting impulsively, clients are encouraged to refocus on whether a problem exists that could be solved. To recognize whether a problem exists, people are taught to examine signs of physical (e.g., nausea) and emotional distress (e.g., sadness, anger). The next step is to identify the problem by determining what exactly the problem consists of, including people that may be involved. It is sometimes helpful to break down the problem into more manageable components. The third step is to brainstorm all possible ways that the problem can be resolved. The goal of this step is not to come up with the best solution, but all potential solutions to the problem. This step can be facilitated by reflecting on similar situations that the client may have successfully solved in the past and gathering information from both social networks and self-help resources. Once all possible solutions have been identified, the next step is to consider the potential benefits and consequences associated with each identified solution. Next, the client

chooses the plan of action that is most likely to solve the problem and is associated with the fewest negative consequences. The last step is to assess whether the solution was successful in resolving the problem. It is helpful to note what worked, what did not, and what could be changed next time. If the solution did not solve the problem, then clients can implement the next best option or brainstorm additional solutions.

Problem-solving training helps clients approach challenges as issues to be solved rather than reacting emotionally and impulsively. The relapse prevention model, first proposed by Marlatt in the 1980s, provides a broader framework for helping clients to think about both preventing and coping with high-risk situations associated with the problematic behavior [47]. This model was designed to be relevant to both behavioral and substance addiction. It typically is introduced to clients toward the end of treatment to help them plan for posttreatment challenges. However, it incorporates perspectives and skills already emphasized in the treatment program and involves four components: (1) identifying high-risk situations; (2) learning coping skills; (3) practicing coping skills; and (4) creating lifestyle balance. Numerous clinical guides and worksheets are available to help clinicians with implementing relapse prevention (e.g., [47]). The model can effectively be introduced and discussed in the group context as clients develop individualized relapse prevention plans.

Less well established, but promising, is working memory training as a treatment for addictions [7]. Although meta-analytic evidence exists that computerized cognitive training in older adults can transfer to non-training but similar tasks (near transfer), and to less similar tasks (far transfer) [58], the utility of working memory training in the treatment of addiction is only just emerging [73].

64.2.4 Maladaptive Expectancies and Motives

The beliefs that people hold in regard to addictive behaviors may lead to and maintain their addictions. Two dysfunctional beliefs have been identified that are important to address in treatment [6]. The first is permissive beliefs. These are maladaptive beliefs that provide a justification for engaging in the addictive behavior, such as *no one will find out if I do it just this time.* The second dysfunctional belief is called anticipatory beliefs. These beliefs relate to what people believe engaging in the addictive behavior will do for them, for example, *going to the casino will make me feel better.* Anticipatory beliefs may be closely related to people's motivations for engaging in addictive behaviors, specifically coping motives. Although three motives have generally been identified in regard to addictive behaviors (enhancement, social, and coping), engaging in addictive behaviors to cope with negative emotions is associated with the severity of addictive behaviors (see Kim and Hodgins [38]). Furthermore, coping motives have been found to underlie comorbid addictions [30, 44] and thus represent a transdiagnostic mechanism that can be targeted in treatment.

Cognitive behavioral interventions have shown efficacy in reducing maladaptive expectancies in addictive disorders [6, 41, 45, 49]. One well-known technique used in cognitive behavioral therapy is a thought record. Thought records help clients identify dysfunctional thoughts, their triggers, and develop skills to reframe dysfunctional beliefs to more adaptive and realistic beliefs [6]. There are generally five components to a thought record. The first is the date and time that a client identifies the occurrence of a dysfunctional thought or belief. Second is the context in which the dysfunctional thought occurred. Here, clients are asked to provide as much context as possible, including who they were with (if anyone), the location, and any other relevant details. This aspect of the thought record helps clients to identify potential triggers for their dysfunctional thoughts. The third component is to note emotional experiences associated with the dysfunctional thoughts, including the intensity of their emotional experiences. This is an important component of the thought record as dysfunctional thoughts are more likely to arise during periods of negative affect. The next step is to identify the dysfunctional thought, including labeling the

specific type of the dysfunctional thought (e.g., permissive or anticipatory) if possible. Clients are then taught skills to connect the dysfunctional thought to specific emotions. Indeed, a key principle of cognitive behavioral therapy is that our thoughts, emotions, and behaviors are all interconnected. Clients are then taught skills to change the dysfunctional thoughts to more helpful and realistic ones. To help this process, clients can ask themselves the following questions: (1) what is specifically dysfunctional about this thought? (2) Is this dysfunctional thought accurate? (c) What evidence do I have to support it? For example, a client who identifies the anticipatory thought, *going to the casino will make me feel better* may challenge this thought with *going to the casino might make me feel better in the short term, but will lead to more negative feelings in the long term* or *last time I went to the casino to make myself feel better, I ended up spending my rent money, which caused me more problems.* After the dysfunctional thought has been challenged, clients are asked to re-examine the intensity of their emotional experiences. More often than not, clients will report a reduction in the intensity of their negative emotions. The last component of the thought record is to identify helpful actions, which are behaviors that reduce the likelihood of engaging in the addiction, such as calling a supportive friend or family member, going for a walk, and/or engaging in relaxation exercises. The thought record can be completed both in individual sessions and in group treatment. In group treatment, clients volunteer to work through a personal example. Group members can be involved by asking for their input if a client is having difficulties with reframing their dysfunctional thoughts and/or asking group members what thoughts and/or emotions they may experience in similar situations.

Coping skills interventions can also be used to target maladaptive expectancies and motives. Coping skills training helps clients build skills to cope with difficult life events in a more adaptive manner, that is, being able to cope with difficult situations without the use of the addictive behavior [53]. One component of coping skills training is increasing pleasant activities [53]. If addictive behaviors constitute a maladaptive coping mechanism for negative emotions, then a possible intervention strategy is to increase positive emotions. Increasing pleasant activities serves several purposes. First, it is common for clients to find an abundance of time when they are in active recovery from their addiction. Thus, increasing pleasant activities helps to fill the void left by the addictive behavior and helps to prevent negative emotions such as boredom. To increase pleasant activities, clients, first, brainstorm a list of activities that they find pleasurable. The activities can be social events or activities that clients can do on their own such as reading a book. The activities can also involve monetary costs or can be free, such as going for a walk in the park. Once clients have identified a list of pleasant activities, they are asked to commit to engaging in the activities by scheduling them throughout the week. Clients often find it helpful to schedule a variety of positive activities throughout the week.

64.2.5 Deficits in Social Support

Lack of social support and interpersonal difficulties are strongly associated with addictive behaviors (see [38]). Additionally, the lack of social support, or the wrong type of support such as enabling, is associated with worse treatment outcomes, including increasing the risk of relapse [17, 76]. In response to this, several intervention strategies have been developed to increase social support and improve interpersonal relationships, which have demonstrated efficacy in the treatment of addictions [32, 51]. A common intervention to address deficits in social supports is joining self-help support groups such as 12-step programs or Self-Management and Recovery Training (SMART) Recovery. These mutual support groups are of great therapeutic benefit as they provide clients with a support network consisting of others who are also in recovery as well as potential access to a sponsor who can offer support during times of crisis. There exists self-help support groups for a variety of behavioral addictions (e.g., gambling, shopping, sex, eating), and there is evidence to suggest that these

support groups lead to improved outcomes [36]. In addition to mutual self-help support groups, family- and couple-based therapies such as the community reinforcement and family training approach [51] and behavioral couples' therapy [60] have been developed and show promise in the treatment of addictions.

Interventions that teach communication skills are an important component in addressing deficits in social support. Indeed, communication skills have shown to increase satisfaction and quality of interpersonal relationships [10] as well as treatment outcomes in addiction treatment [65]. To this end, clients are taught skills to communicate assertively. Assertive communication consists of being honest, direct, and expressing your thoughts, feelings, and wishes in a way that respects your own rights as well as the rights of others. Assertiveness is the most effective form of communication and is associated with improved interpersonal relationships, increases in receiving support, and increases in self-esteem and self-confidence [62].

When applied to the treatment of addictions, assertiveness skills can be used to express negative emotions, asking for support, refusal skills, and more (Table 64.3). For example, when expressing negative emotions, assertive communication first involves describing the behavior of the person that is causing the negative emotions. It is important to reference a specific behavior that is external to the person rather than resorting to blaming. The next step is to state the effect that the behavior is having on yourself. Thereafter, a request can be made to stop the behavior and state a positive reaction if they comply with the request. The same general steps can also be used to ask for social support. The development of refusal skills, such as the broken record technique is also an important component of addiction-specific communication skills [53]. In the broken record technique, clients develop skills to respond to a request to engage in an addictive behavior by politely declining. If the first refusal is not successful, clients once again repeat the refusal and so forth much like a broken

Table 64.3 Assertiveness skills in addictions treatment

Assertiveness Skills	Steps/Tips	Example
Expressing negative emotions	1. Describe the behavior of the other person that is causing you negative emotions. 2. State your feelings about the behavior. 3. Make a request to change the behavior. 4. State a positive reaction.	You are asking me again to go to the casino with you. I am upset by that since I told you, I have stopped gambling. I would appreciate it you don't ask me to go to the casino or any other place where there is gambling. If you stop asking me to go to the casino or any other place where there is gambling, then we can continue spending time together. If you keep asking me to gamble with you, we can't hang out together.
Asking for support	1. State exactly what you need help with. 2. Express how you are feeling about the problem. 3. Make a specific request how your support person can help.	I am supposed to be attending my first 12-step meeting tonight and I am feeling anxious and scared. Would you be able to come with me just for the first few sessions while I become comfortable? It would really help my anxiety if you came with me.
Refusal skills	1. Be direct and honest. 2. Keep it brief. 3. Be polite. 4. Speak slowly.	*Kate:* John, let's go to the mall this weekend, we haven't gone together in a while. *John:* Sorry Kate, but I'm trying to reduce my shopping *Kate:* Oh come on, it will be just like old times. Going once won't hurt right? *John:* No, I can't go to the mall with you. *Kate:* I promise I won't tell anyone. *John:* No, I can't go to the mall with you. *Kate:* Come on, I will pay. *John:* No, I can't go to the mall with you.

record. The following five steps can be used to start practicing communicating in an assertive manner [1]:

1. *Prepare.* Write a brief assertive message, focusing on a behavior external to the person, how their behavior has affected you, the change you are asking for, and the consequences of changing and not changing the behavior.
2. *Ask yourself the following questions*:
   (a) Am I violating someone else's personal rights?
   (b) Is it an ongoing concern of mine?
   (c) Is my message free from judgments and blame?
   (d) Will I likely get my needs met?
3. *Practice delivering the message.* This can be done in front of a mirror or can be role-played with a social support.
4. *Choose a time to meet with a person*. Pick a quiet, private place and give yourself enough time to have a good conversation.
5. *Communicate your message assertively.*
   (a) Begin by saying something like, "Thanks for taking the time to talk with me."
   (b) Avoid small talk.
   (c) Stick with your message.
   (d) Keep it brief.

   (g) Thank the person for listening and for any helpful and positive response.

64.2.6 Compulsivity and Maladaptive Perseveration of Behavior

Compulsivity and maladaptive perseveration of behavior are termed loss of control or, more accurately, impairment of control in the addiction literature [75]. The incentive-sensitization theory of addiction provides empirical support for the role of compulsivity in the manifestation of addictive disorders, including behavioral addictions [72]. According to the model, liking, (i.e., the hedonistic aspect) and wanting (i.e., the compulsive aspect) are separate states. Early on, individuals engage in addictive behaviors for the hedonistic effect, but, over time and with repeated engagement, individuals continue to feel compelled to engage in the addictive behavior without "liking" it. The behavior becomes a compulsion that is cue-dependent, triggered by certain situations, people, places, or internal states. Treatment focuses on handling the cues differently.

The relapse prevention model described earlier (see deficits in self-regulation) encourages the use of stimulus control strategies to avoid such high-risk precipitants. Strategies that separate the individual from cues associated with their addictive behavior are often identified and frequently used in recovery, particularly during the initial phases of recovery [27, 31, 69, 70]. Clinically, clients are asked to identify these risky situations based on their personal history and based on self-monitoring of urges to engage in the addictive behavior during the treatment process. Worksheets to facilitate this process are common [47, 53]. Development of a specific and concrete plan to avoid cues is feasible for some situations (e.g., blocking of problematic Internet sites; discarding drug use paraphernalia) but not others (avoiding shopping; avoiding feelings of dysphoria). Instead, coping strategies are required and, as described earlier, relevant coping skills can be trained and practiced in individual and group therapy sessions.

Cue exposure interventions can also be useful. Cue exposure involves repeatedly exposing the person to high-risk situations (conditioned cues), preventing the typical addictive behavior response and training alternative behavioral and cognitive responses. Cue exposure interventions were designed to help clients practice these responses while in the state of arousal that the cues generate. Cue exposure involves training specific coping skills but also attempts to address the compulsivity and impairment of control associated with the addictive behavior. The goal is to weaken the cues as well as provide an alternative well-learned coping response.

Like other exposure models, cues are typically presented, using a graded hierarchy with the cues that elicit the strongest urge reserved for later in the treatment process. Exposures are organized to allow individuals to experience a reduction in self-reported urge while actively attending to the cue. Cue exposure requires individualized sets of stimuli, so it is easier to administer it in individual sessions. However, group models have also been developed [53] that focus on cues common to multiple clients (e.g., negative affect). The stimuli cues can be real (e.g., exposure to a slot machine or pornography website) and enhanced by imaginal imagery (imagine that you are sitting at this machine at the end of a very long and stressful day…), or completely imaginal. Similar to exposure treatment for anxiety, more frequent and longer sessions appear to be more effective [53].

64.2.7 Relapse Prevention and Addiction Substitution

Lapses and relapses are a common process during recovery from addictions [25, 28]. Thus, relapse prevention is an important intervention component in the treatment of addictions. In relapse prevention, we find it is helpful for clients to have an understanding of the difference between a lapse and relapse. A lapse can be thought of as a brief and very limited return to engaging in an addictive behavior. In contrast, a relapse is more chronic and can be considered a return to an ongoing pattern of addiction. However, clients who are involved in 12-step programs may view lapses and relapses as being one and the same. Nevertheless, interventions to prevent lapses and relapses have been well documented. Relapse prevention interventions consist of reducing the likelihood of lapses and relapses from occurring in the first place. If a lapse does occur, skills are then implemented to manage the lapse and prevent it from evolving into a relapse [47]. For example, in addition to identifying high-risk situations (i.e., triggers) discussed earlier, clients develop skills to identify potential warning signs of lapses, including affective, behavioral, and cognitive signs. If a lapse does occur, it is important to normalize to clients that lapses are part of the recovery process and, importantly, prevent lapses from becoming relapses. According to the relapse prevention model [47], lapses are likely to turn into relapses due to the abstinence violation effect, which are dysfunctional thoughts related to the lapse such as *since I watched pornography again, it's impossible for me to quit my sexual addiction.* Clients can use their skills in completing thought records to identify and challenge the abstinence violation effect and reduce the likelihood of experiencing a relapse.

We highly encourage clinicians to not only monitor lapses and relapses but also assess whether clients are increasing their engagement in other addictive behaviors, a concept known as addiction substitution. Addiction substitution occurs when a person who recovers from one addiction (e.g., alcohol), subsequently develops a new onset addictive disorder (e.g., gambling) or relapses to a previous addiction. Addiction substitution is of clinical importance as it may increase the chances of relapse and/or result in the development of a secondary addiction [71] and is thought to be a common process during recovery ([29]). In our experience, people are more likely to substitute to addictive behaviors that they perceive as being "not addictive" such as behavioral addictions and substitute to high-base rate addictions such as alcohol and nicotine [29].

64.3 Summary and Implications

Behavioral addictions are among the more common psychiatric disorders and are becoming increasingly relevant in the fields of clinical psychology and psychiatry. There is now a substantial body of empirical literature, examining various aspects of behavioral addictions, including its etiology and clinical characteristics. Unfortunately, the treatment of behavioral addictions has generally lacked the same empirical and clinical attention. In this chapter, we provided an overview of transdiagnostic mechanisms of behavioral and substance addictions and their

intervention possibilities. We believe that a transdiagnostic approach would have tremendous utility in the field of addictions, including the treatment of emerging behavioral addictions. To this end, we have recently developed a transdiagnostic treatment model of addictions, called the Component Model of Addiction Treatment (CMAT; [38]), that targets the shared underlying mechanisms (which we refer to as component vulnerabilities) reviewed in this chapter.

64.3.1 Component Model of Addiction Treatment

The CMAT was designed as a pragmatic transdiagnostic treatment model for both behavioral and substance addictions. Although several theories and models that conceptualize addictions based on their similarities have been proposed, the CMAT was the first treatment model of addictions based on the common transdiagnostic mechanisms. Similar to that of other transdiagnostic treatment approaches, the CMAT may have some important benefits for the treatment of behavioral and substance addictions when compared to disorder-specific protocols. First, behavioral and substance addictions tend to co-occur. For example, 40% of people experience problems with more than one addictive disorder, consisting of both behavioral and substance addictions [40]. As the CMAT targets underlying mechanisms found across addictive disorders, the CMAT may lead to improved outcomes for not only the primary addiction but also for comorbid addictive disorders. Second, the CMAT may be used by clinicians to provide treatment for both traditional addictive disorders (e.g., alcohol, cannabis, gambling) as well as emerging ones (e.g., video gaming, shopping, sex). A unified treatment approach to substance and behavioral addictions would not only be more efficient for clinicians but would also meet the treatment needs for people who are experiencing problems with behavioral addictions. Third, the CMAT may reduce the likelihood of addiction substitution, given that the CMAT was designed to target the underlying commonalities across addictions. Indeed, addiction substitution is more likely when people engage in self-help compared to seeking professional treatment [29]. A decrease in the likelihood of substitution following treatment may be due to clinicians addressing some of the underlying mechanisms that led to the addiction.

64.3.2 Clinical Applications of the CMAT

Although the CMAT is a working model, we believe it can be delivered as an individual or group treatment. While psychoeducation should remain an important aspect regardless of the modality, it may be of particular benefit when delivering the CMAT in a group format. This is because some clients may question why they are in a group with someone who is seeking help for behavioral addictions, when they may be seeking treatment for a substance use problem. Thus, psychoeducation should focus on the commonalities across addictions rather than on the specific diagnosis. This is a similar approach used in transdiagnostic group treatment for anxiety disorders [59]. The focus on commonalities not only helps people to understand both behavioral and substance addictions from a transdiagnostic perspective but also helps clients come to a common understanding that they are all here to overcome their addiction, rather than seeing themselves as being different, thus building group cohesion.

In regard to the different transdiagnostic mechanisms, we believe it is important to address all the identified components. However, treatment should be tailored based on the client's specific needs. Some clients may have greater deficits in motivation, and thus more clinical attention would need to be focused on enhancing motivation and readiness for treatment. Others may be motivated to engage in treatment but may have difficulties in managing intense negative affect. As such, clinical attention may need to focus on helping the client develop the skills to identify and manage their difficult emotions. A careful biopsychosocial assessment, consisting of both a clinical interview and self-report measures, can assist in treatment planning, by identifying which transdiagnostic

mechanisms may require greater clinical attention, as well as to identify other relevant factors that may need to be taken into account during the course of treatment.

With the exception of psychoeducation and motivational enhancement, we do not propose any specific sequencing to the treatment. Indeed, there are several ways that a clinician can sequence treatment. First, the sequencing of treatment could be based on clinical assessment and judgment, regarding which transdiagnostic mechanism is most likely contributing to the maintenance of the addiction. Second, the sequencing could be dependent on client preference, which takes a collaborative approach to treatment and may help to engage clients in treatment and enhance motivation. Third, the sequencing of treatment could be made on identifying which transdiagnostic mechanism may be the most likely to lead to immediate treatment improvements. Regardless of how clinicians proceed in treatment, we strongly suggest that the treatment of the transdiagnostic mechanism be linked together rather than treating them as separate components. For example, maladaptive expectancies can be tied to urgency by examining the link between thoughts and emotions, using cognitive behavioral therapy principles. In addition, the clinical interventions associated with some of the components require skill development over time and over multiple treatment sessions, which is most efficiently achieved through blended sessions. For example, mindfulness and cognitive restructuring require practice and reinforcement over multiple sessions.

Although the CMAT conceptualizes addiction as representing a common underlying disorder, we, like Shaffer et al. (2014), acknowledge that addictive disorders also present with unique manifestations, which may require clinical attention. For example, cognitive fallacies related to odds of winning are unique to gambling and have been shown to be an etiological and maintaining factor for gambling disorder [22]. As such, the treatment for clients presenting with gambling disorder may need to address these specific dysfunctional thoughts [20]. A unique and frequent comorbid condition of compulsive buying is hoarding [54]. Specifically, the acquisition aspect of hoarding behavior may be particularly important in the expression of compulsive buying and thus may need to be addressed in treatment [16]. For compulsive sexual behavior, treatment may need to include strategies to reduce the likelihood of sexually transmitted infections [64]. Last but not least, for gaming disorder, more clinical attention may be needed in developing social skills. This is because some people may turn to video games to meet social needs [48], given the increasingly immersive nature of gaming to the exclusion of non-gaming relationships [42].

While we believe the CMAT has significant promise in the treatment of addictions, it is in need of empirical investigation to test its efficacy. While the interventions included in the CMAT are empirically supported, delivering the interventions from a unified and transdiagnostic conceptualization of addictions is not. To this end, we are currently in the process of developing a treatment protocol with the aim of pilot testing the CMAT in individual and group formats. Additionally, we are aiming to pilot the CMAT in Canada and Brazil to determine the CMAT's cross-cultural utility. The CMAT was conceptualized to be an evolving treatment model, with the ability to include newly identified transdiagnostic mechanisms and their interventions. Empirical studies of CMAT will also help to determine which transdiagnostic mechanisms may be particularly important in the treatment of addictions.

64.4 Conclusion

There has been a recent interest in addressing transdiagnostic mechanisms in the treatment of several psychiatric disorders [75]. We believe that the field of addiction will benefit from a similar treatment approach. Indeed, a transdiagnostic treatment model of addiction may have significant advantages over specific disorder treatments and will ultimately aid in improving the treatment of millions of people experiencing problems with behavioral and substance addictions. To this end, we provided an overview of transdi-

agnostic mechanisms of behavioral and substance addictions, and the CMAT is the first attempt at developing a unified transdiagnostic treatment model of addiction. With time, it is our goal to develop the CMAT into an empirically supported treatment for addictive disorders.

65 Psychological Management of Gambling Disorder With or Without Other Psychiatric Comorbidities

Enrique Echeburúa and Pedro J. Amor

Contents

Abstract

This chapter deals with the new developments in the treatment of disordered gambling with or without other psychiatric comorbidities, as well as with the challenges for further research. Abstinence versus moderated gambling as therapeutic goals is an issue that raises many concerns and that needs to be addressed. Current psychological treatment for gambling disorder (GD) involves a number of different options, including inpatient treatments, individual and group cognitive-behavioral options, Gamblers Anonymous, and intervention in relapse prevention. Most of the treatment is delivered on an outpatient basis. The most evidence-based approaches for GD are cognitive-behavioral therapy and motivational enhancement therapy. Also, psychopharmacological therapy may reinforce psychological therapy and have incremental benefits when patients have comorbid disorders. A relevant issue related to treatment intensity and the

emergence of a plethora of so-called brief interventions. Responsible gambling may be a therapeutic option for young gamblers or people without a severe dependence. Further information is required about treatment for online gambling addictions and for dealing with specific populations (e.g., women and young people). Finally, the interventions should be tailored to the needs of the patients.

Gambling disorder · Comorbidity · Internet gambling · Psychological management · Effective treatments · Relapse prevention

65.1 Introduction

Gambling disorder (GD) is a relatively common and often disabling psychiatric condition characterized by intrusive urges to engage in deleterious gambling behavior in terms of time invested and money wagered, which results in significantly negative effects on gamblers' daily lives and on quality of life. Unlike the DSM-IV, in the DSM-5, GD has been placed in a new category on behavioral addictions. This reclassification of GD alongside other chemical addictions is more appropriate because there are more commonalities between them and they are treated using similar methods [17].

DSM-5 criteria for GD focus on preoccupation with gambling, need to gamble increasing amounts of money, and repeated unsuccessful efforts to control gambling. From a clinical perspective, two elements are the most representative of GD: continuous or obsessional chasing of losses and family, job, and social disruption by gambling.

Men are more likely to be gamblers than women and also more likely to develop gambling-related problems than them. However, there is evidence that gambling problems have increased among women in recent years. In addition, GD is associated with poorer measures of mental health in women compared to men. Women are more likely than men to gamble in order to relieve feelings of depression and anxiety and to escape dysphoria. Whereas men frequently begin gambling early in life, report slow emergence of problems, and seek help well after developing problems, women start gambling later in life, then rapidly develop dependence, and seek help more quickly [16].

The prevalence of GD varies considerably across different studies. Anyway, about 0.8–1.5% of the adult population can be classified as probable pathological gamblers, while the prevalence of problem gambling is 2.5%. In addition, pathological gamblers often suffer from comorbid disorders, such as mood disorders, generalized anxiety, posttraumatic stress disorder, substance addictions, or abnormal personalities, such as borderline and antisocial personality disorder [8].

Finally, patients with dual diagnoses are highly prone to adverse outcomes in several domains: increased rates of hospitalization, violence, victimization, homelessness, nonadherence to treatment, and poor overall response to treatment [24].

65.2 Psychological Intervention for Gambling Disorder

The interventions for GD that have been reported in the literature are quite similar to methods of treating other addictions and include approaches that are behavioral, cognitive, pharmacological, addiction-based and multimodal, and self-help groups, such as Gamblers Anonymous (GA). Often, these approaches are combined to varying degrees in most treatment programs or counseling settings.

65.2.1 Treatment Goals for Gambling Disorder

Abstinence versus moderated gambling is an issue that raises many concerns and that needs to be treated. Like in the case of chemical addictions, the gold standard for disordered gamblers' recovery is total abstinence. Abstinence is closely associated with recovery of pathological gamblers [13].

However, complete abstinence from gambling may not be necessary for successful treatment in problem gamblers who have behavioral problems and negative consequences of gambling, but they are not still dependent on gambling. In these cases, evidence supports strategies aimed at reducing harmful negative consequences incurred through involvement in risky behaviors. Controlled gambling can be defined as gambling in the absence of the subjective sense of impaired control and adverse financial consequences, based on self-rating and confirmation from a partner or significant other. Strict abstinence goals may discourage problem gamblers from seeking treatment.

Irrespective of the need of going on with clinical trials comparing these therapeutic goals, both targets are necessary for different kinds of patients [12].

65.2.2 Effective Treatments for Gambling Disorder

Current treatment for GD involves several options, including intensive individual and group cognitive-behavioral options and pharmacotherapy. Most of the treatment is delivered on an outpatient basis. Inpatient care is generally limited to patients with severe acute crises, treatment failures, and severe comorbid disorders, particularly depression and attempted suicide.

65.2.2.1 Behavioral Therapies

Behavioral approach considers gambling behavior as having three components: antecedents (financial pressure, gambling cues, positive or negative emotions, interpersonal factors, urges to gamble), overt or covert behavior itself (money spent in gambling, coping strategies to deal with anxiety or depression, thinking about gambling or about how to attain money), and consequences, both positive (autonomic arousal, opportunities to socialize, escape from personal problems, monetary gain) and negative (anxiety and depression, low self-esteem, work and relationship conflict, financial loss). Anyway, gambling-based arousal is the central factor in the reinforcement process. Approach to gambling in regular gamblers is triggered by a wide range of environmental features: driving the car, leaving work, the sight of money in the wallet, and so on. Gambling is also highly reinforcing because of the variable pattern of reinforcement and the tension relief [30].

Behavioral therapy considers pathological gambling a learned behavior and relies on techniques such as stimulus control, systematic exposure, and skill development (e.g., relaxation techniques and improving stress management and social skills) to reverse the learned behavior and the association between arousal and conditioned elicitors. Reduction in gambling is expected if patients can successfully develop and use alternative coping responses to deal with urges to gamble. Behavioral counseling, in which the gambler is given verbal reinforcement for desired outcome behaviors, and in vivo exposure, in which the gambler is exposed to gambling behaviors but is not allowed to gamble, are also mentioned in the literature [30].

Stimulus control involves limiting access to money, not visiting venues that offer gambling, and not spending time with people associated with heavy gambling. As treatment advances, the control of stimuli is gradually faded, except avoiding gambling friends. Recovering gamblers are also encouraged to take themselves off mailing lists from the casino, to meet with a financial planner, to cancel all credit cards, and to turn over control of money to another person. Self-exclusion from gaming venues can be an adjunct to treatment. Actually, participants tend to comply with the commitment of abstinence and have more positive outcomes when they are also involved in complementary treatment or self-help groups [40].

Exposure with response prevention is focused on making patients experience the desire to gamble and teaching them how to resist it in a gradually more self-controlled way. The aim of systematic exposure to cues and situations of risk is to make the cues lose their power to induce urges and gambling behavior. If responses are prevented or controlled, the stimulus-response relationship will weaken. In addition, patients are taught alternative strategies to cope with their

anxiety. Exposure tasks take place 6 days a week for a minimal time of 15–20 min. Patients cannot drink alcohol or take other drugs during the exposure tasks. Only stimuli relevant to the individual should be included if generalization is to occur in the natural environment. The characteristics of the application of this technique are shown in Table 65.1. This type of therapy is designed to deal with cravings and urges for gambling by increasing confidence in the ability to impose self-control over gambling.

Apart from some pioneering studies, a behavioral controlled investigation with a waiting list control group was carried out by Echeburúa et al. [11]. They compared the effectiveness of cognitive and behavioral techniques in a Spanish sample of 64 men and women who met DSM-III-R criteria for pathological gambling. Participants were randomly assigned to one of four treatments: individual stimulus control and in vivo exposure with response prevention, group cognitive restructuring, a combination of the first two, and a waiting list control group. At 12-month follow-up, the most favorable outcome was associated with the first two groups, which reported therapeutic success rate (abstinence or one or two gambling episodes in which the amount gambled did not exceed the amount gambled in the week prior to treatment) of 69% and 37%, respectively. The behavioral therapy was found to be more effective than the group cognitive restructuring in terms of reducing gambling frequency.

Table 65.1 In vivo exposure therapy for gambling disorder

Exposure	Characteristics
1st week	The co-therapist (a relative or a close friend) is together with the patient when he is practicing exposure to a slot machine
2nd week	The co-therapist goes with the patient to the gambling site but stays outside waiting for him when the patient is practicing exposure exercises
3rd week	The co-therapist stays at home when the patient goes to the gambling site to practice exposure exercises. If the patient is in a jam, he can phone the co-therapist
4th week	The co-therapist no longer takes part in the exposure task

More recently, Smith et al. [50] evaluated the differential efficacy of cognitive therapy and exposure therapy through a randomized controlled study (N = 87). Both groups experienced comparable improvement at 12-week and 6-month follow-up. Therefore, cognitive and exposure therapies are both effective treatments for problem gambling.

In sum, according to the meta-analysis of Pallesen et al. [42], interventions involving developing relaxation skills, exposure to gambling cues, and direct behavioral action are effective in improving gambling urges, time and money spent, and abstinence. In addition, behavioral change is related to cognitive change after treatment.

65.2.2.2 Cognitive-Behavioral Therapies

Excessive gambling can be driven by distorted and maladaptive cognitions, such as illusion of control, superstitious thinking, or misperception of probability. Two major beliefs (gambling outcomes can be correctly predicted and controlled) appear to describe the problem gamblers' irrational cognition. Disordered gamblers believe that they are able to control random or chance events by relying on superstitious behavior or methods. This illusion of control is stronger as gamblers become more familiar with a game. Thus, they can believe that a big win is imminent and persist despite mounting losses, with an unrealistic hope that they will recover their losses if they persevere with the gambling (the gambler's fallacy) [34].

Cognitive therapy aims to help patients challenge and overcome irrational thoughts that are believed to initiate and maintain the undesirable behavior. Subjects are taught to be aware of the link among thoughts, behavior, and emotion. Many patients do not understand the concepts of probability and randomness, believing that they can exert some control over whether they win or lose. Treatment typically involves teaching subjects strategies to correct their erroneous thinking by providing corrective information through education, logical discussion, or behavioral experimentation. Thus, the therapist will ask the gamblers to describe what they are saying to

themselves when gambling. If the erroneous perceptions and understanding of randomness in the gambler can be corrected, then the motivation to gamble should decrease dramatically. Cognitive therapy also aids gamblers in coping with urges to gamble, managing negative emotions, and training in problem-solving techniques [34].

Randomized clinical trials have focused on combined cognitive and behavioral approaches (CBT) (cognitive correction, problem-solving training, and assertiveness training) [7, 36].

CBT is effective in treating pathological gambling and the associated problems [3, 45]. Both individual and group CBT appear effective for reducing gambling [41]. *Individual* CBT may be enhanced if patients receive compliance-improving interventions, such as a reinforcement of self-efficacy, reminder phone calls, assessment feedback, and a weekly decisional balance exercise to complete. *Group* CBT may be enhanced if individuals have interactive written exercises. In this way, that mapping may serve to individualize the group treatment, leading to greater effect [39].

However, the CBT studies have not yet determined the optimal number of sessions needed to reduce gambling symptoms and maintain improvement [22].

Furthermore, an individual eight-session manualized form of CBT has also been compared, either delivered by a professional counselor or completed alone by the patient in a self-help workbook (WB) with a group referred to GA. Although participants in all groups reduced gambling, CBT in both conditions was better than only GA in terms of days gambled and number of gambling criteria met. Nevertheless, the number of GA meetings attended was significantly associated with gambling abstinence [44]. Additionally, Campos et al. [3] compared the differential efficacy of two CBT modalities through WB for the treatment of GD: WB with therapist guidance or WB only. Although both groups reported fewer gambling symptoms at treatment completion and at follow-up, WB with guidance increased abstinence from gambling compared to WB only.

Lastly, the mindfulness-based and CBT-based treatment as usual interventions appear to be effective at reducing GD behavior and associated distress [38]. In this study, these intervention modalities were more effective than the manualized form of CBT to generalize the improvements in quality of life, mental functioning, and certain mindfulness facets.

65.2.2.3 Motivational Enhancement Therapy

Another approach adopted to help problem gamblers focuses on the use of short-term brief motivational enhancement therapy and telephone counseling, mailed self-help workbooks, and online resources. Brief treatment is defined as that using less professional resources or time (four or fewer sessions) than usual face-to-face interventions (typically, six to twelve sessions of therapist contact). This therapeutic modality may be an important innovation to helping people with gambling problems who fail or refuse to seek treatment in traditional therapeutic settings and may enhance patients' sense of control over their own recovery [30].

Motivational interviewing (MI) is often a 50-minute face-to-face or telephone session used to build commitment to change [55]. MI focuses on patient's intrinsic motivation for change and on patient's strengths to enhance self-efficacy. MI strategies act in some way to resolve ambivalence and promote greater commitment to change.

This approach has proven to be effective, at least with those with less severe gambling problems [29]. In the latter study [27], at a 24-month follow-up, 77% of the entire sample was rated as improved, but gamblers receiving the workbook and a telephone motivational support reported less frequent gambling and lower severity scores than workbook-only group. In other studies of the same group [28], patients who received the MI plus workbook gambled less and spent less money than workbook-only group.

A combined MI and CBT program applied in group or individual format [41], or even adapted to a Web-based format [4], can improve GD behaviors, as well as gambling correlates. Moreover, the addition of MI to CBT can reduce

treatment attrition and improve outcomes [53]. Grant et al. [20] compared a six-session CBT program, combining imaginal cue exposure plus the negative mood induction (focused on the negative consequences of gambling while the urge is active) with GA. The 64% of participants assigned to behavioral program maintained abstinent at 1-month follow-up as opposed to only 17% of patients assigned to GA.

However, these motivational approaches, which are more attractive to gamblers and may result in an increase of treatment seekers, cannot be so effective with severe pathological gamblers or patients with comorbid pathology. More research is needed to determine the efficacy of these programs when compared to more established CBT.

Finally, in a randomized clinical trial, a high dropout rate (83%) was found when applying any of the three forms of Internet-based intervention (personalized feedback on their *gambling* status by email, an email plus CBT workbook, and the same CBT program emailed with personalized guidance) in non-help-seeking problem gamblers who were recruited because of their disordered gambling [37]. Although some improvements were identified in the three treatment groups (without statistically significant differences among them), the group that had a higher percentage of dropouts was the one that included the guidance of a professional.

65.2.2.4 Gamblers Anonymous

Modeled after the traditions and spiritual principles of Alcoholic Anonymous, Gamblers Anonymous is the primary self-help group and uses an abstinence-based treatment program. GD is conceptualized as an illness which can be arrested but never cured, so people affected by this problem have a permanent predisposition for losing control over their gambling.

The therapeutic rationale for GA is that the twelve steps to recovery will lead gamblers to attain abstinence. The group format is intended to provide a sense of common purpose and understanding, emotional and spiritual support, and hope. Anonymity allows for members to feel safe in sharing openly with other members [30].

The efficacy of GA has not been demonstrated in controlled studies. Relapse rates tend to be quite high. Stewart and Brown [51] found that total abstinence was reported by only 7.5% of members surveyed one year after their first attendance and by 7.3% at two years. Attrition rate is also high. People attending GA have better gambling outcomes than those who do not, even though they are engaged in professional treatment concurrently [44].

The therapeutic effectiveness of GA has also been explored with respect to participation by the gambler's partner. There is a trend for higher abstinence rates for gamblers whose partners are present at meetings compared with gamblers whose partners do not attend.

There is a particular need for studies of the role of GA in recovery and treatment outcomes. Another study found that there were not any differences on key gambling variables (e.g., frequency, abstinence rates, money wagered) at 12 months between a program of CBT and twelve-step therapy [52]. If there is a high dropout rate from GA, as the literature suggests, then it is important to investigate its causes and strategies for reducing it.

In sum, GA may be increasing in popularity, but whether participating in meetings makes a significant and lasting impact is still not well known.

65.2.3 Relapse Prevention

A challenge in the treatment of pathological gambling is preventing relapse. Many personal and environmental factors interact to influence the risk of relapse for any individual trying to recover from an addiction. Relapse prevention is focused on training patients to identify high-risk situations for relapse, such as social pressure, negative emotional states (e.g., anxiety, depression, and anger), and interpersonal conflicts, and providing them adequate strategies for coping with problematic situations. Pathological gamblers are deficient in the number of coping skills they have available and in their ability to flexibly choose the skill most appropriate to the stressful, or

potentially relapse-triggering, situations they face. Relapse prevention techniques increase the likelihood of engaging in adaptive coping behaviors.

Successful recovery also involves the development of new skills (e.g., cognitive reframing) and lifestyle patterns that promote positive patterns of behavior. The integration of these behaviors into day-to-day activities is the essence of relapse prevention.

The problem-solving approach is oriented to increasing the gamblers' abilities to cope with urges or cravings and to deal with anxiety, depression, or personal crises for which gambling is an escape. For example, substance abusers with a gambling problem utilize significantly more avoidance and impulsive coping styles.

Echeburúa et al. [13] evaluated the efficacy of providing relapse prevention strategies as a follow-up to behavioral treatment focused on total abstinence from gambling. Sixty-nine pathological gamblers received behavioral treatment (stimulus control and exposure with response prevention), followed by random assignment into one of the three conditions: individual relapse prevention, group relapse prevention, or no treatment control group. The results related to the 12-month follow-up relapse showed a success rate higher in both individual (83 percent) and group (78 percent) relapse prevention than in the control group (52 percent). There were no differences between both experimental modalities. These results raise the need of relapse prevention programs in the treatment of pathological gambling. This study reported a dropout rate of 14.5%. On the other hand, most relapses were observed in the first three months after treatment. The main triggers of relapse were inadequate money management, negative emotional states, alcohol abuse, craving, and social pressure [14].

65.2.4 Pharmacotherapy

Pharmacotherapy is a relatively new approach to the treatment of GD and may be effective for reducing gambling urges and behavior. A variety of medications have been examined with varying results. Actually, there are no approved medications for the treatment of pathological gambling [23].

Neurobiological studies suggest the involvement of serotonin, norepinephrine, and dopamine in GD because these transmitters are strongly associated with reward pathways. The norepinephrine system has been associated with arousal and novelty seeking, dopamine with reward and motivation, and serotonin with impulsivity and compulsivity [32].

The medications target one or more of these neurotransmitter systems. The current pharmacological strategies for treating GD suggest the use of serotonin reuptake inhibitors (SSRI), opioid antagonists, and mood stabilizers.

SSRI antidepressants can reduce urges to gamble or prevent from compulsive behaviors. The rationale for this medication is the phenomenological association between GD and compulsivity. These medications are also helpful if anxiety disorders are associated with GD [47].

Opioid antagonists (naltrexone) can block feelings of euphoria related to gambling behavior and result in reductions of gambling urges and thoughts and in improvement in psychosocial functioning. The rationale for this medication is the similar neurological pathways for GD and substance addictions and the commonalities between clinical symptoms of both disorders. This class of medication, dosed at 50 mg/day, should be considered a first-line treatment for GD [23]. Naltrexone may be particularly helpful for those with strong gambling urges at treatment onset and/or a family history of alcoholism [47].

In turn, mood stabilizers, such as lithium or topiramate, can reduce the use of gambling to regulate negative mood (most of all, if bipolar tendencies are present), but some recent controlled trials have failed to show any significant treatment effect for topiramate on the primary or secondary outcome measures.

Another avenue of approach is the use of medication to treat comorbid conditions. In practice, this is probably the most frequently cited reason for putting gamblers on medication. Comorbid disorders for which medications are commonly prescribed include depression, bipolar disorder, and attention-deficit hyperactivity disorder.

In sum, certain medications, such as opioid antagonists [1], may be beneficial in treating this disorder. Pharmacotherapy research needs to be expanded to determine if this approach has an important role in the treatment of pathological gamblers and plays an adjunctive role to psychological treatments [2]. We still do not know if medications provide therapeutic effect by ameliorating the pathological gambler's cravings, ruminations, or negative feelings. Heterogeneity of GD treatment samples may also complicate identification of effective treatments. In addition, some studies have reported high placebo response rates [47] and high rates of study dropout (30–50%) [43].

65.3 Issues in Treatment

Only a small proportion of the individuals who are suffering from GD (about 6 percent) seek formal treatment. The satisfactions provided by their addiction, a desire to handle the problem by themselves, and shame have been identified as contributing factors to resistance to treatment. Motivation becomes adequate when people identify gambling as a destructive agent in their life. Natural recovery from problem gambling can occur in about 35%, but most disordered gamblers report a chronic course, with symptom severity fluctuating over time [22].

Therapists have been confronted with the problem of treatment compliance. For pathological gamblers, compliance is an issue because they are often ambivalent about giving up their gambling or altering long-standing patterns of coping, no matter how ineffective. Some people do not seek treatment, some drop out after one or two sessions, and some can decide to terminate treatment after a few weeks thinking that their problem has been solved. It is a challenge to identify the characteristics and the reasons of individuals who refuse treatment, drop out, or simply do not show up for the first session. There are no obvious solutions to these matters, but motivational enhancement therapy, behavior contracts, and flexible treatment goals might improve treatment compliance.

Despite the growing trend toward harm reduction strategies and controlled behavior approaches for addiction problems, most gambling treatment programs, like those that treat substance abuse, favor abstinence. Some programs, however, particularly those dealing with problem gamblers in their early stages, aim at reducing and controlling rather than stopping gambling. Anyway, clinical trials comparing treatments with varying treatment goals are necessary [33].

A relevant issue relates to treatment intensity and the emergence of a plethora of so-called brief interventions. A distinction should be drawn between minimal intervention or advice in a primary care setting and brief intervention within a specialist context (one to three sessions). It is difficult to know if there are remarkable differences between brief and extended interventions for pathological gamblers. For instance, there are important differences between treatment-seeking populations as distinct from those that are selected as a result of opportunistic screenings. Anyway, it is relevant to investigate the active ingredients of brief interventions which seem to be, at least, relatively successful [22].

Advances in family therapy for treating substance abuse problems have been adapted for gambling disorders, such as a self-help workbook of the Community Reinforcement and Family Therapy (CRAFT) model (focused on the training of family members to use behavioral principles to reinforce non-gambling behaviors) [31] or a coping skills training program for those with a pathological-gambling partner [48]. Further research is warranted to improve the design and targeting of these approaches.

65.4 Internet Gambling

Internet gambling can be defined as any type of wagering that takes place by using the Internet. Common forms of online gambling are online poker, online casino, sports betting, and online bingo, though there are some other ways to gamble using the Internet that hold strong potential for additional growth, e.g., gambling by mobile devices and gambling on the Internet games [35].

Men are more likely to gamble using the Internet than women. Emotional states, maladaptive cognitions, and life events can serve as triggers for Internet abuse. The pervasiveness of Internet gambling sites on the Web makes it an especially risky form of gambling. One of the most attractive features of Internet gambling is its convenience (e.g., playing comfortably at home and at a convenient time is reported to be the most important reason for playing online poker). The anonymity of Internet gambling presents an opportunity for the development of gambling-related problems. For example, because of anonymity, people may gamble under the influence of alcohol or drugs, be underage, or even gamble from the school or workplace. Solitary gambling, like Internet gambling, where people can gamble at their own pace with no outsiders interrupting or any other distractions, is also a risky factor. Computers and the Internet create isolation and a sense of fantasy. In summary, a cursory consideration of numerous risk areas logically suggests that the Internet might increase the speed of the negative effects of gambling or exacerbate gambling-related problems [25].

Minors might gain access to a credit card and gamble with other people's money. This raises concerns that children and adolescents' participation basically is unrestricted. In addition to being illegal, such an occurrence would be problematic because early exposure to gambling is linked with the development and persistence of gambling-related problems [6].

Appropriate treatment for online gambling addiction is still being researched. Treatments that are effective for gambling addiction work well for online gambling addiction. It is important to consider the individual needs when devising a treatment plan to tackle an online gambling addiction. Every person is different and could be addicted for different reasons.

Stimulus control involves for the Internet gambling addicts to engage in opposite activities, use of timers to end online sessions, set time limits, prioritize tasks, and record Internet usage to abstain from Internet abuse.

Group therapy is commonly suggested as a treatment option as well. If patients are attending support groups such as GA, they can use that group to help cope with their online gambling addiction.

Online gambling addiction, gambling addiction, and Internet addiction, which are all closely related, can create problems outside of the individual. They can cause damage to one's finances, marriage, and even their entire family. In these cases, financial counseling, marriage counseling, and family therapy are all beneficial treatment options.

In conclusion, a combination of individual, family, and group therapy may be the best option, although individualization should be emphasized. Medication (e.g., ISSRs) may be needed to treat associated anxiety or depression [2]. Anyway, our understanding of Internet gambling is still quite limited. More evidence-based research is required for treatment options regarding this topic.

65.5 Treating Comorbid Gambling Disorder and Severe Mental Disorders

65.5.1 Treatment of Gambling Disorder with Affective and Addictive Disorders

There are several studies on the efficacy of treatments when there is dual pathology, especially between GD and mood disorders or alcohol/substance abuse. Psychological treatments effective in treating *comorbidity between GD and depression* are CBT and imaginal desensitization plus motivation interviewing [9].

Pharmacological treatments, such as opioid antagonists [21], memantine that was associated with diminished *gambling* and improved cognitive flexibility [19], citalopram [56], and sustained-release lithium for bipolar spectrum disorders [5], may reinforce psychological therapy.

On the other hand, psychological approaches may be effective in treating *comorbidity between GD and alcohol/substance abuse*: CBT, motivation interviewing, Internet-delivered self-help

CBT, 12-step therapy, solution-focused therapy, and dialectical behavior therapy [9]. Anyway, when there is comorbidity between GD and other problems (i.e., anger and substance abuse), it is advisable to treat them concurrently in order to optimize treatment outcomes.

65.5.2 Treatment of Gambling Disorder with Schizophrenia

There are higher rates of pathological gambling in schizophrenic populations (10%) than in the nonschizophrenic population (1–5%) [26]. These patients also have greater alcohol use severity, higher depression scores, and more outpatient mental healthcare utilization.

Apart from some case reports (e.g., [49]), there is only one controlled trial that tested the clinical effectiveness of a cognitive-behavioral program specifically adapted for pathological gamblers with chronic schizophrenia (N = 44), with posttreatment and 3-, 6-, and 12-month follow-up assessments [15]. In this research, psychological treatment comprised a 20-session program including a) psychoeducation about the nature and the features of the disorder; b) stimulus control of money and avoiding routes of risk as well as gambling friends; c) gradual exposure in vivo with response prevention, focused on experiencing the desire to gamble and learning how to resist this desire in a gradually more self-controlled way; and d) relapse prevention, focused on training the patient to identify high-risk situations for relapse, such as social pressure, negative emotional states, and interpersonal conflicts, and providing him/her adequate strategies for coping with problematic situations.

Adaptation of CBT for these individuals dually diagnosed with GD and chronic schizophrenia took into account several aspects: the active role of the therapist to help patients fulfill the self-reports; the presence of a co-therapist (a family or staff member) in order to enhance motivation for treatment, to encourage patients to carry out in vivo exposure tasks, and to check information provided by patients; and the implementation of the program in the stabilization phases of the schizophrenia. This modified CBT (stimulus control and gradual in vivo exposure with response prevention) has proven to be an evidence-based psychosocial intervention for patients with these dual diagnoses [15].

In this study, individuals dually diagnosed with GD and chronic schizophrenia have benefited from medication and supportive psychological treatment to cope with GD. Thus, the improvement rate in the experimental group was 73.9% (with all patients being treatment completers), versus 19% in the control group at the 3-month follow-up.

Predicting relapse in GD in individuals with chronic schizophrenia after treatment can be useful in targeting patients for aftercare services. The therapeutic failure rate was 43%, and it was associated with the age of first episode of schizophrenia, the number of episodes, and the age of onset in gambling behavior [10].

Finally, a qualitative study identified unique patterns of responses specific to individuals with schizophrenia or schizoaffective disorder. Specifically, gambling as filling a need for activity and gambling as a means of connecting with the society/world were the notable reasons for engaging in problematic gambling [54].

65.6 Concluding Remarks

Behavioral and cognitive-behavioral therapy appear to be the most successful treatment approaches in different formats (individual, group, and self-directed), regardless of the type of gambling behavior practiced [18]. Both individual and group CBT appear to be effective in the treatment of GD and its correlates. Group therapy is not only just cost-effective; it also enables gamblers to learn from and support each other. Individual therapy may be more suitable for those who can afford therapy and those who prefer discussing life events on a one-to-one basis [41]. Further research is needed to determine the optimal number of sessions [22].

However, it continues to be controversial which form of CBT is best and for whom and

what is the optimal duration of therapy. Many behavioral interventions often include cognitive components, so it may be difficult to isolate the most potent agent of change. However, the presence of irrational beliefs and attitudes about gambling in pathological gamblers do not always justify confronting them with a cognitive approach. Interestingly, a behavioral approach, which is focused on short-term cessation of gambling behaviors, can also result in a decrease of erroneous beliefs of patients, without treating them specifically [13].

Pharmacotherapy appears to have a role in the treatment of coexisting depression, rather than as a primary treatment for GD. However, research on the pharmacological treatment appears promising, particularly in the case of opioid antagonists [1]. There is growing recognition that multiple treatment components should be considered given the patient's specific configuration of problems. Thus, patients with dysphoria should be evaluated for antidepressant medication, family therapy may be indicated in the presence of extreme family estrangement, and substance abuse counseling may be necessary for those whose addictive behavior also includes alcohol or other drug abuse. Inpatient programs for severe pathological gamblers, with comorbid disorders or attempted suicide (or suicidal ideation), continue to be in use, but more rigorous research on effectiveness is warranted because to date there are no randomized trials [22].

Very few studies have examined the combination of drug and behavioral treatments. Similarly, despite their high rates, there have been very few studies on the treatment of GD in conjunction with comorbid disorders, such as depression and personality or drug or alcohol use disorders. Irrespective of the effectiveness of CBT for pathological gamblers with or without other mental disorders, treatment must be adapted to these different circumstances. Thus, gamblers who have comorbid schizophrenia may require more sessions of therapy (i.e., 20 sessions) and a treatment focused more in behavioral than in cognitive components [15].

As problem gambling significantly affects patients' relationships with their families, interventions for gambling problems have also been directed at affected families. Family interventions are at an early stage of development and evaluation. It will be important to determine their efficacy and cost-effectiveness compared to treatment provided to the gambler alone [30].

Virtual counseling (Internet or computerized therapy) is another treatment option. Presently, there are only a few gambling specialty treatment programs, and one way to expand treatment services is to provide telephone and Internet counseling. Some pathological gamblers may be reluctant to enter individual or group therapy due to stigma, lack of resource availability, or denial. Numerous chat rooms have emerged for GA 12-step fellowship and are available anonymously 24 h a day.

Gambling studies should focus particularly on treatments that have manual-guided treatments. Poor specification of the therapeutic methods used hinders the replication of successful programs. Not only do therapist's manuals guide interventions, but also they facilitate the clarification of the specific contribution of particular treatment components.

Interventions should be tailored to the needs of the patients [10]. Substantial progress has been made in understanding the treatment of this disorder, but there is not yet research basis for matching patients to treatments according to different characteristics (e.g., subtypes of gamblers, different types of gambling, gender of gamblers, or comorbid disorders).

There is growing evidence for the effectiveness of psychosocial interventions, such as motivational interviewing (brief, easy to be administered, and cost-effective) and cognitive-behavioral therapy, to cope with specific needs of people with dual diagnosis [55]. However, there are serious implementation barriers related to service organization, staffing levels, training, and – most importantly – the difficulties of engaging people with a severe mental disorder in treatment.

Programs that combine pharmacotherapy and psychosocial treatments for GD into a single comprehensive package are most likely to have good treatment outcomes, at least regarding treatment retention.

Finally, since the population of mentally ill pathological gamblers is heterogeneous, it would be interesting to evaluate a patient-treatment matching strategy intended to improve the cost-effectiveness of treatment for these dual-diagnosed patients.

Gambling and Gaming Addictions in Women

66

Joseph Althaus, David Zendle, and Henrietta Bowden-Jones

Contents

Abstract

This chapter provides a summary of contemporary research perspectives on both gambling and gaming disorders in women.

A discussion of the prevalence of gambling in women is given, as is an overview of gender-specific differences in the kinds of gambling that individuals engage in. A description of the nature of disordered gambling in women is then provided, incorporating a summary of gender differences in the progression of gambling disorder. Comorbidities of gambling disorder in women are described, with a particular focus on barriers to treatment among women. Treatment methods are summarised, incorporating a description of initial advances in pharmacotherapy.

The research literature on gaming disorder among women is then treated. Gender differences in both prevalence of gaming and the prevalence of disordered gaming are described. An overview is provided for a nascent literature investigating potential neurobiological explanations for gender differ-

66.1 Gambling Disorder in Women

Gambling disorder (GD) is a maladaptive pattern of gambling behaviour that persists despite negative consequences. The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* [1] (DSM-5) includes nine diagnostic criteria, four being required for diagnosis: (1) tolerance; (2) withdrawal; (3) loss of control; (4) gambling preoccupation; (5) gambling in response to negative affect; (6) chasing losses; (7) lying to conceal gambling extent; (8) jeopardising relationships, work, career or educational opportunities; and (9) relying on others for bailouts. *Problem gambling* (PG) is a general term used in research where screening measures identify problem gamblers without clinical interview confirmation.

66.1.1 Definitions and Diagnostic Criteria

Technology has changed how games are played, from socially to alone; they are more available and globalised (local and cultural differences have reduced). The British Gambling Prevalence Survey (BGPS) series showed statistically significant increases in female gambling from 65% in 2007 to 71% in 2010 (disproportionally greater among older women). Gambling rates in the United Kingdom are now similar among males and females. Women prefer lotteries, slot machines, scratch cards and bingo compared to male preference for poker, sports betting, fixed odds betting terminals (FOBT) and casino games. Female PG has doubled from 0.1% to 0.2% in the same period [53].

Targeted advertising has increased female vulnerability to gambling. In France, following the legalisation of online gambling in 2010, studies to 2014 show a significant increase in gambling prevalence among women in the previous 12 months (44.4% in 2010 vs. 54.8% in 2014) and a doubling in female problem gambling in the year (1.4% vs. 2.8%): the proportion of women to men remaining the same (25% vs. 75%) [6, 7].

Gambling preferences may be socially determined, so liable to change with changes in society. British records demonstrate that in the mid-twentieth century, most women (66%) bet in some form, often through illegal street betting. Two out of five women bet on horses in 1951 compared to one out of ten in 2010. The 1960s Betting and Gaming Act legalised and regulated betting shops, introducing austere interiors designed to prevent loitering, which almost certainly discouraged women from using them. By the mid-1970s, less than 2% of women bet at least monthly on horses or dogs. Bingo, popular among male servicemen in the late nineteenth century, expanded into public spaces women were familiar with and was promoted as glamorous and aspirational. Legislators had created an environment attractive to women, contrary to that seen with bookmakers [52]. That some women are engaging more in gambling, as barriers to entry and social contexts change, could be seen to represent a resurgent interest in gambling among women – part of a cyclic pattern rather than a new phenomenon.

PG rates among interactive gamblers are three times higher than overall rates (2.7% vs. 0.9%) in Australia. In these gamblers, electronic gaming machines (EGM), interactive poker, casino games and sports betting were associated with increased severity of PG. Interactive gambling may not cause GD but is likely to exacerbate it. Policymakers could focus on gambling most associated with harm [16].

66.1.2 Gender Differences in Development and Course of Illness

International gender-focused research finds differences between male and female problem gamblers in terms of reasons and preferences for gambling, progression, mental health and treatment seeking.

Women gamble to escape loneliness, dysfunctional relationships, violence, isolation and childcare and to self-medicate perceived intolerable levels of stress, anxiety and depression. They engage in a narrower range of gambling activities offered by low-skill, high-absorption games [22]. Men gamble more widely, on fast-moving activities, for excitement and to outperform others [8].

Pathological and problem gambling is seen in a range of sociodemographic groups. The risk of PG for women increases with decreasing socioeconomic status [20]. In an Australian cross-sectional study [5], men and women were found to be equally susceptible to the addictive potential of gambling, the strongest independent risk factor for both genders being positive gambling expectancies (of enjoyment or financial gain) [27]. Other risk factors associated with PG in women include deprivation, marginalisation (in Māori women), violent partners and/or childhood [31] and the interaction of dysphoric moods and 'avoidance' coping [47]. Gender-sensitive public health initiatives are needed, and for female problem gamblers, prevention/intervention should focus on coping skills. Measures targeting positive gambling expectancies may also improve intervention outcomes for both genders.

Women consistently start gambling at a later age than men, progress more quickly to PG or gamble for shorter durations before seeking treatment [40]. This 'telescoping' is also found in women substance abusers [57]. Theories exist as to why, none of which satisfactorily explain the phenomenon. Female preference for more addictive games (slot machines, electronic bingo) does not account substantially for the telescoping effect. Links between psychopathology and gambling disorders, appearing strongly in women with anxiety and depression and in men with alcohol dependence, do not explain gambling progression: studies have not yet proved a causal relationship. In relation to neurocognitive measures, male gamblers score higher on risk-taking measures than female gamblers, although no gender differences are found on impulsivity measures. A few neuroimaging studies have begun to investigate neural mechanisms – women with GD showed increased dorsomedial prefrontal, posterior insula and caudate activation when viewing gambling-related videos, compared to men with GD, but the extent to which these relate to telescoping is unknown [55].

Using data from the BGPS 2010, investigating differences in age of first gambling experience among cohorts of women in the United Kingdom, two patterns are evident. Younger cohorts started gambling at a younger age than older cohorts, and among younger cohorts, age 16 marked a pivotal point in starting to gamble, reflecting the legal milestone for engagement in the national lottery, scratch cards and football pools. There appears to be a further cohort effect in operation: fewer of those aged 25–31 had gambled by age 16 (40%) than those aged 16–24 (50%). Within this cohort, the youngest are gambling earlier still, implicating the Gambling Act 2005, which permitted applications for land-based gambling venues, increased gambling opportunities and vastly expanded advertising [52].

Recent subgroup analysis shows younger women aged 16–34 gamble more frequently, across multiple products, and demonstrate more PG. EGM use is most common among women overall, whilst younger women are more likely to bet on sports and gamble at casinos. There are significant differences in the perception of harm associated with horse and sports betting, young women perceiving these as less harmful than older women and non-gamblers [29].

66.1.3 Comorbidities and Suicide

GD is frequently associated with comorbid psychiatric disorder, including depression, anxiety disorders, bipolar affective disorder, personality disorders and SUDs. Its presence is associated with

greater severity of gambling problems and related consequences, including suicide – the leading cause of death in GD (31%), followed by neoplasia (16%) and cardiovascular disease (12%) [21].

A recent Spanish study demonstrates that female problem gamblers with a criminal history were younger, had greater GD severity and dysfunctional personality traits and showed higher levels of comorbid psychopathology than those without. This population is especially vulnerable and could benefit from public policies that target their mental health needs [30].

The same authors clustered women with GD into subtypes based on clinical and sociodemographic variables, finding those with the most severe GD confirmed novelty seeking as well as impaired self-direction, and psychiatric comorbidity, all of which can interfere with treatment. These findings concurred with studies of males with GD [17].

66.1.4 Treatment Seeking (Including Barriers to Treatment)

Female pathological gamblers, underrepresented in treatment, perceive barriers to seeking professional help more than males. Research identifies lack of social support, poverty, lack of childcare, guilt and shame due to stigmatisation and difficulties in finding appropriate treatment. Women using gambling helplines are more likely to have mental health problems, gambling-related financial problems and prior treatment for mental health than men [26]. Higher levels of comorbid psychiatric disorders, difficult biographical backgrounds (significantly higher rates of childhood neglect, abuse and trauma) [3], 'avoidance' coping strategies [13] and increased feelings of guilt or shame and/or fear of being stigmatised discourage women from seeking treatment [19].

Women earn less than men and thus gamble with a higher percentage of their income in comparison, especially older women (on average, 249% more than men of their income in the month prior to treatment) [33].

Non-gendered Australian research has found that help-seeking for PG is crisis driven, prompted by suicide attempts, court charges, arrests, financial ruin or relationship conflicts [8]. Qualitative research further supports this finding in females. Despite low help-seeking rates, women are at least as likely as men to seek professional and non-professional help for PG. Other research indicates barriers that may differ by gender [42]. [43] found men were discouraged by stigma and attitudes to treatment seeking from calling a helpline. In contrast, others found women more likely to feel guilt or shame [18] and to fear consequences of treatment entry (removal of children or injury from abusive husbands) [48].

Women made up 12.5% of a population in treatment in Austria and Germany, were 10 years older than their male counterparts, had greater GD severity and were more likely to live alone or alone with at least one child (50% of the women vs. 28% of the men), suggesting relative social isolation [28]. Just 10–15% of patients in gambling treatment institutions are women [56].

There is a lack of suitable treatment approaches and settings for women, who may feel greater discomfort in a male environment, especially if suffering from traumatic experiences. Available treatment may be incompatible with financial and time constraints for women, who may also fear losing custody of their children.

66.2 Treatment

Individual CBT results in greater improvements (96% recovered or improved) than self-directed workbooks with Gamblers Anonymous (GA) referral (81%) or GA referral alone (77%) [34]. Men were more likely to be abstinent from gambling than women at the end of an eight-week program, but these differences dissipated by the 12-month follow-up.

In a randomised trial of brief interventions, one short advice session was more effective than single-session motivational enhancement therapy (MET) or MET followed by three CBT sessions. It was the only intervention associated with clinically significant improvements in gambling hab-

its after 9 months. Gender was not associated with response to these treatments [35].

Female gambling addicts need a group setting, not associated with addictions, where they feel heard. *Donne in Gioco,* an Italian female-only therapy group focusing on relationships, narration and metaphor in systemic therapy, places emphasis on the 'here and now', with reference to relationship networks [37].

A Swiss study of the effectiveness of self-exclusion found that the incidence of PG was lower among those who had self-excluded previously than in those who do so for the first time [46]. This finding may motivate Swiss casinos to promote voluntary exclusions.

At the National Problem Gambling Clinic in Britain, where females comprise just 7–8% of all referrals, women have high attrition rates. In addition to practical barriers, cost, distance and waiting times, research demonstrated internal barriers: fear, denial, stigma, feeling misunderstood and a sense of ambivalence – a fear of success of treatment – gambling having offered a temporary sense of control. CBT may not be the optimum model to facilitate emotional processing for those displaying high avoidance of their difficulties, for whom psychodynamic treatment may work better [38].

Women often prefer online therapy, helplines and forums, overcoming practical accessibility issues and concurring with other recent research in the field [23].

Sagris and Wentzel [45] reported that feminist cognitive behavioural strategies, such as challenging beliefs, exploration of roles and myths, using mutual aid to encourage self-help and lobbying for policy change, reduced stigma, shame and loneliness. Women can carry high levels of guilt; provision of anonymous online and telephone treatment and development of self-help resources and tools may be more effective still than stigma-reduction campaigns.

Preventative measures such as public health messages and the promotion of self-regulatory strategies (e.g. to contain EGM gambling) need to be assessed for their relevance and resonance with women problem gamblers. The implementation of responsible gambling features on EGMs (the ability to set precommitment limits, receive personalised gambling feedback and access gambling expenditure records) as well as reforms to EGM design, such as lower maximum bet sizes, would also help to reduce gambling-related harm among women. Screening older women presenting with comorbid mental disorders could detect those with GD, expediting therapy.

66.2.1 Pharmacotherapy

Drug treatments for GD in men and women are in their infancy. The efficacy and utility of a number of drugs have been tested, but currently, no drug is approved for GD. In a recent case series, 50 mg a day of the opioid antagonist naltrexone led to marked reduction in cravings to gamble in all 10 patients (20% women), as tested by pre-and post-commencement Gambling Craving Scale (GCS) at 6-week follow-up. The study provides evidence for the efficacy of naltrexone in PGs who have failed to respond to psychological therapies, although care should be taken when prescribing to those with concurrent alcohol use disorder who show evidence of treatment resistance for PG associated with relapse of gambling [51]. Opioid antagonists are advocated as a treatment modality for PG, and there is scope for a randomised controlled trial to ascertain long-term outcomes and tolerability once cessation has occurred.

66.3 Gaming Disorder in Women

Internet addiction has been proposed as a diagnostic entity and studied for over 20 years [especially in light of work by Kimberly Young (e.g. [54])]. However, there has been debate and disagreement regarding a standardised definition. Prevalence of addictive internet use worldwide varies, and comparability of available studies has been limited by variable diagnostic criteria and assessment tools and differing populations screened.

Increasingly, specific online activities are recognised for their addictive potential: online gambling, gaming, use of pornography, shopping, chatting, repeated email checking and use of

instant messaging and social media. Definitions for such addictions are heterogeneous: they vary, and many are not yet determined. Diagnostic instruments are not sufficiently standardised, aetiological models and preventive and therapeutic concepts are not sufficiently evaluated and long-term randomised controlled trials (RCT) are lacking.

Problematic gaming is most commonly conceived of as a behavioural addiction rather than a disorder of impulse control [10, 25]. Important similarities between behavioural addictions and substance use disorders (SUD) include initial pleasure, progressing to increased use with diminished enjoyment. Shared neurobiological features include activation and neuroadaptation in the reward pathways [15].

66.3.1 Definitions and Diagnostic Criteria

Although recreational for most, gaming becomes excessive for others, leading to various negative consequences: dropping out of or doing badly at school, being repeatedly fired from jobs, impaired personal relationships or neglected personal hygiene.

In 2013, *internet gaming disorder (IGD)* was included in Sect. III of the DSM-5 [1] in a list of conditions requiring future study. This addition suggested that IGD may be identified by the presence of five or more of nine criteria within a 12-month period. These criteria include:

(1) tolerance; (2) withdrawal; (3) loss of control; (4) gaming preoccupation; (5) gaming to escape negative affect; (6) loss of interest in offline relationships, social interaction and entertainment; (7) deception to conceal gaming extent; (8) jeopardising relationships, work, career or educational opportunities; and (9) continued excessive gaming despite knowledge of these consequences.

Gaming disorder (GmD) is to be classified as a disease in the eleventh revision of the International Classification of Diseases (ICD-11) [41], under 'disorders due to addictive behaviours'. GmD is defined as:

> A pattern of gaming behaviour ('digital-gaming' or 'video-gaming') characterized by impaired control over gaming, increasing priority given to gaming over other activities to the extent that gaming takes precedence over other interests and daily activities and continuing or escalating gaming despite negative consequences.

It is differentiated from non-pathological gaming by significant distress or impairment in personal, family, social, educational, occupational or other important areas of functioning and must have been evident for at least 12 months.

Given this recent change in the ICD-11, we will refer to addictive internet gaming or pathological online gaming as gaming disorder (GmD) unless otherwise specified.

66.3.2 Gaming Prevalence and Patterns

Gender differences in specific problematic online activities have attracted attention.

A German study of problematic online behaviours showed more females than males using social networking sites (77.1% vs. 64.8%), whereas the reverse was true for online video games (7.2% vs. 33.6%) [44].

Mirroring this, in [2], researchers found that gender was significantly associated with individual's social media addiction screening scores, with females tending to score higher on measures of social media addiction than males. Conversely, male participants tended to score higher on measures of addiction to video games than females. Similarly, in [9], researchers found that male adolescents were more likely to report gaming. Furthermore, among gamers, males were more likely to report gaming problems than their female counterparts. However, by contrast, in [36], researchers analysed problematic internet activities in a representative sample of Swiss adolescent females. Results were unable to show that problematic internet use was associated differently with levels of either online gaming or social networking. Further work is necessary to deter-

mine the extent to which problematic gaming occurs among males and females when the relative prevalence of these activities among genders is taken into account.

The prevalence of problematic gaming is unclear. According to one recent systematic review of publications from 1991 to 2016, 5.5% of the population met criteria for IGD [32]. However, a recent study of large-scale national cohort sample suggests that only a very small proportion of the general population (between 0.3% and 1.0%) might meet these criteria [39]. This demonstrates the variance in the scientific literature. Prevalence rates of IGD are widely derived from rates observed for internet addiction, so may be inaccurate at best. Finally, no reliable gender-specific prevalence rates exist.

66.3.3 Gender Differences in Risk, Aetiology and Comorbidity of GmD

Despite an interest in GmD by researchers, few studies have focused on gender differences, and conclusions are vague. In females, risk factors may include having had below secondary school education and high anxiety and depression scores [4]. Being alexithymic may almost double the risk of IGD (odds ratio = 1.88, $p = 0.030$). However, significant replication work is required to confirm the robustness of these results. Furthermore, whether alexithymia contributes to the development and/or maintenance of IGD or results from prolonged, repeated, problematic online gaming is not known.

In a recent study of both genders, females with IGD were found to have reduced cortical thickness in the left and right rostral middle frontal gyri (MFG), the left superior frontal gyrus, the left supramarginal gyrus, the right posterior cingulate cortex and the right superior parietal lobule, compared with female recreational game users (RGU). These are small, statistically significant differences in cortical thickness. Low craving scores in female IGD subjects were associated with thick right ($r = -0.290$, $p = 0.018$) and left ($r = -0.359$, $p = 0.003$; Bonferroni corrected) rostral MFG. The authors suggest that females may therefore be more vulnerable to IGD, though causation cannot be demonstrated without longitudinal studies, and further preregistered replication work is necessary to confirm the robustness of these findings [50].

Cravings are an important feature of addiction and constitute a diagnostic criterion for substance use disorders though not for GD or GmD. In a recent functional magnetic resonance imaging study, Dong et al. [11] found that gaming-related cues elicited greater cravings in males with RGU than females with RGU and that related corticostriatal-limbic brain activations correlated more consistently with craving responses in males than females, suggesting potential biological mechanisms for male vulnerability in developing IGD [11].

In a related study, Dong et al. [12] made two distinct and significant observations. First, both male and female IGD subjects showed reduced left dorsolateral prefrontal cortex (DLPFC) activation compared with RGU subjects. Left DLPFC activation (which contributes to executive control) may therefore be a target for treatment (e.g. transcranial magnetic stimulation or transcranial direct current stimulation) in IGD as it is in other addictions [12]. Second, IGD status was associated with increased activation of the caudate in both males and females, post gaming, but RGU males showed higher caudate activation than females. The caudate (being a component of reward circuitry and may promote motivations to pursue rewards) findings led the authors to speculate that this difference may relate to female resilience to developing IGD (compared to males) but that once they develop IGD, gaming may impair executive control and make it harder to stop. However, these notions are speculative and warrant specific examination in future preregistered longitudinal studies [12].

In a population of 472 students aged 13–21, emotional dysregulation was associated with substance and non-substance addictions (GmD, GD, alcohol and drug abuse), but no significant gender differences were found. In the same study,

IGD was associated with poor parental and peer attachment in both genders, females scoring significantly higher on maternal and peer attachment problems. The authors conclude that 'IGD may be related to the need for relational satisfaction in adolescence' [14].

Young people with IGD may have a high level of comorbid symptoms from underlying autism spectrum disorder, ADHD, anxiety and depression, though studies examining gender patterns are lacking [49].

66.4 Screening and Treatment

Various assessment tools have been developed to measure IGD: all are self-report questionnaires with no clinician-administered interviews, many derived from existing internet addiction scales [24]. If internet addiction and IGD are to be regarded as distinct clinical phenomena, then tools for each need to be assessed separately. More research is needed, using the new ICD-11 (GmD) criteria in combination with the DSM-5 (IGD), to produce diagnostic and screening tools which will then need to be validated for a range of clinical populations.

A systematic search for keywords related to gaming disorder in Medline, PsycInfo, and Embase found no published randomized controlled trials for treatments of GmD at the time of writing. There is a dearth of research on treatments for GmD altogether, and no studies have yet looked at gender-specific needs in treatment of GmD. More research is needed into the prevalence of GmD, and clinical tools and parameters need validating. Brain-based biology, socio-economic/health impact, empirically justified intervention and policy approaches all need to be investigated with gender-focused longitudinal studies and controlled trials in cross-cultural populations. Preregistration and the application of open science principles are essential in order to build confidence in the robustness of this work. The way in which gender moderates problematic internet activities, including GmD, warrants specific research.

Key Points

- The prevalence of gambling has increased among women in recent years and is likely to represent a cyclic resurgence in gambling among women, linked to societal change and targeted advertising, rather than a new phenomenon.
- Women consistently start gambling at a later age than men, progress more quickly to PG or gamble for shorter durations before seeking treatment.
- Gender differences in gambling preferences are evident: women prefer lotteries, slot machines, scratch cards and bingo while men prefer poker, sports betting, FOBT and casino games. However, younger women (aged 16–34) are increasingly using EGM.
- Motivations for gambling among women include escape from loneliness, dysfunctional relationships, violence, isolation and childcare and to self-medicate perceived intolerable levels of stress, anxiety and depression.
- The incidence of problem gambling among women has risen in recent years, and is linked to lower socio-economic status, deprivation, marginalisation, violent partners and/or childhood and the interaction of dysphoric mood and 'avoidance' coping.
- Comorbid psychiatric disorders often associated with GD include depression, anxiety disorders, bipolar affective disorder, personality disorders and SUDs – suicide being the leading cause of death in GD (31%).
- Barriers to seeking professional help faced more predominantly by women than men include lack of social support, poverty, lack of childcare, guilt and shame due to stigmatisation and difficulties in finding appropriate treatment.
- There is a lack of suitable treatment approaches and settings for problem

gambling among women, who may feel greater discomfort in a male environment, especially if suffering from traumatic experiences.
- Available treatment for problem gambling may be incompatible with financial and time constraints for women, who may also fear losing custody of their children.
- When it comes to treatment, individual CBT results in greater improvements (96% recovered or improved) than self-directed workbooks with Gamblers Anonymous (GA) referral (81%) or GA referral alone (77%). However, CBT may not be the optimum model to facilitate emotional processing for those displaying high avoidance of their difficulties, for whom psychodynamic treatment may work better.
- Women with GD need a group setting, not associated with addictions, where they feel heard. Women often prefer online therapy, helplines and forums, overcoming practical accessibility issues.
- Preferences for treatment may be partly due to the observation that women can carry high levels of guilt; provision of anonymous online and telephone treatment and development of self-help resources and tools may be effective in this regard.
- Drug treatments for GD in men and women are in their infancy. In a recent case series, 50mg a day of the opioid antagonist naltrexone led to marked reduction in cravings to gamble in ten patients (20% women). However, care should be taken when prescribing to those with concurrent alcohol use disorder.
- Online gambling, gaming, use of pornography, shopping, chatting, repeated email checking and use of instant messaging and social media have been recognised for their addictive potential. However, definitions for such disorders are heterogenous, diagnostic instruments are unstandardised, aetiological models and therapeutic concepts are not sufficiently evaluated and RCTs are lacking. There is a dearth of research into gender differences in gaming disorder.
- Gaming is more prevalent among males than among females, and studies have suggested that males may be more likely to suffer from problematic gaming even when these increases in prevalence are taken into account. However, the overall prevalence of problematic gaming behaviours is unclear. Furthermore, no gender-specific prevalence rates exist.
- Various neurobiological explanations for gendered differences in problematic gaming have been proffered. However, significant preregistered replication work is necessary to confirm the robustness of these explanations.
- There are no published randomised controlled trials for treatments of GmD at the time of writing. There is a dearth of research on treatments for GmD altogether, and no studies have yet looked at gender-specific needs in treatment of GmD. More research is needed into the prevalence of GmD, and clinical tools and parameters need validation.

Contents

Abstract

The Internet has arguably revolutionized our lives in a completely unprecedented way. Despite its countless benefits, threats such as problematic Internet use (PIU) (or Internet addiction) have also emerged. This chapter gives a brief overview of the main research questions, topics, and controversies of the field of problematic Internet use. More specifically, it discusses the concept of Internet addiction and its major criticisms, the development process of diagnostic criteria for gaming disorder (GD) as a specific Internet-use-related disorder, the etiology and theoretical models of general and specific problematic Internet use, the assessment and prevalence estimates of problematic Internet use and gaming disorder, and the main treatment approaches. This chapter closes with conclusions and suggestions for future research directions.

67.1 Introduction

The Internet has arguably revolutionized our lives in a completely unprecedented way. It has virtually changed every aspect of our modern lives from communication to entertainment, from doing science to being a parent, and from navigating in an unknown city to cooking from recipes shared by strangers. With the recent omnipresence of smartphones, we basically keep all the knowledge of human kind in our pockets, we are able to speak and see almost anyone on the planet in real time, and we are able to shop, gamble, bank, or work 24/7. Furthermore, this incredible technological advancement not only affected young "tech-savvy" males but literally everybody belonging to both genders, all ages, and all socioeconomic groups across the planet. Nevertheless, the most shocking aspect of this incredible change is arguably its speed. In the 1980s, less than 40 years ago, at the dawn of the Internet, no one could have possibly imagined a world we live in today.

The history of the Internet dates back approximately to the 1970s when the Advanced Research Projects Agency Network (ARPANET) was established. The ARPANET was the supreme network of regional academic and military networks, which allowed information sharing between geographically distant computers [33]. Shortly after this, in the 1980s, the Internet was born as a technology supporting different communities of researchers and developers, as well as other communities for daily computer communications, mostly via email. It was then the 1990s when the Internet has gradually become accessible to the wider public through the large-scale linking of different commercial networks [33]. Growth has been exponential since then, as institutional, personal, and mobile computers were connected to the network in an ever-increasing manner. By now, Internet services and technologies have been incorporated into almost all major areas of modern life.

Besides the undeniable positive impact of the Internet in countless areas, possible risks have also emerged. It was at the end of the 1990s when the first clinical case studies were published about people who used the Internet in such an excessive manner that it resulted in significant impairment to their personal, social, and professional lives [11, 48]. According to the early scientific observations, these cases resembled addictive disorders. The subjects were preoccupied with using the Internet; demonstrated withdrawal symptoms and tolerance; lost control over the activity; lost interest in other social, occupational, and recreational activities; disregarded the negative physical or psychological consequences of Internet use; and were prone to relapse after periods of abstinence or control [13, 48]. For this reason, DSM-IV criteria for substance dependence and pathological gambling [1] were mostly used for clinical diagnosis and in research as well. The term "Internet addiction" (IA), applied in that early period, also mirrors the conceptual similarity with psychoactive substance use dependence and pathological gambling.

67.2 The Concept of Internet Addiction and Its Major Criticisms

IA is an umbrella term referring to a collection of online behaviors (e.g., social networking sites, online games, shopping, porn, gambling) one can be addicted to. Nevertheless, the concept of IA has been heavily criticized. The main criticism concerns the "Internet" component. Starcevic [43] and several other researchers argue that the term IA represents a misnomer. More specifically, being addicted to the Internet implies being addicted to a delivery mechanism, a medium or channel through which specific activities such as gaming, gambling, viewing pornography and related sexual behaviors, shopping, or chatting are accessed or performed. In this sense, it is like saying that a person with alcohol problems is addicted to bottles [16] or a person with gambling problems is addicted to casinos [43]. To address this concern, several researchers have proposed to avoid the concept and the term IA entirely and replace it with concepts referring to specific online activities such as online video game addiction [43].

The second major criticism concerns the "addiction" component. It has been argued and lengthily debated that the addiction framework might not be the best to capture and explain the condition. One reason is that according to some studies (e.g., [27]), behavioral addictions are fairly transient or episodic in nature, characteristic for certain life stages and remitting with the change of circumstances, while substance-related addictions are usually chronic and progressive if not treated [44]. Consequently, it has been argued that alternative theoretical models such as the model of compensatory Internet use [15] may explain these conditions better. This model proposes that problematic Internet use is the consequence of maladaptive coping (i.e., people alleviate dysphoric moods by using certain online applications) or a way of meeting particular needs. Furthermore, it is also a strong concern that the "light" use of the term addiction may depreciate the severity and importance of traditional substance-related addictions and lead to the overpathologization of otherwise healthy everyday behaviors [4, 43]. However, the research activity (e.g., literature reviews, original research) of the WHO working groups leading to the inclusion of gambling and gaming disorders in the eleventh edition of the International Classification of Diseases (ICD-11) as disorders due to addictive behaviors (more details of these processes are presented in the next section) brought to light new evidence supporting the idea that gaming disorder and, perhaps, the problematic use of other specific online activities are correctly considered addictions (see Ref. [5]).

Nevertheless, addressing these criticisms, several alternative terms were proposed and used as well, such as excessive Internet use, problematic Internet use, pathological Internet use, compulsive Internet use, and Internet use disorder (IUD), and similar terms were also applied to the specific online activities such as gaming or social media use (e.g., problematic gaming, compulsive social media use). In this chapter, we will be mostly using the term "problematic Internet use" (PIU) as an umbrella term for the pathological use of specific Internet activities.

67.3 The Development of Diagnostic Criteria: From Internet Addiction to Gaming Disorder

Despite the heavy criticisms, the clinical presence of PIU-related cases and research in this field and in the field of other so-called behavioral addictions such as exercise addiction, work addiction, or cybersex addiction have grown exponentially since the first case studies were published [4, 38]. However, as in the case of many other new disease candidates, terminology, definition, diagnostic criteria, and assessment have been highly inconsistent. Without official diagnostic criteria, researchers and clinicians used several different theoretical frameworks and created countless assessment instruments to identify and interpret problematic cases [30].

Nevertheless, this increased clinical presence and research interest have urged researchers to make efforts to unify the field by reaching some consensus in the aforementioned areas (terminology, definition, diagnostic criteria, and assessment). As a result, during the development of the fifth revision of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5; [2]), the American Psychiatric Association charged the Substance Use Disorder Workgroup to review the scientific literature regarding behavioral or non-substance addictions and to make a proposal regarding their possible inclusion. This preparatory work was a long process; it has lasted for several years, in which the workgroup has reviewed the literature in gambling, Internet use, gaming, work, shopping, sex, and exercise. The proposals they made have been changing during this process. At an early stage, the working group proposed the inclusion of Internet use disorder (IUD) in Sect. 3 (entitled "Emerging Measures and Models" including conditions that need further study), but then, they modified this proposal to only include Internet gaming disorder (IGD; as a specific form of IUD) because this was the only Internet activity with enough evidence of clinically significant impairments. The other important proposal made by the working group was to

realign gambling disorder in the same chapter with substance use disorders due to their overlap with respect to etiology, biology, comorbidity, and treatment [39].

The inclusion of IGD in the DMS-5 was in line with the long-proposed suggestion to replace the concept of general IA (or addiction "to" the Internet) with conditions concerning specific online activities (or addictions "on" the Internet) [12, 43]. This approach was then further supported by the inclusion of gaming disorder (GD) as an official diagnostic category in the Substance-Related and Addictive Disorders section of the ICD-11 in 2019 along with gambling disorder.

It is also important to mention that both inclusions stirred heated debate among scholars. Some of the diagnostic criteria for IGD, namely, preoccupation, withdrawal, tolerance, deception, and escapism as well as the name and the content of IGD, were strongly criticized [14, 22]. However, one can argue that this intense debate was useful in moving toward a larger international consensus, which finally manifested in the inclusion of GD in ICD-11 and the development of the GD definition. According to the World Health Organization [47], gaming disorder is "manifested by a persistent or recurrent gaming behavior (i.e., 'digital gaming' or 'video-gaming') characterized by an impaired control over gaming, increasing priority given to gaming over other activities to the extent that gaming takes precedence over other interests and daily activities, and continuation of gaming despite the occurrence of negative consequences. The behavior pattern is of sufficient severity to result in significant impairment in personal, family, social, educational, occupational, or other important areas of functioning. These features and the underlying pattern of gaming are normally evident over a period of at least 12 months in order for a diagnosis to be assigned, although the required duration may be shortened if all diagnostic requirements are met and symptoms are severe." If we break down this definition, it only includes those IGD criteria that were more or less consensual (i.e., behavioral salience, loss of control, losing interest in and reducing other recreational activities, continuation of the playing behavior despite negative consequences, and risking/losing relationships and opportunities).

As a conclusion, a growing consensus can be observed among scholars, which supports the idea that although Internet use can be problematic for some individuals, it is very important to specify the online activities in particular that cause the problem. Consequently, the general concept of IA or PIU is increasingly replaced with conditions involving specific online activities. Among these, the most prominent ones are online gaming, the use of social networking sites, and perhaps the consumption of online pornography. In the following sections, we will focus on general PIU and GD.

67.4 Etiology and Theoretical Models of General and Specific Problematic Internet Use

The cognitive behavioral model of pathological Internet use [9] was one of the first to theorize IA and propose a model for its etiology. According to the model, there are distal and proximal contributory causes to the symptoms of pathological Internet use. Psychopathology (e.g., depression, social anxiety) is a distal necessary cause as it might make the person vulnerable to develop and subsequently maintain pathological Internet use. The other key distal contributor is the positive reinforcement the individual gets from using the Internet, perhaps directly interacting with the aforementioned vulnerabilities (e.g., getting more positive feedback from people online than offline). Maladaptive cognitions about the self and the world are proximal causes of pathological Internet use. These include self-doubt, low self-efficacy, and negative self-appraisal in the form of thoughts such as that the person thinks that he/she is worthless offline but good on the Internet or that he/she thinks that the Internet is the only place he/she is respected. Furthermore, it is suggested that these thoughts are guided by a ruminative cognitive style which prevents the individual from taking action and contribute to more severe and prolonged pathological Internet

use. It is also Davis' model that clearly distinguishes specific pathological Internet use (SPIU) and generalized pathological Internet use (GPIU). In the case of SPIU, the person pathologically uses a specific Internet activity such as online gambling or gaming, while GPIU involves a general, multidimensional excessive use of the Internet such as chat rooms and email (note that this is an early model) or wasting time with no direct purpose. Maladaptive cognitions might cause both SPIU and GPIU, while the behavioral symptoms of pathological Internet use (mostly cognitive in nature such as obsessive thoughts about the Internet, diminished impulse control, decreasing interest in other activities, social isolation) reinforce the maladaptive cognitions resulting in a vicious circle and maintaining pathological Internet use.

A more recent theoretical framework of specific Internet use disorders is the person-affect-cognition-execution (I-PACE) model proposed by Brand et al. [6]. The model proposes that specific Internet use disorders are the consequence of interactions between predisposing factors such as personality-related features (e.g., impulsivity, low self-esteem, low conscientiousness); social cognitions (e.g., loneliness, perceived social support, social distrust); biopsychological factors (i.e., genetics, early childhood experiences, stress vulnerability); psychopathology (e.g., depression, social anxiety, ADHD) and motivation for use (specific motives of the specific online activities such as escapism in the case of online games); moderators, such as coping styles (e.g., avoidance) and Internet-related cognitive biases (i.e., expectancies, illusions, implicit associations); and mediators, such as affective and cognitive responses (i.e., cue reactivity, craving, urge for mood regulation, attentional bias) to situational triggers (e.g., confrontation with Internet-related cues, perceived stress, personal conflicts, negative mood) in combination with reduced executive functioning (e.g., decision-making) or inhibitory control. Pavlovian and instrumental conditioning (e.g., positive reinforcement) processes may strengthen these associations within an addiction process. According to the model, the interaction between affective mechanisms (e.g., cue reactivity and craving) and top-down control processes may progressively lead to increased urges to use the specific Internet activity and reduced inhibitory control abilities while specific Internet-related disorders are being developed. The authors also assume that individuals with different types of Internet use disorders have specific personality profiles. Although the components and processes proposed in the model are based on previous theoretical and empirical research, further empirical studies are needed to test the hypothesized mechanisms in a systematic way. Nevertheless, the model may serve as a comprehensive explanatory framework for the development and maintenance of specific Internet-related disorders and, as such, is greatly helpful for formulating clear research hypotheses in future studies.

Majority of research to date is cross-sectional in nature providing a long list of comorbid psychopathologies for both general PIU and specific PIU such as gaming disorder or problematic social media use. According to these studies, major depression, dysthymia and depressive symptoms, general and social anxiety disorders, substance use disorders, low life satisfaction, low well-being, loneliness, low self-esteem, low emotional stability, attention deficit hyperactivity disorder, borderline personality disorder, impulsivity, hostility and aggressive behavior, and sleeping disorders are all related to PIU, usually with low or moderate effect sizes [26, 28, 29]. When reviewing the studies involving clinical samples, Kuss and Lopez-Fernandez [29] concluded that the presence of comorbidities (e.g., mood and anxiety disorders, other impulse control and addictive disorders) appears to be the norm rather than the exception. However, due to the overwhelming degree of correlational research in the field, the directionality and causality of these relations remain unclear. According to the longitudinal studies conducted to date, the relationship between psychopathology and PIU appears to be rather reciprocal, meaning that poor mental health is a considerable precursor to PIU, while PIU is also succeeded by a diminished level in mental health [3, 32]. It is also worth mentioning that experimental design is not suit-

able to explore the etiological and causal processes in PIU (or the field of behavioral addictions more broadly) as opposed to other fields such as the study of media- or video game-induced violent behavior where it is used very often.

67.5 Assessment of Problematic Internet Use and Gaming Disorder

One of the most crucial, most studied, and also most debated topics within the field of PIU is assessment. The very first IA-related publications have already proposed ways to assess the problematic behavior (e.g., [50]), and newer and newer instruments have been continuously proposed since then resulting in an almost unmanageable amount and variety of scales using diverse theoretical backgrounds, diagnostic criteria, and – very often – ad hoc cutoff thresholds for both general and specific PIU [20, 30].

According to systematic reviews, the Internet Addiction Test or shortly IAT proposed by Young in her early publications [49] is the most popular screening instrument for general PIU [30] but also one of the most popular instruments for problematic gaming [20]. It has 20 items that are scored on a 5-point Likert scale. The instrument lacked a psychometric development process both regarding its items and for its proposed cutoff thresholds. Its psychometric properties have been explored in several subsequent studies yielding varying results [23, 30]. Furthermore, results regarding its factor structure are highly inconsistent meaning that models with one to six factors have been reported in studies that subsequently attempted to validate the instrument. Consequently, although the IAT has by far been the most often used instrument in the field, its psychometric properties do not support such a popularity.

The Problematic Internet Use Questionnaire (PIUQ; [10]) and the Compulsive Internet Use Scale (CIUS; [37]) are both frequently used screening instruments demonstrating good psychometric properties. The PIUQ has 18 items, the CIUS has 14, and both are rated on 5-point Likert scales. Both instruments have been translated into several languages and used in cross-cultural research showing adequate psychometric qualities [31, 35].

Another popular instrument used most often in Asia is the Chen Internet Addiction Scale [8]. The scale has 26 items scored on a 4-point Likert scale. The instrument demonstrated good psychometric properties in its original development study, and it has clinically proposed cutoff scores both for large-scale epidemiological surveys (demonstrating a good diagnostic accuracy) and for clinical practice (having a higher sensitivity than specificity to reduce the number of false-negative cases) [25].

The Scale for the Assessment of Internet and Computer Game Addiction (AICA-S; [46]) and the Checklist for the Assessment of Internet and Computer Game Addiction (AICA-C; [45]) were based on criteria for gambling disorder and substance-related disorders and have been used in both epidemiological and clinical research with promising results.

The inclusion of Internet gaming disorder in the DSM-5 as a tentative condition in May 2013 was an important milestone in the assessment of problematic Internet use. Before that, instruments were highly inconsistent, and many of them lacked a proper validation process. King et al. [20] found 18 instruments measuring problematic gaming in the "pre-DSM-5 era," and there were no two instruments among them covering the same diagnostic criteria. The inclusion of IGD in DSM-5 brought along the development of numerous new screening instruments for problematic gaming (rather than general problematic Internet use), which were more consistent and have been developed more carefully than their predecessors. However, even these have several shortcomings that need to be addressed in the future.

The Ten-Item Internet Gaming Disorder Test (IGDT-10; [24]) is a screening instrument that operationalizes the IGD criteria with 10 items (the last IGD criterion is covered with two items) and a 3-point Likert scale using clear and unam-

biguous wording. It has been translated into numerous languages and demonstrated good psychometric qualities both in the original developmental study and in cross-cultural settings [21]. The Internet Gaming Disorder Scale-Short Form (IGDS9-SF; [40]) is a short screening scale operationalizing the IGD criteria as well. The scale has 9 items assessed on a 5-point Likert scale. It has demonstrated good psychometric properties and has been translated into several languages and applied in different cultural settings. Lemmens et al. [34] also developed screening instruments to operationalize the IGD criteria. They tested four different versions, a 27-item and 9-item polytomous scale and a 27-item and 9-item dichotomous scale, and found that all four scales were reliable and valid, but the dichotomous 9-item version appeared to be the most practical for diagnostic purposes. According to a recent review of these instruments, the shortcomings of these scales are problematic wording in the case of the IGDS-SF9, the lack of full IGD coverage in the case of Lemmens and colleagues' scale, and the need for more quality studies in the case of IGDT-10 and IGDS-SF9 [17].

The inclusion of gaming disorder (GD) in the ICD-11 was another huge milestone. We now have a diagnostic definition and criteria which may serve as a gold standard for the assessment of problematic gaming and perhaps also for other Internet-related disorders as suggested by numerous experts in the field [6]. However, the definition needs to be operationalized to be suitable for clinical use and research. The WHO has now established a working group to lead "The WHO Collaborative Project on the Development of International Screening Tools for Disorders due to Addictive Behaviors" [7]. The project aims to develop (i) a lay-administered fully structured diagnostic interview for GD, (ii) a clinician-administered semi-structured diagnostic interview for GD, and (iii) diagnostic research criteria for GD in the upcoming years. The working group comprises experts from all around the world and aims to integrate their knowledge to establish assessment tools that can be applied across the globe.

67.6 Prevalence Estimates of Problematic Internet Use and Gaming Disorder

Estimating prevalence rates of PIU and its specific forms is of primary importance to assess the demand for prevention and intervention programs and to determine the scale of the problem in general. However, majority of the studies that aim to estimate such prevalence rates suffer from severe methodological shortcomings that undermine the reliability of the results. The most important shortcoming affecting the entire field of PIU is the aforementioned lack of diagnostic criteria. Without a consensual definition, it is impossible to conduct reliable assessment. Therefore, the unification of the field is pressing, and both the inclusion of IGD in the DSM-5 and the WHO's efforts are important steps toward such a consensus. Other important shortcomings of epidemiological research include the use of unreliable assessment tools and non-probability sampling. The literature is overwhelmed with studies using convenience samples and reporting "prevalence rates" like those would be the true proportion of clinical cases. This directly leads to the pathologization of non-problematic cases resulting in an unnecessary moral panic concerning Internet use. Furthermore, in the case of disorders, which are relatively rare, screening instruments (even with high diagnostic accuracy and even in representative samples) inherently yield a very high rate of false positives (i.e., cases which score positive on the screening test while not being disordered in the clinical sense) (for a more detailed explanation, see Ref. [36]). Therefore, even proper epidemiological research conducted with large-scale representative samples most probably overestimates the true prevalence rates of PIU.

According to systematic reviews, prevalence estimates of PIU largely vary indicating a high uncertainty in the field of assessment. For instance, a study reviewing epidemiological data between January 2014 and February 2015 reported prevalence estimates ranging from 1% in a representative German community-based sample and 18.7% in a representative sample of

school-based adolescents in Taiwan [41]. Another review of epidemiological research in PIU carried out between 2000 and 2013 found prevalence estimates ranging from 0.8% in Italy to 26.7% in Hong Kong, but it included studies with convenience samples too [28]. Prevalence estimates for problematic gaming usually range between 1% and 9% in representative adolescent samples [22]. Nevertheless, taking into consideration the aforementioned severe methodological (and theoretical) shortcomings and the high rate of false-positive cases yielded by screening instruments, true prevalence rates (cases with valid clinical diagnosis) of PIU and problematic gaming are most probably somewhere around or even below 1%.

67.7 Treatment Approaches to Problematic Internet Use

Given that the behavioral addiction framework is the leading framework to theorize PIU, treatment attempts are also derived from addiction treatment methods (e.g., substance use disorders, gambling disorder). According to a systematic review conducted by King et al. [19], studies reporting PIU treatment most often applied cognitive behavior therapy (CBT), motivational interviewing, reality training, or self-devised psychological interventions. The cognitive behavioral approach claims that problematic cognitions coupled with behaviors play a role in the development, maintenance, and relapse of PIU and therefore focuses on identifying, challenging and changing maladaptive cognitions (e.g., thoughts, beliefs, and attitudes) and behaviors, improving emotional regulation, and learning more adaptive coping strategies that can successfully be used in solving current problems. The therapist helps the client to monitor their Internet use, set clear and attainable goals, and identify and modify cognitive distortions [18].

Monitoring use (e.g., by systematically recording the types and duration of online activities, as well as emotions and outcomes related to them) draws attention to the negative consequences of excessive use such as loss of sleep, relationship conflicts, and neglect of other activities and increases motivation by making the client more aware of the vicious cycle of PIU (i.e., excessive Internet use creates problems that the client seeks to escape from by being online).

The main goal of therapy is to reduce the amount of time spent online to a degree that no longer interferes with the client's healthy functioning. In contrast with substance use disorders where abstinence is often the goal, in the case of PIU, controlled use is usually aimed for given the essential role Internet plays in our modern lives. During therapy, it is very important to reveal the needs certain online activities fulfill in the client's life (e.g., dealing with stress, reducing social anxiety) and to address them by developing alternative ways and improving skills to meet those needs (e.g., social skills training). It is also recommended that clients in the early stages of reducing online time should try to commit to healthy lifestyle choices such as eating and sleeping regularly, engaging in sports, and finding alternative hobbies; to minimize deliberate exposure to situations that initiate Internet use (e.g., muting notifications, using a traditional wristwatch instead of checking the time on their smartphones); and to make Internet use less convenient and accessible (e.g., putting away the smartphone while reading/cooking, blocking the use of certain apps after reaching a preset time limit) [18, 42]. Furthermore, given the high incidence of comorbid disorders, PIU treatment may benefit from therapeutic approaches that combine treatments for co-occurring disorders in order to increase the efficacy of the treatment [29].

Besides monitoring Internet use and setting clear and attainable goals, identifying and challenging faulty cognitions that maintain PIU and replacing them with more adaptive thoughts that promote healthy behavior are some of the main objectives of CBT. Cognitive distortions or Internet-related cognitive biases are important factors in both aforementioned PIU models (the cognitive behavioral model of pathological Internet use and the I-PACE model) that increase the individuals' dependence on the Internet and maintain PIU. According to Davis [9], such cognitive distortions include a negative view of the

self and a positive view about the Internet and one's online presence and are manifested in thoughts such as "I am only good on the Internet"; "I am a failure offline, but I am successful online"; and "the Internet is the only place where others respect me." These faulty cognitions need to be revealed, challenged, and modified during therapy along with increasing the client's self-efficacy and positive self-appraisal.

Although there is an increase in treatment facilities offering interventions for PIU across the globe, reliable data concerning treatment efficacy is still highly limited. Efficacy studies are scarce, and the existing ones suffer from several methodological shortcomings. According to King et al. [19], these limitations include inconsistencies in the definition and diagnosis of PIU, a lack of randomization and blinding techniques applied in the treatment studies, a lack of adequate comparison or control groups, and insufficient information concerning recruitment dates, sample characteristics, and treatment effect sizes. Consequently, efficacy studies with better study design and more thorough reporting are highly necessary and should be one of the important directions for future research in PIU.

67.8 Conclusion and Future Directions

The Internet has changed our lives in completely unforeseeable ways. Having an entirely offline life few decades ago, we suddenly found ourselves in a completely interconnected world, having the possibility to live online if we wish to do so. The Internet offers us everything: we can order food while sitting in front of our desks, we can complete most of our administrative tasks from home, we can work online, we have access to endless forms of entertainment, we can make friends and live a social life, and we even have infinite ways to acquire sexual pleasure. Consequently, it is not surprising that a lot of people are "binge-using" the Internet and a minority of them experience addiction-like symptoms and suffer severe negative consequences due to their Internet use.

Similar to other technological innovations (e.g., television, microwave oven), the sudden popularity of the Internet caused a moral panic (especially in the media), as well as raised enormous research interest while stirring heated debate among scholars. After about two decades of intense research in the field, it appears that consensus was reached in some essential questions such as the existence and the importance of the phenomenon (i.e., excessive use of the Internet causes severe problems in the case of a small group of users, and these symptoms are similar to the symptoms of substance use and other addictive disorders) and the importance of specific Internet activities (e.g., gaming, buying, watching pornography) over general Internet use and also that gaming disorder should be an official diagnosis. However, a lot of questions still remain to be answered, and much more quality research is needed to have a clearer picture. Future tasks include distinguishing the individual characteristics and addiction mechanisms of specific online activities, investigating whether other specific Internet-use-related behaviors (e.g., problematic social media use) should be included in official diagnostic systems, developing unified assessment tools to determine reliable prevalence rates across cultures, carrying out large-sample longitudinal studies and clinical and qualitative studies to understand the etiology (risk and protective factors, causal relations in the development of the disorders) as well as the natural course of PIU, and carrying out efficacy studies for different prevention programs and treatment methods to find the most optimal ways to help those in need.

68 Conceptual and Methodological Considerations of Gaming Disorder and Internet Gaming Disorder

Linda K. Kaye, Daria J. Kuss, and Hans-Jürgen Rumpf

Contents

Abstract

This chapter provides an overview of the current conceptual and methodological challenges in light of gaming disorder recently being included in the ICD-11 (WHO, Gaming disorder, 2018). This is discussed in reference to the DSM-5 (APA, Diagnostic and statistical manual of mental disorders. 5th ed. Arlington: American Psychiatric Association, 2013) with its more tentative approach of adding Internet gaming disorder (IGD) in the appendix as a condition for further study. The debate is summarised to present the disparities between these two diagnostic manuals, along with a range of other key conceptual challenges which call for a cautious approach when inferring diagnostic efficacy from these clinical manuals. These issues include definitional differences, impact of game classifications and the various behaviours afforded to these based on game type, game function and form of gaming. Further to this, methodological issues are drawn out to highlight the potential limitations of the academic evidence base in this field. As such, this chapter provides a critical review of the conceptual issues with considerations of the practical and clinical implications.

Keywords

Internet gaming disorder · Gaming disorder · Internet games · Digital gaming

68.1 Introduction

The gaming industry is a multi-billion pound industry, which in 2018 was estimated to reach a market value of $137.6 billion and to attract players in excess of 2.2 billion [66]. Clearly, digital gaming is a highly sought-after pursuit, highlighting its pertinent role in public interest and society. For the vast majority of players, gaming serves as an enjoyable leisure pursuit, in which the average time spent playing per week is approximately 10 hours for those between 11 and 64 years [66]. However, for some, gaming behaviour may become problematic, which may start to have a detrimental impact upon other aspects of one's lifestyle. Theorising the extent of this detriment often involves referring to criteria used within the addiction field, whereby a distinction may be drawn between those who are "excessive" players and those who may be considered "addicted" [6, 7, 16]. However, there remains substantial academic debate surrounding the applicability of addiction criteria to digital gaming [8, 34, 41]. That is, whereas some scholars propose there is efficacy in using diagnostic approaches [30, 53, 54, 60, 64], others highlight that there is not yet a sufficient consensus in the academic community to warrant agreed clinical diagnostic criteria [19, 67], if indeed it is deemed necessary at all. Despite this, health policy has already offered clinical diagnostic criteria for addiction relating to digital gaming. That is, the American Psychiatric Association has listed "Internet gaming disorder" (IGD) in the appendix of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5; [1]) as a "condition for further study", but the World Health Organization (WHO) has outlined "gaming disorder" (GD) as an established clinical condition in the recently published ICD-11 [71]. These policy advancements have driven a wide range of research agendas, which have sought to establish the validity of gaming addiction as an independent clinical condition (e.g. [4, 24, 33, 36, 42, 59]). Despite the wealth of research evidence pertaining to gaming addiction, which to date is typically framed in relation to IGD, there are many queries which remain unaddressed within both health policy guidelines and the academic literature. These are highlighted in the following sections.

68.2 Conceptual Definitions

When exploring the diagnostic criteria afforded to gaming disorder [71] and Internet gaming disorder [1], it is clear that there are some variations. Specifically, gaming disorder is characterised by "a pattern of persistent or recurrent gaming behaviour ('digital gaming' or 'video-gaming'), which may be online (i.e. over the Internet) or offline, manifested by (1) impaired control over gaming (e.g. onset, frequency, intensity, duration, termination, context), (2) increasing priority given to gaming to the extent that gaming takes precedence over other life interests and daily activities and (3) continuation or escalation of gaming despite the occurrence of negative consequences" [71]. The ICD-11 further states that this pattern of behaviour should have been severe enough to have a significant impairment on specific important areas of functioning (e.g. personal, social, occupational areas [63]). Normally, criteria should be evident for at least 12 months (either continuously or episodically); however, the required duration may be shortened if all diagnostic criteria and requirements are met and symptoms are of sufficient severity. In contrast, the DSM-5's Internet gaming disorder does not specify the aspects of life of these impairments, but does state that the impairments may be mild, moderate or severe and are based on the amount of time spent playing games and the general impact on overall functioning [1]. Further, it refers to repetitive use of "Internet-based games" leading to the experience of at least five diagnostic criteria within one year. Criteria include preoccupation with Internet games, withdrawal, tolerance, loss of control, loss of interest in other

life activities, continued use of Internet games despite negative consequences, deception about the amount of Internet game use, escapism from negative symptomology and loss (or risk of loss) of relationships, job, educational or career opportunities.

These definitions appear to vary in operational terms, particularly in relation to how clinical diagnosis is established through fulfilling a specific set of criteria. Whilst GD, in its current clinical description, does not specify if two or three criteria should be present, IGD quantifies a set amount of criteria (five or more) which should be met for diagnosis to be taken forward. In the future, diagnostic guidelines for ICD-11 are anticipated specifying the required number of criteria. For this purpose, sound empirical data are needed. Given the different approaches in DSM-5 and ICD-11, one may raise debate over the convergences and divergences. That is, if their measurement criteria are different, how confident can one be in assuming they are both measuring the same construct? For this purpose, crosswalk analyses will be of special importance.

The inclusion of IGD in DSM-5 as a condition for further study was acclaimed by many researchers. It has stimulated further studies and led to the development of a number of measures to assess IGD and to approaches to applying the DSM-5 criteria to other Internet activities [49]. Whilst a number of studies confirm the approach in general, the concept has been criticised. In particular, concerns were raised that individuals could falsely be classified to have IGD. It has been argued that criteria were taken from the substance use disorder area, whilst in fact, IGD criteria are largely based on the DSM-IV criteria for defining pathological gambling. Nevertheless, both share criteria stemming from substance use disorders.

Some researchers have questioned a distinction between gaming-related problems (e.g. interference and impairments in life events) and addiction-related symptoms (e.g. tolerance, withdrawal, mood modification) which are noted to often be conflated within empirical work [8]. It has been suggested that a reformulation of IGD is needed based on findings that these symptoms and problems are relatively exclusive from each other in the majority of adolescent players [42]. Studies in this regard have used latent class analysis techniques as a means of determining distinctions. For example, Colder Carras and Kardefelt-Winther [8] identified four classes of player: "IGD class" (2.2%), "normative class" (63.5%), "engaged class" (7.3%) and "concerned class" (23.6%). These latter two classes would be misclassified based on their reporting of gaming-related problems only. Similarly, Myrseth and Notelaers [50] identified five classes: never symptoms (46.2%), rarely symptoms (22.3%), occasionally symptoms (23.5%), problem gamers (6.9%) and disordered gamers (1.2%). This has prompted recommendations for establishing greater distinction between problems and symptoms, as well as the potential for better formulation of user groups or classes of players who may have distinct phenomenology and patterns of behaviour [8]. This may go some way to help inform clinical practices surrounding diagnosis and treatment where necessary. Alongside this, there are also recommendations for participatory approaches, involving samples of gamers who may be able to help refine and improve content validity of IGD criteria [9].

Another criticism according to the DSM-5 approach refers to the distinction between core addiction criteria including withdrawal, conflict and relapse/loss of control and peripheral criteria like salience, tolerance and euphoria. This is based on the model of Charlton and Danforth [7] and is discussed in a recent paper on the distinction between high involvement and pathological involvement in video games [5]. The authors come to the conclusion that the ICD-11 approach has advantages by being more close to core criteria with a reduced probability to falsely identifying gaming as an addictive disorder.

Recommendation 1
Distinguish between addiction symptoms and gaming-related problems to identify different player classes.

Furthermore, the inspection of the DSM-5 approach – extended to other behaviours like social network use besides gaming and based on factor analyses in three samples – reveals that some of the criteria show quite high endorsement rates [4]. Interestingly, the youngest sample's data were characterised by a different factor structure. Whilst the other two samples' data show a one-factor structure, in the data of a sample of students in vocational schools, a second factor occurred characterised only by the criterion of escapism from negative mood. This might be interpreted in that using specific online activities to relieve negative mood is very common in young cohorts and might not reflect pathological or addictive use. Taken together, criteria of the DSM-5 might lead to false-positive results in detecting gaming disorder. However, additional studies and comparisons with the ICD-11 approach are necessary.

68.3 Game Classifications and Behaviours

Both IGD and GD refer to online and offline games. In the DSM-5, the term Internet gaming disorder was chosen to better distinguish this condition from the term gambling disorder [55]. However, it is explicitly stated in the DSM-5 that IGD could involve offline games. Although it is likely that criteria should work comparable for different kinds of online and offline games, it might be useful to compare subgroups of players and to further specify characteristics of games that are related to addictive behaviour. This raises a number of conceptual challenges in respect of pinpointing the specific behaviours or specific types of games being referred to within these definitions. Although these labels may be attempting to define the same behaviour, arguably, they may be referring to different things. This presents a key limitation of much research in this field, in the general lack of specificity in how GD and IGD relate to the diversity of games themselves and indeed gaming as an activity. That is, within the IGD research specifically, this has predominantly defined the reference point in studies as "online games" or, in some cases, has been even less specific [46, 59, 65]. Arguably, there are a range of forms of "online" gaming which are Internet-mediated and thus by definition would appear under the remit of IGD (e.g. social networking site games).

Typically, the conceptualisation of "online games" would most likely align to hardcore forms of gaming, played for leisure (e.g. massively multiplayer online games (MMOGs)), although recent evidence has provided initial insight into the "perceived addictiveness" of smartphone games [3], with opposite results found in another study [47]. However, online gaming can take many forms. Of specific relevance here is that even for different types of MMOGs, there are observed variations in player characteristics, preferences and behaviours. Particularly role-playing games as a subtype of MMOGs tend to be associated with greater playing times relative to other types of games, such as shooter games and real-time strategy games [51]. Arguably, using a generic reference point such as "online gaming" or "Internet gaming" is too broad to capture the nuances of player characteristics and behaviours for the various types of games on the commercial market. Specifically, this relates to a number of key issues: (1) variety of the types of games, (2) variety of the function of gaming and (3) variety in the form of gaming. These are discussed next.

68.3.1 Game Types

Digital games are highly diverse as is evidenced by the range of game types which exist on the commercial market. To understand "excessive gaming", it is useful to approach this from the perspective that gaming behaviours are framed by not only individual and contextual factors but also the structural components of games themselves [18, 28, 29, 39, 40]. Indeed, previous studies have proposed a taxonomy approach to understanding how the structural components of digital games may be related to gaming behaviours [28]. Within this taxonomy, the structural components are identified as social features,

manipulation and control features, narrative and identity features, reward and punishment features and presentation features. This has been a helpful approach to operationalise within research, which has revealed differences in how these structural components relate to different gaming behaviours [29]. For example, reward and punishment features (e.g. finding rare items and earning points) and manipulation/control features (e.g. mastering controls and managing game resources) were some specifically highlighted features which interact with players' perceptions of the game and the likelihood of problematic patterns of play [31]. In line with the notion that reward features may encourage problematic play, other researchers have highlighted the limiting effect of the "random reward ratio" and instead indicated a more fixed ratio pattern would be a way of designing more ethical multiplayer online role-playing games [35]. Further, in relation to smartphone games, an analysis of player reviews has found that games being described as "challenging" is the most common keyword associated with them being perceived as "addictive" [3]. In general, a recent review article summarised that based on the current literature on structural characteristics of digital games, it is primarily the features of games which take a long time to achieve which are most likely to be associated with problematic play, such as mastering challenges and earning experience points [18], which is in line with the game mechanics of motivation having been found as predictive of addictive MMORPG play [43].

Based on the fact that the empirical literature has revealed structural components of games to be influential in varying gaming behaviours, it seems logical to assume this would also impact upon excessive gaming which may translate to behaviours synonymous with addiction. This presents an issue when scrutinising the currently available literature referring to IGD and GD, given that studies have largely failed to specify the game type within empirical enquiry. As such, an assessment of the available literature therefore suggests that we perhaps know a lot about IGD, but not how this may vary by game type. Considering game type may be widening the debate about diagnostic criteria, and perhaps, the game-type issue is relevant to the understanding of players' problematic experiences of games.

The clinical implications of this are noteworthy and highlight that any associated treatment plans might benefit from specificity in respect of the "game" aspect of "gaming addiction". A way forward with this may be realised through applying the aforementioned taxonomy approach for characterising structural game features in respect of their presence and importance for players of different types of games. Using this taxonomy as a basis, empirical research has found it to underpin different typologies of players [68]. That is, six types of gamers have been found: story-driven solo gamers, social gamers, solo limited gamers, hardcore online gamers, solo control/identity gamers and casual gamers [68]. Therefore, it may be that such an instrument can form a part of a screening protocol, whereby there is at least some additional intelligence as to how the game type interacts with individual and contextual components of gaming behaviour.

Recommendation 2
Use the video game taxonomy [28, 29] to identify game-specific components associated with gaming-related problems and addiction symptoms.

68.3.2 Gaming Function

As well as games themselves being diverse, gaming behaviours can also be rather varied. In part, this can be related to specific game types (as previously noted) but may also be represented by the fact that there may be different functions of gaming for different players [23]. For example, although most players will engage in gaming for leisure purposes, gaming can also function as a professional domain for many. That is, esports is becoming increasingly recognised as a mainstream sport in which athletes (the terminology here being pertinent to distinguish them from

being "players" or "gamers") undergo intense training and compete in professional tournaments, akin to the rituals which are commonplace for other professional sportspeople or athletes. Esports has garnered interesting debate, particularly in respect of it being more typically conceptualised as a professional sport rather than gaming [10, 20]. As such, although the medium of this activity is digital games (e.g. usually through online multiplayer games such as *League of Legends*), the domain itself is considered professional sport, so it is questionable whether the function of gaming should actually be considered under the umbrella of "gaming", which might have implications in light of IGD or GD. A number of empirical questions can be derived from this issue which should be answered in future research: (1) Does IGD or GD occur in professional esports? (2) Is this related to being successful or unsuccessful? (3) How does the motivation to become an esports gamer contribute to developing signs of addictive use?

68.3.3 Gaming Forms

Beyond gaming functions varying between being professional and leisure-related, there are other conceptual distinctions to be drawn out, particularly in respect of the form of gaming. This includes whether gaming behaviour is considered "hardcore" or "casual" [22]. Within this, casual gaming would be typically represented by someone who plays "easier" or "lighter" games, often in short burst rather than longer uninterrupted sessions, which would be more typical in their hardcore counterparts [11, 21, 38]. Variations may also be found in the consoles which are used between these two forms of gaming, in which hardcore gaming may often be more likely to take place on console or PC devices and casual gaming usually on mobile devices [23]. Clearly, there are some variations present in the behaviours afforded to these forms of gaming. In respect of the current literature particularly on IGD, because studies tend to hold a generic reference point as "online games", this may be capturing players across a continuum of both hardcore and casual players. This could benefit from a more specific enquiry in which distinction is drawn out further to more fully establish gaming behaviours between these distinct forms. This is important as it can help provide a more informative account of how IGD and GD may be represented differently in theoretically varied patterns of play or players. Although it is conceivable that IGD and GD would not be so highly prevalent in casual gaming, establishing empirical evidence to ascertain this is still warranted.

This chapter so far has provided an overview of some conceptual-based challenges which exist in relation to the current understandings of IGD and GD. However, from an empirical standpoint, there are also some methodological issues to highlight, which bring into question the validity of measurement tools within this field. These are discussed next.

68.4 Behavioural Measures

Academic approaches to understanding problematic or addictive technology use, including gaming, have typically relied on self-reports of individuals' personal experience with a given technology [13]. One exception here is the work on gambling which, in a number of cases, has capitalised on online behavioural tracking data to understand gambling intensity and "at-risk" users (see [17] for an overview). However, in respect of digital gaming and indeed the vast majority of empirical work on problematic technology use, this approach has been largely omitted. Commentators in this field would argue that this is problematic based on the fact that users' estimates of their technology-related behaviours are often inaccurate [2], and psychometric scales used to measure "addiction" (particularly in respect of smartphones) are not likely to be sensitive enough to predict technology use behaviours [12]. As such, this raises queries surrounding the validity of psychometric scales used within empirical enquiry and screening protocols for assessing gaming-related addictions.

In general, the methodological approaches to assess IGD and GD are characterised by a num-

ber of weaknesses and do not reach the common standards found in mental health [62]. The instruments used in the academic literature as a means of measuring aspects of gaming addiction include the Internet Gaming Disorder Scale-Short Form (IGDS9-SF; [57]), the IGD-20 [58], the IGDT-10 [32], the Game Addiction Scale [45] or adapted scales from those validated for pathological gambling [15], as well as those adapted from Young's [73] more generic classification of "internet addiction" (e.g. Problem Video Game Playing Test [31]). Unfortunately, none of these instruments have been validated against behavioural metrics which correspond to gaming behaviour, so the extent to which these may be entirely valid as a means of understanding facets of gaming addiction is unclear. In particular, garnering user data could be specifically informative for understanding diagnostic criteria relating to tolerance to gain objective measurements on the way.

Recommendation 3
Make use of digital data garnered through gaming platforms and user metrics to gain more objective data to corroborate with existing instruments.

Offering an alternative approach, it has been noted that an area of promise in the study of technology use may be to move away from "addiction" or "problematic use" [33] and instead focus on cognitive usage, such as attentional lapses and mind wandering in respect of specific technology use [12, 13, 48]. This notion is also supported by evidence suggesting that implicit cognitions associated with technology usage may hold some merit in understanding the underpinning processes, which may translate into addictive behaviour [12, 13, 69]. This is further supported by neurobiological and neurophysiological evidence that those labelled as having IGD show poorer cognitive control and are more prone to attentional bias towards game-related cues than healthy controls [25, 44], which has been verified largely in experimental research [52]. This can go beyond self-report, which may only measure expectancies associated with a given behaviour and be subject to judgement-memory relationships which may compromise one's perceptions of one's behaviours [14, 72]. Therefore, obtaining more implicit association measures which may capture attentional bias or cognitive salience may be a worthy candidate for further study in relation to gaming-related addiction. In particular, this may provide corresponding evidence for diagnostic criteria relating to salience or preoccupation.

Recommendation 4
Explore the use of implicit association measures to further explore cognitive and attentional processes underpinning gaming behaviour.

At the same time, it is important to mention that measures based on tracking or implicit associations have practical limitations and cannot be used as easily as self-report questionnaires. Furthermore, the more disguised assessment with new methods might have implications on the motivation to participate in screenings or diagnostic procedures. Therefore, self-report measures might be more appropriate for reaching large groups in epidemiological surveys or for the purpose of case finding for preventive measures. At the same time, indirect technology-based assessments might be feasible and important in clinical settings which will be outlined below.

68.5 Clinical Implications

Based on the commentary provided within this chapter, a number of key issues are presented which hold practical implications for clinical practice. These are summarised in Table 68.1 for ease of reference.

In general, these represent both conceptual and methodological challenges to the current understanding of IGD and GD. In general, the literature suggests that there is insufficient evidence from

Table 68.1 Summary of issues outlined with suggested recommendations and implications

Issue	Recommendation	Clinical implications
Observed distinctions between addiction symptoms and gaming-related problems which often are not accounted for in academic practice or health policy	Latent class analysis approaches which may reveal distinct player classes	More specific or tailored treatment provision which may vary between being more game-focused (gaming-related problems) and more generic (addiction symptoms)
Game types are not specified in health policy	Video game structural taxonomy scale as part of clinical screening	More specific insight into the interaction of game-related components within symptomology to better inform treatment provision
Psychometric gaming addiction scales may be inaccurate and lack validity to actual behaviours	Make greater use of digital data garnered through gaming platforms and user metrics	Clinicians will have objective data to corroborate with existing assessment instruments to ensure adequate validity. Particularly relevant for understanding tolerance
Self-report measures may capture cognitive expectancies and not predict behaviour	Explore further use of implicit association measurements	Clinicians will have additional approaches to assess cognitive saliency or attentional bias as part of screening and/or assessment practices. Particularly relevant for understanding preoccupation or salience

treatment studies which can confirm the long-term benefits of gaming addiction treatment interventions [26, 37]. However, a current randomised controlled trial confirmed short- and long-term efficacy of a cognitive behavioural therapy approach [70]. For preventive and policy measures, the evidence base is relatively sparse [27, 56], and there is clearly a paucity of brief intervention studies [61]. Treatment and prevention approaches may benefit from the aforementioned issues. This may include paying more attention to the nuances of game-specific components, which interact with individual- and contextual-level factors to determine gaming-related cognition and behaviours. Further, the empirical literature itself would greatly benefit from more intricate and objective approaches to garnering users' gaming data to correspond with widely used psychometric instruments in this field. This may help enhance the validity of measurement tools in this area, and this serves to underpin the ongoing empirical work committed to better understanding IGD and GD.

In conclusion, although there is a large quantity of academic work in this field, particularly framed in relation to IGD, there remains a lack of sufficient attention to game-specific enquiry, which may contribute in improving treatment and prevention. Given that different types of games, often based on their structural characteristics, result in varying psychological affordances and playing behaviours, it is pertinent to include further detailed guidance on how these components interact with individual- and contextual-level factors in fostering problematic gaming behaviour. Further, this endeavour may also be supported concurrently by considering how this relates to gaming-related problems (as a distinct category from addiction symptoms), whereby some distinction may be drawn for establishing different classes of players to better establish "at-risk" candidates. Both these recommendations acknowledge the role of empirical approaches to support this, whereby academic evidence can help better inform clinical practices. In addition to this, empirical approaches can also be aided through corroborating objective behavioural tracking data particularly to understand tolerance and preoccupation as two key addiction symptoms which may relate to problematic rather than addictive gaming behaviour. These may therefore support existing screening and assessment practices by ensuring that these are sufficiently valid instruments to use within academic and clinical practice to measure GD and IGD. One could speculate that teasing out the aforementioned nuances may increase knowledge on GD and IGD and thus set up a precedence for more efficacious treatment and intervention provision.

Compulsive Buying Disorder

69

Tatiana Zambrano Filomensky
and Hermano Tavares

Contents

Abstract

The increasing availability of credit has made buying a frequent behavior in everyone's life. Compulsive buying disorder (CBD) is characterized by loss of control over buying, accruing debts and psychosocial distress. Reported by the founding fathers of modern psychiatry, Kraepelin and Bleuler described it as a monomania and named it oniomania. CBD may have a profound impact upon both individuals and society; however, it remains absent from current diagnostic classifications. There are still doubts regarding the psychopathology and nature of CBD; some regard it as a behavioral addiction or a member of two different groups either the bipolar spectrum or the obsessive-compulsive spectrum of disorders. Conservative estimates describe a prevalence of around 2% in the general population with an extra 6% at risk for CBD. An association with female gender is usually described, but it

has been recently challenged. The CBD construct is based upon three concepts: emotional activation, urges, and affect regulation. Current and lifetime psychiatric comorbidities are usual among treatment-seeking compulsive buyer, respectively 50% and 90%; the most common are mood, anxiety, and impulse control disorders. Accounts of subtypes of CBD patients describe a thrill and pleasure-seeking impulsive type and an emotionally stricken compulsive type. Selective serotonin reuptake inhibitors (SSRIs) in general and citalopram in particular have been used to treat CBD, but so far, its efficacy remains undetermined. Modulation of dopamine pathways within the brain reward system has been speculated as a promising pharmacological approach. So far, the best evidence-based treatment approaches come from cognitive behavioral models.

Compulsive buying · Behavioral addictions · Impulsivity · Compulsivity · Neurobiology · Treatment

69.1 Introduction

Since antiquity, the act of buying has been present in society. The emergence of currency modified cultural and moral values, marking a period in which power went from being determined by the family name to being defined by commerce, gaining momentum with the adoption of monetary systems [85]. The act of buying continued to distract and enrapture people throughout the subsequent millenniums, driving commerce and influencing governmental structure. The lack of control over this behavior aroused the concern that we could be facing a clinical disorder.

Compulsive buying disorder (CBD) was described at the beginning of the twentieth century by two descriptive psychiatrists, Kraepelin and Bleuler. Both founded their descriptions on Esquirol's concept of monomania. Kraepelin, the first to elaborate the syndrome, titled it oniomania – from the Greek words *onios* (for sale) and *mania* (insanity), describing it as a pathological impulse. He underscored the predominance of the female sex and believed that oniomania would be a subclinical variation of kleptomania. Bleuler emphasized the impulsive nature of the disorder and likened it to the insanities of impulse along with pyromania (apparently much more abundant at that period than it appears to be today) and kleptomania [81].

CBD did not arouse the interest of researchers in the following decades, except among those studying consumer behavior [81] as well as psychoanalysts that elaborated case reports [49]. During the early 1990s, three independent clinical case series studies involving 90 individuals were published, after which CBD once again returned to be globally discussed [9, 77], with reports originating from countries such as Germany, Brazil, Canada, France, England, and the United States [81]. This renewed interest was probably fostered by the perception of the profound impact that CBD may have upon individuals as well as on society. Indeed, it is estimated that in the United States, compulsive consuming generates more than US$4 billion in annual purchasing.

Despite being described by researchers and scholars for more than a century, CBD continues to be, inexplicably, undefined and understudied. It is absent from modern classifications in psychiatry, except possibly for classification in the residual category of disruptive, impulse-control, and conduct disorders in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), including the subgroup of impulsive disorders featuring loss of control over specific behaviors, alongside pyromania and kleptomania [1]. CBD could also be regarded as an addiction. Indeed, it was briefly cited in the introduction of the substance-related and addictive disorders chapter in the DSM-5, as a potential addition to the realm of behavioral addictions, currently represented solely by gambling disorder in the aforementioned chapter. The scenario is even bleaker in the case of the International Classification of Diseases of the World Health Organization, since

CBD was not even mentioned on either its previous tenth edition or its latest, the 11th edition. The debate over CBD's classification has made little progress, so far.

The first accounts of CBD classification tended to regard it as an addiction [32]. In accordance with this view, Nataraajan and Goff [66] described two independent factors related to the occurrence of a compulsive buying episode: an urgency or desire to buy and loss of control over buying. Others consider CBD to be an excessive behavior secondary to mood disorders, associated within the frameworks of mania, hypomania, or mixed episodes in bipolar disorder (BD), or as a subsidiary symptom of hoarding, on the obsessive-compulsive disorder spectrum [27]. In one of the few attempts at empirically clarifying this matter, Filomensky et al. [27] investigated 80 individuals undergoing outpatient treatment for either bipolar disorder, OCD, or CBD, regarding impulsivity, obsessive-compulsive traits, hoarding, and mood spectrum of symptoms. Compared to the other two conditions, CBD patients scored significantly higher on all impulsivity measures and especially on the non-planning subdimension. In the hoarding spectrum, they scored higher on the acquisition subdimension, but not for difficulty discarding or cluttering subdimensions. Manic symptoms were distinctive of BD patients, while elevated scores on the contamination/washing and checking dimensions differentiated OCD patients. A discriminant model built with these variables correctly classified 79% of the CBD outpatients, 71% of the bipolar patients, and 77% of the OCD. The authors concluded that given the high impulsivity involved and the intense acquisition desire, CBD, like gambling disorder, was closer to a behavioral addiction.

There is also a stream of researchers who criticize the attempts to classify compulsive consumption as a disorder, stating that it implies medicalization of variations within the spectrum of consuming behaviors [47]. Unfortunately, this view ignores the reality that CBD is a prevalent and severe syndrome and stigmatizes the attempts to recognize, understand, and treat the condition.

69.2 Epidemiology

Studies estimating the prevalence of CBD in the general and in specific populations report rates of approximately 2% to 8%. In spite of the increasing scientific and layman interest in the disorder, there is no evidence to suggest that the prevalence of CBD is increasing. A recent meta-analysis examined 40 studies from 16 different countries (n = 32,000). The pooled prevalence rate in adult population was 4.9% (3.4–6.9%), with a higher estimate for young individuals, specially university students reaching 8.3% (5.9–11.5%), and for individuals approached in shopping sites 16.2% (8.8–27.8%). The usual assumption that highly industrialized developed societies with a higher level of consumption would favor the expression of CBD was somewhat challenged since location, i.e., the United States versus other countries, did not present meaningful associations. Nonetheless, comparisons between jurisdictions and diverse cultural milieu were hampered by considerable sample heterogeneity, mainly due to diverse CBD screenings and varying time frames (current versus lifetime). The female gender was strongly associated with CBD as usual [53, 54].

Indeed, previous reports had already pointed to a male-to-female ratio around 1:4 to 1:5, however, they were almost all conducted in clinical settings [27]. Kraepelin and Bleuler had already proposed the predominance of the female gender in CBD, suggesting that the female compulsive buyer was in search of risk and excitement, much like the risk-seeking behavior in male gambling. For Dittmar and Drury [18], the prevalence of the female gender in CBD appears as a compensation strategy to combat negative emotions and low self-esteem. They state that the gender difference is genuine and should not be attributed to the underrepresentation of males in clinical samples, basing their conclusion in a study conducted in the general population of the United Kingdom, in which 92% of the respondents considered compulsive buyers were women. Conversely, Dittmar [19] carried out another survey about consuming behaviors in adolescents, between the ages of 16 and 18. The results indicated a CBD

prevalence ratio similar to the adult survey but without gender imbalance. The same was observed by Lejoyeux et al. [52] while investigating the occurrence of CBD in medical students. Thus, it seems that this gender imbalance is likely to appear in younger samples. There are also relevant differences regarding the sample source (clinical site versus general population) and the method of data collection (face-to-face interview versus anonymous survey). For example, a study by Koran et al. [43] interviewed approximately 2500 American adults through an anonymous telephone questionnaire. They determined a CBD prevalence rate of about 5% and a ratio of men to women of 1:1, which indicates a rather larger participation of men than usually reported.

Nonetheless, gender differences seem relevant and considerable in CBD in a varied set of aspects such as demographics, psychiatric comorbidities, and features of the buying behavior itself. A Brazilian study [12] investigated gender differences in CBD treatment-seeking individuals. Compared to the female compulsive buyer, the male compulsive buyer was more often of non-heterosexual orientation, had fewer years of education, and was more often diagnosed with sexual addiction and intermittent explosive disorder, suggesting a more severe and impulsive presentation. Conversely, a Chinese study in college students found differences in the mediation of the compulsive buying behavior with mood compensation strategies working as a significant mediator for women, but not for men [7]. Finally, regarding favored purchasing, the differences are also noteworthy, with female compulsive shoppers targeting mainly clothes, handbags, shoes, perfumes, makeup, and jewelry while men prefer electronics and objects that display elevated social status such as expensive suits, watches, electronic gadgets, and cars [4, 9, 55].

69.3 Course and Consequences of Compulsive Buying Disorder

It is believed that CBD begins toward the end of adolescence, around 18 years of age, or at the beginning of adulthood. This is the period in which the adolescent develops more autonomy and emancipation from the nuclear family, when they are likely to acquire credit for the first time [4]. Nevertheless, the perception of buying behavior as a problem occurs later, around 30 years of age, and treatment seeking between 31 and 39 years of age.

Before 18 years of age, uncontrolled buying is generally associated with a more diffuse general pattern of behavioral disinhibition, which can include smoking, alcohol and drug misuse, and premature sex [74]. Besides, 24-hour shopping made possible by online credit card purchasing could be a contributing factor to adolescent onset. Indeed, it has been reported that among computer compulsive users, up to 19% would fulfill criteria for CBD [4]. In view of this fact, it is likely that some compulsive shoppers will enter their adult lives already with a substantial debt.

CBD is commonly associated with severe personal impairment, both financial and familial, as well as other psychiatric disorders, including personality disorders [4, 81]. Although there is a lack of longitudinal studies for CBD, some studies indicate that the course of the disorder can be chronic or recurrent [9, 77]. However, the treatment of CBD can modify the course of the disorder, as shown in a study in which patients who responded to treatment with citalopram maintained states of remission in 1 year [42]. More recently, Black et al. [5] published a 5-year follow-up of 17 CBD individuals. Psychiatric comorbidity had significantly decreased at follow-up, interest and actual shopping also decreased for roughly half of individuals, and 18% reported having overcome CBD. However, CBD revealed a mostly recurrent nature with usual triggers such as urges to shop, boredom, negative emotions, and the desire for positive emotions. CBD severity was significantly associated with mood disorders both at baseline and follow-up, and although on average severity and impulsivity decreased over the course of 5 years, the majority of individuals still had ongoing symptoms of CBD. However, the small sample size of this study compromises the generalization of its findings to CBD individuals in general.

Perhaps, the most meaningful longitudinal study on CBD to date was performed by Zhang et al. [88]. They conducted a survey on residents of two New York counties (N = 548), who were followed from adolescence until their forties with a focus on quality of life and cost of CBD. The main findings were CBD was associated with a significant decrease in quality of life and family income, even after controlling for demographics and concurrent mental health issues. Quality of life and family income had a significant but weak association (16% of variance explained); however, the monetary cost of CBD was not trivial, subtracting an estimated amount of US$138,000 per family income. In other words, CBD weighs upon the individuals and their families in two fronts: well-being and financial health.

69.4 Diagnosis and Assessment Scales

Usually, compulsive buying episodes occur in a solitary manner, routinely, or in the form of purchasing binges. Sometimes to lessen the guilt, compulsive buyers will also buy for their partners, family members, or friends. When buying for themselves, they often – though not necessarily – hide the objects in closets, drawers, or the car trunk. Many of such purchases may never be used. There is no pattern to stores or commercial places in which these episodes of excessive spending occur; however, buyers do have their "favorite" shopping places, catalogues, and online sites. A study that evaluated excessive Internet use among compulsive and non-compulsive buyers concluded that buying through the Internet is more common among compulsive buyers. The same applies for purchases made through the television [60].

In 1989, O'Guinn and Faber defined compulsive buying as an addictive behavior characterized by "a response to an uncontrollable drive or desire to obtain, use, or experience a feeling, substance, or activity that leads an individual to repetitively engage in a behavior that will ultimately cause harm to the individual and/or others," underscoring the chronic and repetitive nature of CBD [81]. Valence and colleagues (1988) proposed that CBD was a three-pillar construct defined as 1) a strong emotional activation when exposed to a shopping environment and shopping opportunities, 2) tension and buying urges elicited by the exposure to such stimuli, and 3) shopping and buying as means to obtain affect regulation, shortly lived because it is usually followed by post-purchase guilt [84] Moreover, it is likely that later negative consequences (indebtedness, family and friends' reproaches, etc.) enhance the negative affective state, which in turn will lead to stress-relief-seeking behavior through further shopping and buying, thus closing a cycle of self-reinforced behaviors. Both groups of researchers developed their own scales based on these roughly equivalent approaches to CBD. One study pointed to the complementary nature of these scales, reflecting the interrelated aspects of both models. Although subtle, the difference between shopping (perusing showcases and malls and analyzing objects in display) and actual buying (the exchange of money for the acquisition of a desired object) seems relevant. Indeed, it appears that Valence's approach has a better focus over shopping behavior and its effect over affect regulation, while Faber and O'Guinn's perspective seems to better capture the extremes of uncontrolled buying, associated behaviors, and consequences. Thus, their scale may be better suited for the assessment of clinical samples. In both cases, the models suggest that CBD cannot be characterized solely by impulsive purchasing, which for that purpose has to be combined with attempts at emotional self-regulation by shopping and buying.

In 1994, McElroy and colleagues proposed the following diagnostic criteria for CBD, emphasizing the inability to resist the impulse to buy:

A. Maladaptive preoccupation with buying or shopping or maladaptive buying or shopping impulses or behavior, as indicated by at least one of the following:
   1. Frequent preoccupation with buying or impulses to buy that is experienced as irresistible, intrusive, and/or senseless.

2. Frequent buying of more than can be afforded, frequent buying items that are not needed, or shopping for longer periods of time than intended.

B. The buying preoccupations, impulses, or behaviors cause marked distress, are time-consuming, significantly interfere with social or occupational functioning, or result in financial problems (e.g., indebtedness or bankruptcy).

C. The excessive buying or shopping behavior does not occur exclusively during periods of hypomania or mania. These criteria are currently the most employed, despite the scarcity of studies endorsing their validity and reliability. Although the lack of official and specific diagnostic criteria for CBD remains, McElroy's criteria have been internationally adopted, and it has been the diagnostic reference for almost all studies conducted on CBD until now.

It is important to differentiate normal from uncontrolled buying. Essentially, the distinction is not based on the quantity of money spent in relation to the income level, but on a subjective feeling of irrepressible urges to buy, the experience of being out of control while buying (e.g., feeling as if one's behavior was led by an external force), the extent of worry, the degree of distress suffered by the individual, and the appearance of adverse and negative consequences. At any moment of their lives, people may experience an occasional shopping binge, particularly in special occasions such as birthdays or holidays. However, isolated episodes of unrestrained buying should not be confused with CBD's impulsive, harmful, and recurrent purchasing.

Several researchers have developed instruments for the investigation and diagnosis of CBD, or for severity assessment. The Minnesota Impulsive Disorders Interview (MIDI), developed by Christenson et al. [9], is a semi-structured interview, which evaluates the presence of CBD, kleptomania, trichotillomania, intermittent explosive disorder, compulsive sexual behavior, pathological gambling, and compulsive exercise. Grant et al. [34] report that based on McElroy's criteria for CBD, the MIDI presented a sensibility of 100% and specificity of 96%.

Faber and O'Guinn's [22] previously mentioned scale, the Compulsive Buying Scale (CBS), is a 7-item self-report one-dimension scale with high internal consistency (Cronbach's alpha = 0.95) that seems to reliably distinguish normal from compulsive buyers, with estimated sensitivity of almost 90% and 85% of specificity.

Monahan and colleagues adapted the Yale-Brown Obsessive-Compulsive Scale (YBOCS – 1989) to measure the severity of CBD. The YBOCS-Shopping Version (YBOCS-SV) evaluates cognitions and behaviors associated with CBD. It has been mostly used to assess the effects of treatment in clinical trials. The mean pre-treatment score for CBD patients was 21 (range 18–25), which was grossly larger than the mean score of 4 (range 1–7) for healthy controls. Unlike the other scales that base their approach on the impulse control disorder framework, due to its original source, the YBOCS-SV is able to tap into compulsive aspects of CBD [26].

In that sense, the Richmond Compulsive Buying Scale is unique in its attempt to combine both impulsive and compulsive aspects of CBD. The authors also tried to address another conceptual limitation due to a tautological flaw in the definition of psychiatric disorders by which a behavioral syndrome constitutes a disorder because it implies negative consequences and the reason why it causes negative consequences is because it is a disorder. Thus, Richmond's CBS focuses on behavioral aspects of buying rather than shopping and purposefully avoids tapping into negative consequences. It has convergent validity with Faber and O'Guinn's CBS, and its 6-item simple structure makes it feasible for population surveys [13, 14].

Finally, the Compulsive Buying Follow-up Scale (CBFS) was developed with the goal of providing periodic assessment of individuals undergoing CBD treatment and identifying clinical recovery. It contains six multiple-choice questions and can be used as either self-report or interview format, tapping into compulsive buying frequency, time and money spent buying, craving

for shopping, debts in relation to one's income, and emotional distress due to compulsive buying. The CBFS presented significant correlations with all scales cited above as well as measures of depression and anxiety, with sensitivity to change and accuracy for detecting clinical recovery. Its simple structure makes it useful for repetitive assessments in clinical sites [14].

69.5 Psychiatric Comorbidity and Relationship with Other Mental Disorders

The association of CBD with other psychiatric disorders is the rule rather than the exception, with comorbidity most often seen with mood, anxiety, hoarding, substance use, eating, and other impulse control disorders [3, 4, 9, 55, 62, 65, 68, 77].

A bicentric study analyzed data from US and German treatment centers and found that approximately half of the sample had at least one current psychiatric comorbidity, mainly an anxiety disorder, and that 90% fulfilled criteria for at least one Axis I diagnosis during the lifetime. The main diagnoses were mood disorder (74%), anxiety disorder (57%), and impulse control disorder (21%) of which intermittent explosive disorder was most common [59].

It is not uncommon for CBD patients to build up collections of similar items varying one single aspect, e.g., color, size, or design, to zealously stock and hoard them, not allowing other people to interfere with them. For this reason, a relationship with obsessive-compulsive disorder (OCD) has been speculated. However, there have been few studies on this topic. Only one study found a relevant association, reporting that seven (35%) out of 20 patients consecutively admitted for CBD treatment had a lifetime diagnosis of OCD [55]. Conversely, CBD has been described as a frequent comorbidity among OCD and eating disorder patients [24, 25]. In OCD, the association with CBD has been related to an impulsive subtype, with more depression and alcohol-related symptoms ([21, 51]). A more recent and larger study conducted in multicenter study treatment-seeking OCD patients (N = 993) found that 7.5% of participants had comorbid CBD. CBD was associated with female gender, hoarding symptoms, poorer insight, social phobia, binge eating disorder, Internet use disorder, and kleptomania [40]. The hoarding behavior seems to be the psychopathological link between the two disorders [27] and for both of them a marker of a compulsive trait and severity [30]. For CBD, severity goes hand in hand with psychiatric comorbidity; thus, presence of hoarding behavior is associated with mood, anxiety, and eating disorders [45].

With regard to personality disorders, very few studies have investigated Axis II disorders in the population of compulsive buyers. The two most important studies revealed that the disorders most observed were from clusters B and C: borderline, obsessive-compulsive, and avoidant personality disorders. The first study demonstrated that around 60% (N = 46) of the compulsive buyer patients presented with at least one of the personality disorders mentioned above [77] and the second around 73% (N = 30) [62]. More recently, a study with a large sample among patrons of a shopping mall (N = 1409) investigated the relationship between CBD and borderline personality disorder (BPD); 26% of CBD individuals fulfilled criteria for BPD. This relationship was mediated by self-esteem, impulsivity, and general psychiatric distress, again with a modulation effect from gender with distress and self-esteem being more relevant, respectively, for men and women [53, 54].

Finally, a relationship between Parkinson's disease and behavioral addictions, or hedonic impulsive behaviors, including shopping and buying, is an ever-growing issue. Whether it remains controversial if behavioral addictions are more frequent in de novo Parkinson's patients, there is no doubt about the relationship between high incidence of those disorders and treatment with dopamine agonists. However, with CBD being such a prevalent disorder in the general population, the prevalence ratio between Parkinson's patients and non-Parkinson's individuals does not seem particularly imbalanced, quite different from gambling, binge eating, and hypersexuality with their

frequencies varying from two to five times higher for Parkinson's patients [31]. Nonetheless, clinicians should be aware of the increased risk of precipitating maladjusted, hedonic, impulsive behaviors (including buying) for patients undergoing treatment with dopamine agonists. Having previously experienced difficulties with those behaviors is certainly a risk factor for developing behavioral addictions when initiating treatment with dopamine agonists. This risk could be greater for dopamine agonists with a higher affinity for the D3 receptor; for instance, the frequency of such behaviors in Parkinson's patients treated with pramipexole as an add-on agonist was as high as 32% [78].

69.6 Psychopathology Dimensions

The compulsive buying phenomenon could be approached from three concentric strata. The first and most inner one is related to temperament traits and basic drives. The second one comprises attempts at self-regulation and construction of a self-image, and lastly, the most external strata relate to the interface between the individual and societal and culturally bound values.

In the inner stratum, the feature that most clearly comes to light is impulsivity. The evidences of an association between CBD and impulsive traits of personality and impulse control disorders are abundant [63, 64]. This seems to be a feature shared between all the so-called behavioral addictions, with evidences pointing to impulsivity as a preceding factor, like in gambling disorder [70]. Unfortunately, the cross-sectional nature of almost all studies on CBD precludes causality assumptions between impulsivity and loss of control over buying. Moreover, there is still an open question which is what is fueling the loss of control and driving the behavioral response? The recurrent association with hoarding symptoms hints that these patients are led by an acquisition drive [27]. The evidences of an association between buying and eating point to a potential common root, a primal drive toward perusing the environment in search of valuable resources that must be collected and stored either in one's own body as energy reserve (i.e., fatty tissues) or in one's wardrobe or kitchen cabinet. Along those lines, De Mattos and colleagues (2018) reported that mild to moderate (17.6%) and severe (18.6%) binge eating disorder were common in treatment-seeking CBD patients, as well as hoarding symptoms. Additionally, the relationship between severity of binge eating and CBD seemed mediated by hoarding, specially by the clutter dimension.

Advancing to the second stratum, the self-regulation one, a study investigated inhibitory control in CBD. Compared to normal controls, CBD individuals had poorer performance at a go/no-go task and had an even worse performance after a negative mood induction experience [67]. Negative emotions such as anger, anxiety, boredom, and self-criticism have been related to compulsive episodes of buying [56]. When pressured by an intense negative affective state, the CBD patient feels the need to quickly perform a purchase, regardless of the nature of the purchased object, or they may feel a need to purchase an object to which they are particularly fixated, e.g., a nail polish flask and a CD of their favorite artist [81]. The consummation of buying is accompanied by immediate relief of the negative affective but is often shortly followed by unpleasant feelings such as guilt or regret. Several authors underscore this narrow association between buying and the need to regulate negative affective states [10, 23, 60].

In the cognitive sphere, compulsive buying episodes have been associated with means of identity building, "all or nothing" attitudes toward money, hindsight appraisal of purchasing, and gift buying as a way to garner affection and avoid embarrassment [26, 57]. Difficulties at self-regulation and identity building have been assigned as core features of narcissistic personalities and usual features of CBD as well. Indeed, studies have found positive associations between narcissism and compulsive buying. Furthermore, the relationship between impulse control and buying behavior was negatively mediated by materialism, defined as a tendency to consider material possessions and physical comfort as

one's primary source of well-being [75]. On a multilevel approach to personality and individual differences, extrinsic life aspiration factors like financial success, attractive self-image, popularity, and conformity to societal expectations were able to predict CBD beyond basic personality traits [69], which points to the third stratum, the one related with societal norms and values.

Materialism as a life perspective is largely encouraged in our postmodern, consumer-driven behavior societies [73]. As a matter of fact, in comparing full-fledged CBD and moderate risk buyers, Jung and Yi [39] found that narcissism differentiated both groups, but not materialism, suggesting that the latter had a wider unspecific determination over consumer behavior. However, social-cultural factors alone cannot be blamed for CBD occurrence, but it is important to consider their influence. The easy access to growing amounts of credit is a worldwide phenomenon, and in the last decades, there have been a shift in advertising strategies from focusing on the qualities of the purchase to how good purchasing makes you feel [4].

An almost universal selling strategy is to anticipate the pleasure of the acquisition through credit card shopping or other option and to delay the "pain" of payment, to which impulsive individuals may be particularly vulnerable. Indeed, several measures of compulsive shopping have a strong correlation with credit card use and credit card minimum payment [22]. The credit card has become a cultural icon, going beyond a mere form of modern "plastic cash," something particularly noticeable in developing economies, and most appealing to vulnerable women as a promise of more autonomy in societies largely dominated by men [4].

69.7 Subtypes of Compulsive Buyers

Based on the profile of psychiatric comorbidities and the abovementioned psychopathology dimensions, researchers have tried to define subtypes of CBD. De Sarbo and Edwards [16] described two subtypes of compulsive buyers: one group in which the principal trigger of a compulsive episode was the materialism and desire for objects with a tendency to be more impulsive and the second group in which the compulsive episode was more motivated by internal emotions such as low self-esteem and little control over the desire to buy. This second group presented with a higher propensity to develop depression. Likewise, another study pointed to two distinct groups among compulsive buyers: one group in which the motivation for the purchase was guided by positive reinforcement related to pleasant aspects of the purchase and the other in which the purchase occurred as a result of emotional suffering associated with financial problems, interpersonal relationships, and emotional questions, revealing a group with significantly higher levels of debt [83].

Therefore, like previously described for pathological gambling, CBD seems to encompass a double nature, an impulsive side related to purchase cravings and lack of planning and a compulsive side characterized by the avoidance of negative emotions and attempts to control one's affective state; both combined lead to loss of control over buying. The determination of the subtype depends upon which side prevails [80, 87].

69.8 Neurobiology, Genetics, and Risk Factors

Family studies of compulsive buyers show a heavy concentration of mood, anxiety, and eating disorders, substance use, and other impulse disorders, including CBD itself. Evidence also exists showing that traumatic childhood events such as sexual abuse are factors that predispose the development of CBD [4, 55]. A study of 370 gynecology patients investigated the relationship between five traumatic experiences in childhood (before the age of 12) and CBD. The results indicated that childhood trauma is associated with compulsive buying behavior, particularly when the trauma was emotional in nature or involved witnessing violence [76]. However, there are no data on how childhood trauma and early adversities can build a specific vulnerability to consum-

ing behavior or if it would be an unspecific vulnerability factor for various psychiatric syndromes.

There are few neurobiological studies of CBD, and most are concentrated on the loss of regulation over the serotonergic, dopaminergic, and opioid neurotransmission. Due to the diagnostic doubt that haunts CBD, researchers who note similarities between CBD and OCD use selective serotonin reuptake inhibitors (SSRIs), as it is a common and effective treatment for OCD, but so far, its efficacy in CBD and the role of serotonin transmission in CBD remain undetermined [4, 42]).

Potenza [71] proposes that compulsive purchases, pathological gambling, and other self-indulgent behaviors are related to factors involving low dopaminergic activity, the so-called brain reward deficiency syndrome (BRDS). Thus, the preferred biological tools to intervene in CBD would be those directly or indirectly modulating dopamine transmission, through opioid and glutamate modulation, in the brain reward system. Few reports have suggested the benefits of treating CBD with the opioid antagonist naltrexone, raising speculations about the role of β-endorphin and opioid receptors in CBD [33]. A preliminary study with memantine, an antagonist of the N-methyl-D-aspartate receptor, resulted in reduced glutamate excitability, in addition to improving the compulsive buying behavior of patients with CBD [35]. In any case, proposals regarding neurotransmission remain up to now speculative, with no studies so far having directly examined the neurotransmitters involved in CBD, through either plasma levels or cerebrospinal fluid.

Comings [8] found a significant correlation between the polymorphism of the D1 receptor gene and Tourette's syndrome, pathological gambling, alcohol abuse, and CBD, corroborating the BRDS hypothesis. Another study investigating the polymorphism of the promoter region of the serotonin transporter gene did not find any association with CBD. However, it is important to note that this study involved a small sample and studied only the association with alleles of small effect [17]. A recent study carried out by De Neve and Fowler [15] identified an association between the polymorphism of the MAO-A gene and a higher probability of credit card debt. The MAO-A is implicated in the metabolism of serotonin and has one or both of the variant alleles of low efficacy associated with higher probability of addiction and impulsivity.

One study using functional magnetic resonance imaging in nonclinical samples observed activation of the nucleus accumbens when the subjects anticipated an advantageous purchase. This is the same structure overstimulated by drug addictions, which confirms the involvement of brain reward system in buying behavior. Conversely, disadvantageous offers, i.e., excessive prices, activated the insula and deactivated the mesial prefrontal cortex, indicating the involvement of different circuitries in the decision-making process related to purchasing. Interestingly, other studies have associated the insula activity with the experience of physical pain and its emotional component [41].

To date, so far, only one neuroimaging study has been conducted on CBD patients. Authors compared 26 normal controls to 23 female undergoing psychotherapy because of CBD in a functional magnetic resonance imaging study in which participants were exposed to photographs of consumption products and their prices and then they had to decide whether they were going to buy it or not. During the photographs' exposure, there was a significantly higher activation of ventral striatum for subsequently bought versus not-bought products; this discrepancy was even higher for CBD patients. Moreover, regardless of acquisition, i.e., bough or not bought, the activation of the ventral striatum was always higher for the CBD group compared to controls. Similar to the previous neuroimaging study, the activation of the insula was related to a decision of not buying, with a significant higher activation for the control group. Finally, regarding the prefrontal cortex structures, the anterior cingulate cortex (ACC) was also more activated when the decision tended not to buy, with a stronger activation for the control group as well. Conversely, when the decision tended to buying, then, the activation of the ACC was higher for the CBD group.

Interestingly, a high activation of the ACC has been related to decision-making under conflict and depressive mood. As to the other prefrontal structures, the ventral medial and dorsolateral prefrontal cortex were highly activated while participants decided whether to buy or not a product, but no differences were observed regarding CBD patients and the control group [72]. These findings are strikingly similar to other neuroimaging studies conducted over substance and gambling addiction [48].

Another interesting line of research is cue reactivity. One study investigated cue reactivity through electrodermal response toward pictures of consuming products in 66 females assessed for "pathological buying tendencies" (CBD-related symptoms). Both visual analogue ratings of cravings and electrodermal response had a positive and significant relationship with CBD-related symptoms [79]. Another study investigated cue reactivity using analysis of EEG coherence. Widespread EEG coherence differences were found according to preferred and non-preferred products [46]. On both studies, authors concluded that the relationship of the cue-reactivity measures to specific buying stimuli reinforces the perception of the addictive nature of CBD.

69.9 Treatment

69.9.1 Psychotherapy

Recently, Leite et al. [49] conducted a systematic review of psychotherapeutic treatment for CBD, encompassing original articles from 1985 to 2012. Twenty-three valid contributions were located ranging from motivational interviewing, psychodrama, psychoanalysis, family therapy, behavioral therapy, and cognitive behavioral therapy (CBT). Of all possibilities, cognitive behavioral therapy presented the most promising results regarding CBD remission and decrease of impulsive behaviors. Indeed, over the past years, studies regarding the treatment of CBD established important advances, as what existed were previous case reports aligned to the theoretical orientation of the authors. Still, controlled studies evaluating treatment efficacy for CBD, independent of therapeutic modality, remain scarce.

CBT remains as the most tested and studied treatment modality. The first studies were by Lejoyeux and Bernik, both of which suggested that cue exposure and response prevention may be useful in treatment [81]. Bernik and colleagues reported on two cases treated with clomipramine for panic attacks, who also presented with CBD. The medication did not improve compulsive buying behavior; however, both responded well to 3–4 weeks of buying cue exposure and response prevention, although no posttreatment information was provided.

A pilot study carried out by Mitchell et al. [57] involved 28 patients with CBD diagnoses for the treatment with CBT and 11 controls on the waiting list. At the end of 12 weeks, the results showed significant advantages of cognitive behavioral therapy, with subjects outperforming the waiting list controls in terms of the number of compulsive buying episodes and time spent buying. This improvement was maintained over the following 6 months. In 2008, Mueller et al., inspired by the Mitchell et al. [57] study, treated 31 compulsive buyers with a 12-week CBT intervention and compared them with 29 control patients on the waiting list. The treatment sessions specifically dealt with problems related to compulsive buying, restructuring of negative thoughts and emotions regarding buying, control over buying behavior, and problem-solving skills. Throughout the next 6 months, the patients continued to present with improvements when compared with the control group.

Imaginary desensitization was also used to treat a female compulsive buyer with a treatment package that also included motivational interviewing, financial planning, leisure, and cognitive restructuring. The final evaluation was positive, showing a reduction in compulsive episodes [20]. Another uncontrolled study reported on a cognitive behavioral group intervention with an emphasis on cognitive restructuring. Specific sessions were devised to deal with the most common cognitive distortions related to buying such as buying as a way of coping with emotions and building an identity and "all or nothing" type of

thinking. Nine patients participated; they all reported improvement of both cognitions and behaviors related to CBD [26].

Recently, Muller et al. [65] conducted a randomized controlled trial to assess the efficacy of group CBT compared to wait list combined with guidance for self-help delivered over the phone as a control group. The CBT program included motivational intervention, stimulus control, cognitive restructuring, response prevention, problem-solving, and financial counseling. After 6 months of treatment, the CBT group was better than the control group and retained most of the benefits attained with treatment.

Despite the undeniable enthusiasm with CBT for the treatment of CBD, as well as for other addictive behaviors, doubts remain as to what are its most valid components. The studies conducted so far have failed in choosing more rigorous control conditions beyond wait list, such as support therapy devoid of other specific techniques. In its current state, CBT is pretty much a *potpourri* of techniques, sometimes loosely correlated with considerable variation among its components according to who and where it is conducted. The field is in dire need of dismantling studies that could clarify which techniques are working and what they do. Nonetheless, some common denominators can be derived from previous reports of successful CBT including the exploration of behavioral, cognitive, and emotional aspects related to buying behavior, focus on internal and external triggers for buying, the structural analysis of the buying behavior, and its specific consequences [26, 57]. For these purposes, the most commonly reported techniques are cognitive restructuring, coping skills training, relapse prevention, and financial planning [28, 38, 58, 61].

Finally, family or couple's therapy has been cited in few studies as an add-on therapy to the regular treatment, but the field is still missing controlled studies. Guimarães et al. [36] conducted one of the few studies in this regard. They propose that adding family or couple's therapy to the treatment combo provides the strategic advantage of creating a specific space for debating family-related issues that may contribute to maintenance and facilitation of the compulsive buying behavior, such as secret keeping, payment of debts, and nonassertive communication, i.e., quarreling, nagging, and pleading [29].

69.9.2 Psychopharmacology

Similar to psychotherapeutic treatments, controlled clinical trials for CBD are scarce. Lejoyeux et al. [50] suggest that depressive compulsive buyers have an increased chance of improving their compulsiveness when treated with antidepressants than compulsive buyers without depression. A clinical trial with ten patients evaluated the use of fluoxetine in nondepressed compulsive buyers over nine weeks. Nine of the ten patients showed improvement, suggesting that it is not necessary for patients to be depressed in order to benefit from antidepressants [4].

Two more randomized controlled clinical trials with fluoxetine were carried out soon after. The first treated 37 compulsive buyers over the course of 12 weeks and did not find a difference between fluoxetine and placebo [68]. The second studied a sample of 23 CBD inpatients without depression [3]. The participants were randomly distributed to fluoxetine (n = 12) or placebo (n = 11). At the end of 9 weeks and applying the scale of global clinical improvement, 50% of the patients in the fluoxetine group and 64% of those in the placebo group were classified as showing "great" or "very great" improvement. The positive response of the placebo group points to the need to undertake more randomly controlled trials with longer follow-up periods [4, 9].

A clinical trial with citalopram showed favorable results in the double-blind discontinuation study carried out by Koran et al. [42]. Twenty-four patients with CBD were selected, and after 6 weeks of treatment, 17 patients presented with a significant reduction in spending and purchases and an improvement in global functioning. Then, these patients were randomly assigned to either citalopram or placebo maintenance for nine more weeks. The seven patients that took citalopram did not relapse, while five of the eight patients who took the placebo relapsed. After 1 year, 73% of the seven patients who took medication remained in remission from compulsive symp-

toms even after having interrupted medication. The authors suggested that citalopram treatment might have modified the natural course of the disorder. On the other hand, another study with a similar design using escitalopram found no significant effect [44].

Grant [33] reported on the successful treatment of three patients with naltrexone, and recently, memantine was tested in nine CBD patients with encouraging results [35]. Indeed, there is an interest with the potential therapeutic effects of glutamate pathway modulation for addictive behaviors [82] that is yet to be confirmed. Among the alternatives, topiramate shows promise, given that it has showed moderate to considerable effect over substance addictions like alcohol and maybe cocaine [11] and a moderate but definitely significant positive effect for binge eating disorder [6, 13, 14] and maybe for gambling disorder [2, 11]. Given the similarities between gambling and CBD and the putative shared mechanisms with binge eating, topiramate is speculated as a natural candidate for CBD pharmacological treatment. So far, only case reports have been published [37, 86]. A double-blind placebo randomized clinical trial has been registered (https://clinicaltrials.gov/ct2/show/NCT02138058) and recently completed, but the outcome report is still pending.

69.9.3 Self-Help/Community Resources

Other treatments have been elaborated as complementary to those more traditional ones that could be useful. These include self-help books about CBD for individual clarification or group discussion. The Debtors Anonymous group, which was created with the same perspective of Alcoholics Anonymous, is a self-help group coordinated by laymen who have the same difficulties and who provide support and encouragement for those with substantial debt. Simplicity Circles, which exists in some American cities, is a group of volunteers who encourage people to adopt a simple lifestyle, resist consumerism appeal, and abandon CBD. Finally, couple and financial counseling may be beneficial as relationships and financial status of the family become stranded because of chronic CBD [4].

Key Points

- CBD is a disorder marked by both impulsive and compulsive features, associated with excessive acquisition that leads people and their relatives to both subjective and objective social harm that has in financial indebtedness its main external sign, but which is not limited to it.
- CBD has been regarded as either an impulse control disorder or a behavioral addiction.
- Regardless of classification controversies, CBD is one of the most prevalent psychiatric disorders, with estimates ranging from 4% to 8% of the general population.
- Surprisingly, CBD has not been officially recognized by current codes of psychiatric classification, i.e., DSM and ICD. The recent classification of gambling disorder as the first recognized behavioral addiction in the DSM-5 opens the opportunity for the future recognition of CBD, as well as other behavioral addictions.
- CBD is comorbid with a wide range of psychiatric disorders, mainly mood disorders, anxiety disorders, and other addictive behaviors.
- Studies on the neurobiology on buying behavior and the loss of control over it are still in its infancy, but they all point to the involvement of structures from the brain reward system and from the prefrontal cortex, notably those involved in decision-making.
- Likewise, the knowledge on psychopharmacological treatment of CBD is incipient. The best evidence-based treatment up to now is CBT coupled with family support when needed.

Sex Addiction

70

Meyen Hertzsprung and Stephen Amadala

Contents

Abstract

This chapter reviews the concept of 'sex addiction' and discusses what we know of its history, nosology, neurobiology, prevalence and comorbidity, as well as assessment and treatment approaches. Excessive sexual behaviour has been documented clinically in the western world since the eighteenth century. Most recently, a classification of Compulsive Sexual Behaviour Disorder was included as an impulse control disorder in the latest revision of the International Classification of Diseases (ICD-11, 2018). While both its inclusion and classification remain controversial, the hope is that this recognition would spur further research in the area.

70.1 Introduction

Phenomena of excessive sexual behaviour have been documented clinically in the western world since the eighteenth century. It became known in the early twentieth century as 'Don Juanism', characterized by excessive sexual appetite and protracted promiscuity. It became codified in the tenth revision of the International Classification of Diseases (ICD-10 2007) as Excessive Sexual Drive (F52.7), and included in the most recent revision as Compulsive Sexual Behaviour Disorder (ICD-11, 2018 [56]). Its inclusion and classification in the ICD-11 as an impulse control disorder are already controversial [26], as many discussions of whether and how to conceptualize a particular constellation of 'excessive and maladaptive' [37] sexual behaviour has been from the beginning.

In the 1970s, 12-step recovery groups addressing 'out-of-control' sexual behaviour began to arise independently and spontaneously throughout a number of cities in the United States. Most of these groups were formed by members of Alcoholics Anonymous (AA) groups and followed the 12-step format and principles. These groups placed excessive sexual appetites/behaviour within the rubrique of 'addiction' [32]. However, it was the publication of Patrick Carnes' *Out of the Shadows* in 1983 that signalled the emergence of 'sex addiction' into the world of science and media, and the first inpatient treatment programs for 'sex addicts' were introduced.

'Sex addiction' was a grassroots term that seemed to capture the experience of those struggling with 'out-of-control' sexual behaviour, and emphasized commonalities between AA members' experience with sex and their experience with alcohol. Although the term was controversial, by the late 1980s, extensive media coverage popularized the idea of 'sex addiction', and for a time it seemed like every few years various celebrities would admit to 'sex addiction' and enter treatment.

In the 1990s, widespread access to the Internet lent a new dimension to 'sex addiction'. Suddenly 'an essentially unlimited range of sexually explicit texts, still and moving images, and audio materials' were available for immediate and secret consumption [20]. As if the task of definition and classification were not complicated enough, technology further added to the complexity of what was described as compulsive sexual behaviour. Currently, the Internet continues to be the arena of ever-varied forms of cybersex.

The use of the Internet itself has become the focus of considerable attention in the literature, as it can also become problematic. Hertlein and Piercy [29] noted that high levels of general Internet use account for lower levels of family communications and social interactions, and higher levels of depression and loneliness within families. Moreover, among adolescents, the use of online pornography in particular is associated with increased conduct problems and depressive symptoms, and lower levels of social integration and emotional bonding with caregivers [21].

It can be tricky to differentiate between general Internet use and online sexual behaviour. Young [57] identified three subtypes of 'Internet addiction': (1) excessive gaming, (2) online sexual preoccupation and (3) email/text messaging. All three subtypes can and often do have a sexual component to them. Role-playing games often involve sexual encounters between fantasy avatars, and email/text messaging can and has been the means for sharing sexual preoccupations.

'Cybersex' includes activities that may be described as 'passive' (viewing pornographic texts or images) as well as 'interactive' (webcam, sexting). Interactive components in particular defy straightforward classification. Dryer and Lijtmaer [18] take a psychodynamic approach to the meanings of cybersexual encounters, noting that interactive components lend to these encounters a unique kind of 'techno-intimacy'. Their paper highlights the specific dynamics of this 'twilight zone' of techno-intimacy: ways that constitute simultaneous virtual *and* real sexual 'relationships', wherein the individual is able to be both 'there' and 'not there'. This twilight zone bears further exploration, as virtual/real relationships have also become portable with the increasing sophistication of smart phones.

Thus, online sexual behaviour could be a subset of Internet addiction, or it could be a technological variant of sex addiction [47]; both of these also need to be distinguished from online 'affairs' or Internet infidelity [33]. Indeed, as technology advances, the task of delineating boundaries around 'sex addiction' becomes more complicated.

Coleman et al. [14] summarize the various conceptual models proposed over the years to explain problematic sexual behaviour: Money's focus on disruptions in psychosexual development, Carnes' addiction model with its emphasis on family of origin dynamics and trauma, Kafka's model of a dysregulated drive resulting in adverse consequences, Braun-Harvey and Vigorito's sexual health model with a focus on interpersonal/intrapersonal conflicts regarding sexual values, and their own comprehensive biopsychosocial and sex positive model.

Controversy is bound to surface when any class of behaviours is medically pathologized, including sexual behaviours that many consider 'normal' [43]. Kafka's formulation of a hypersexuality disorder diagnosis [37] for inclusion in the Sexual Disorder section of DSM5 was disallowed, despite his framing the diagnosis as a dysregulated appetitive drive, rather than as an 'addiction'.

As already mentioned, the ICD-11 (WHO, 2018) includes a diagnosis of Compulsive Sexual Behaviour Disorder in the section for Impulse Control Disorders:

> Compulsive sexual behaviour disorder is characterized by a persistent pattern of failure to control intense, repetitive sexual impulses or urges resulting in repetitive sexual behaviour. Symptoms may include repetitive sexual activities becoming a central focus of the person's life to the point of neglecting health and personal care or other interests, activities and responsibilities; numerous unsuccessful efforts to significantly reduce repetitive sexual behaviour; and continued repetitive sexual behaviour despite adverse consequences or deriving little or no satisfaction from it. The pattern of failure to control intense, sexual impulses or urges and resulting repetitive sexual behaviour is manifested over an extended period of time (e.g., 6 months or more), and causes marked distress or significant impairment in personal, family, social, educational, occupational, or other important areas of functioning. Distress that is entirely related to moral judgments and disapproval about sexual impulses, urges, or behaviours is not sufficient to meet this requirement.

Krause et al. [40] point out that the definition is meant to preclude overpathologizing: the diagnosis cannot be applied if there is no impairment in control, nor if the psychological distress is solely based on moral judgments. The disorder is not classified as an addiction due to the lack of definitive information about its phenomenology and its neurobiological underpinnings. As with any other type of diagnosis, self-identification is discouraged. Still, its inclusion in the ICD-11 is an important acknowledgment that problematic sexual behaviour is a clinical problem with potential serious consequences if left untreated.

From the early to mid-2000s, increasing attention has been paid to the effects of 'sex addiction' on couples and families. The term 'codependence', widely used with respect to partners of alcohol and drug dependents, came under criticism as a term that pathologized normal reactions to extreme situations [53]. Rather, partners of 'sex addicts' are invited into treatment as those who have suffered a traumatic experience upon the discovery or disclosure of the 'addict's' compulsive sexual behaviours (e.g. [5]).

Indeed, therapeutic work with partners has become a specialty in itself. The Association of Partners of Sex Addicts Trauma Specialists (APSATS) is dedicated to the professional training and certification of 'Partner Specialists' and 'advocate for ethical care and relational healing for partners, addicts, families and communities impacted by sexual addiction and betrayal trauma' [2]. In addition, an entire literature on managing disclosures of problematic sexual behaviour to partners continues to develop (e.g. [48]).

70.1.1 Relationship with Paraphilias

Paraphilias are characterized by intense, repetitive, deviant, sexually arousing fantasies, sexual urges and behaviours lasting at least 6 months and marked by personal distress or indications of

significant psychosocial impairment related to sexual behaviour. In contrast, compulsive sexual behaviour is characterized by excessive repetitive expression of culturally adapted normophilic sexual behaviours.

70.2 Assessment

Treatment begins with a comprehensive assessment and diagnosis. It is important to clarify what precipitated the visit, the behaviours of concern, their frequency, the circumstances under which the behaviours occur, and the sex and age of partners involved. What is the timeline of the behaviours? When were the behaviours at their worst, and what were the factors that contributed to their exacerbation? What has helped reduce the behaviours or the distress? What has been the impact of the behaviour on various aspects of functioning? Particularly important would be a review of current relationships and the impact of the behaviours on family and friends.

With regard to history, the clinician must assess any experience with sexual or physical abuse or neglect, as well as review the medical history, including any treatments for sexually transmitted illnesses. The clinician must inquire into other addictive behaviours and their relationship with sexually acting out behaviours. In addition, assessing for any legal involvement, past and present, would be important, as well as mental health function and any comorbid psychiatric disorders.

A number of screening and assessment instruments are available, including the Sex Addiction Screening Test (SAST); the PATHOS, a short screening interview analogous to the CAGE for alcohol use; the Compulsive Sex Behavior Inventory; and the Sexual Compulsivity Scale. Carnes [9, 10] developed the SAST, a 25-item dichotomously answered self-administered questionnaire. The SAST has demonstrated a single factor with high internal consistency in a sample of 191 sexually addicted, in comparison with 67 nonaddicted, males. A cutoff score of 13 (out of 25) is likely indicative of the presence of problematic sexual behaviour in heterosexual males. The SAST was revised in 2010 (SAST-R, [12]).

The PATHOS (derived from the SAST and SAST-R) has been developed as a brief screening instrument to assist clinicians with identification of individuals who may have ‘sex addiction’ [13]. A score of 3 out of 6 indicates the need for further assessment.

PATHOS questionnaire items are as follows:

1. Do you often find yourself preoccupied with sexual thoughts? (**P**reoccupied)
2. Do you hide some of your sexual behaviour from others? (**A**shamed)
3. Have you ever sought help for sexual behaviour you did not like? (**T**reatment)
4. Has anyone been hurt emotionally because of your sexual behaviour? (**H**urt Others)
5. Do you feel controlled by your sexual desire? (**O**ut of Control)
6. When you have sex, do you feel depressed afterwards? (**S**ad)

70.3 Etiology and Neurobiology

We do not have quality evidence supporting the etiology of ‘sexual addiction’. Most of the literature about etiological mechanisms is based on theory: endocrine dysfunction, incomplete monoamine hypothesis, developmental processes and a courtship disorder, social learning theory and psychodynamic theories. Little is known about the brain pathways that regulate sexual behaviour and cognition. Dopamine, serotonin and androgenic hormones appear to play a critical role [36]. Functional imaging with PET and MRI has corroborated that the amygdala, mesencephalic tegmentum and septal nuclei are activated during sexual response [1]. PET scans of healthy volunteers during orgasm and ejaculation showed strong activation of dopaminergic mesodiencephalic junction and ventral tegmental area; the latter region of the brain is also activated with the ‘rush’ experienced by heroin addicts [44].

Neurobiological correlates of addiction start with the brain reward circuitry: specifically, the mesolimbic reward system ([17].), a region significant for understanding the origins of how addictive behaviours emerge. There is a paucity

of literature on brain imaging during conventional or pathological sexual functioning. Reward circuits such as the dopaminergic and endogenous opiate systems have been implicated in the process of sexual behaviour in much the same way as substance use [23]. The role of the reward system in these disorders is derived from research into Parkinson's disease, whereby treatment with dopamine agonists leads to vulnerability to impulse control disorders such as pathological gambling, hypersexuality, compulsive shopping and compulsive eating [54]. Addiction has usually been defined as dependence on a drug that can 'hijack' the reward system. Any stimuli (drug or behaviour) that transform the basic drive required for survival (like feeding, thirst, reproduction) into actions of craving/seeking behaviours or repetitive out of control behaviours may make it plausible that addiction can occur even in the absence of drug taking [38]. Thus, behavioural addictions may share many of the same pathways associated with chemical dependence. Hence, the theory that, 'if one can alter neurocircuitry with illicit drugs and pharmacology, then one can alter it with behaviour as well' [31].

70.4 Prevalence

The prevalence of compulsive sexual behaviour is unknown due to the lack of large-scale community data and consensus on diagnostic criteria. Researchers estimate rates as ranging from 3% to 6% [4, 35–37, 41]. Erez et al. [19] found the lifetime prevalence rates of sexual impulsivity, a possible dimension of Compulsive Sexual Behaviour, was found to be higher for men (18.9%) than women (10.9%) as per data from the US National Epidemiologic Survey on Alcohol and Related Conditions.

70.5 Comorbidity

One of the consistent findings of studies of those with sexual compulsion was that the great majority have a lifetime comorbid mood, anxiety, psychoactive substance use and/or other impulse disorder diagnoses [16, 49]. In 103 men seeking treatment for compulsive pornography use and/or casual sexual behaviours, 71% met criteria for a mood disorder, 40% for anxiety disorder, 41% for a substance use disorder and 24% for an impulse control disorder [39]. Estimate rates of co-occurring compulsive sexual behaviour and gambling disorder range from 4% to 20% [3, 25].

ADHD (inattentive subtype) was identified as a co-occurring psychiatric diagnosis in those with problematic sexual behaviour [6]. There is a high correlation between 'sex addiction' and substance use disorders, up to 80% in some studies. This tends to complicate the task of diagnosis and treatment.

With respect to personality disorders, Raymond et al. [45] found that the most commonly co-occurring personality issues are Cluster C personality disorders (39%), followed by Cluster B personality disorders (23%). Reid (2012) [46] found that men with compulsive sexual behaviour exhibited higher levels of emotional dysregulation, stress vulnerability and interpersonal sensitivity; these characteristics generalized to hypersexual women. They concluded that personality traits associated with emotional problems, difficulties coping with stress, and interpersonal sensitivity may constitute a precipitating or perpetuating risk factor in the onset or maintenance of compulsive sexual behaviour in adult men and women; and that treatment interventions targeting affect regulation, stress coping, interpersonal coping, interpersonal sensitivity, impulsivity and manipulative tendencies are warranted for both men and women.

Neuropsychiatric illness [54] may induce acute changes in sexual behaviour; similarly, medications, typically dopaminergic agonists [36], may also contribute to hypersexual behaviour. In these circumstances, the hypersexual behaviours tend to be a mixture of normophilic and paraphilic like sexual behaviours (e.g. inappropriate touching and exposing oneself, but not to strangers).

70.6 Treatment Approaches

70.6.1 Psychosocial Approaches

Patrick Carnes, whose autobiographical book *Out of the Shadows* [8] brought 'sex addiction' to public attention, has also been instrumental in the development of the most widely published therapeutic approach to compulsive sexual behaviour [28]. Carnes uses an addiction framework, and his 'Task-Centred Approach', outlined briefly in his introductory workbook *Facing the Shadow* [11], guides the 'recovering addict' through 30 tasks that generally work well in conjunction with a 12-step recovery program such as Sexaholics Anonymous. Each task has a list of 'performables' meant to operationalize the task. For example, the first task is to 'break through denial' and includes the following performables: make a problem list, make a secret list, make a list of excuses and rationales, complete a consequences inventory (list of consequences in various life areas), make a list of people hurt, find a therapist, find a sponsor and make full disclosure to therapist and sponsor. The first seven tasks are meant to guide the 'addict' through early sobriety; tasks 8–19 provide longer-term guidance in individual recovery, and dovetail with tasks 19–30, which focus on 'family recovery'.

While most of the 'performables' can be directly linked to 12-step recovery (e.g. find a sponsor, complete a powerlessness inventory, share your first step), many others can also serve as a menu of helpful worksheets regardless of therapeutic approach, and can easily be used within the context of relapse prevention and cognitive-behavioural therapy (e.g. identify your relapse scenarios, complete a fire drill plan).

Carnes was instrumental in the establishment of the Society for the Advancement of Sexual Health (SASH), a non-profit organization dedicated to promoting an integrative approach to sexual health research, education and intervention that addresses the full spectrum of sexual health, from problematic attitudes and behaviours to the pursuit of fulfilment, freedom and pleasure [50]. SASH holds a conference yearly and offers a certificate for 'Advanced Training in Problematic Sexual Behaviour'.

Carnes founded the International Institute for Trauma and Addiction Professionals (IITAP), 'a global leader among practitioners who treat addictive and compulsive behaviours, whose certifications, training and continuing education programs offer a cutting-edge advantage for practitioners wanting to grow their practice and gain new insights' [30]. Carnes also founded Gentle Path Press, which publishes many of the materials used for training, as well as books recommended through his Task-Centred Approach.

When conceptualized as an addiction, there are many possibilities of extending already established therapies that help with addictive behaviours, such as Motivational Enhancement Therapy, cognitive-behavioural approaches, emotional awareness and mindfulness-based approaches. Participation in 12-step recovery groups is also routinely recommended in conjunction with psychosocial treatment.

Perhaps the most comprehensive therapeutic process used to address problematic sexual behaviour is described by Coleman et al. [14], who focus on identity formation and the development of intimacy in relationship. They begin with a thorough diagnostic assessment, recognizing that at times all that is needed is brief psychoeducational therapy to help people understand their behaviour patterns and resulting consequences and to motivate them to adapt healthier sexual practices. The diagnostic assessment would also allow for exploring and prioritizing possible comorbidities, whether physical or psychiatric.

When intensive therapy is indicated, Coleman et al. [14] recommend that the following areas be addressed, in loosely chronological order: (1) establishing and maintaining appropriate behavioural and emotional boundarie; (2) understanding patterns and dynamics present in the family of origin and developing and practicing more functional patterns; and (3) identifying the effects

of trauma, and then learning how to manage emotions and developing new ways of relating to the self and to others. Work in these areas lay the foundation for continued growth in the following areas: (1) identity formation, (2) self-esteem development, (3) intimacy development and repair, (4) authenticity, and (5) integrity and positive sexuality.

Their approach requires the judicious use of various psychotherapeutic approaches (behavioural, cognitive-behavioural, family and systems, exposure-based therapy, acceptance and commitment, life review) and modalities (individual, couple, group). Although each of these approaches and modalities has long and respectable histories as evidence-based treatments, so far there is little research evidence to empirically support any one treatment approach specifically for problematic sexual behaviour.

70.6.2 Pharmacological Approaches

Pharmacological treatment uses two main categories of medications: specific serotonin reuptake inhibitors (SSRIs) and antiandrogens [27]. Patients with problematic sexual behaviour may present with dysphoric mood symptoms that may warrant antidepressant medications. This usually occurs in the initial phase of abstinence.

There are no randomized control trials for treatment of patients with antidepressants. However, case reports and open-label studies [34, 51] indicate that SSRIs may be of use in the treatment of 'sexual addiction'. This is based on the rationale that serotonergic dysfunction may underlie the condition. Madeo [42] showed in a randomized control trial with citalopram that, in healthy adult males, four weeks of treatment significantly increased the time to orgasm compared to men on placebo. However, the medications did not dampen sexual desire or penile tumescence measurements, suggesting that SSRIs may have differential effects on dampening libido and sexual function in men who are not depressed, or who do not have compulsive sexual behaviour.

In a randomized control trial, gay and bisexual men with 'sexual addiction/compulsivity' who were treated for 12 weeks with citalopram (20 mg–60 mg a day) reported significant reductions in sexual drive, frequency of masturbation and viewing of pornography in comparison to those treated with placebo [55]. In summary, there is some evidence supporting the use of the SSRI citalopram for 'sex addiction', especially in gay and bisexual men.

Naltrexone is an opioid antagonist approved for use in treating alcoholism and opioid dependence. It works by dampening dopamine release, thus reducing the euphorigenic effects of fantasizing and tension building, which are considered the initial steps in compulsive sexual behaviours. There are no randomized trials of opioid antagonists for 'sexual addiction'. Some open-label trials show that high doses of naltrexone reduced frequency of masturbation, sexual fantasies and nocturnal emission [7].

Antiandrogen medications currently used for the treatment of excessive nonparaphilic sexual behaviour are cyproterone acetate (a synthetic steroid similar to progesterone that acts both as a progesterone and an antiandrogen) and medroxyprogesterone acetate. Medroxyprogesterone acetate diminishes libido in men and thus makes it easier to control problematic sexual behaviour. The rationale of using hormone therapies in men with 'sexual addiction' is based on eliminating sexual compulsivity and obsessions by stopping the production of testosterone. This approach is usually reserved for treating paraphilias in men that involve sexual offending involving children and violence [24, 52]. Antiandrogens diminish sex drive in women; hence, the use of antiandrogens in women to control hypersexuality may be of benefit.

Goodman [22] has presented a psychotherapeutic stage model integrating pharmacotherapeutic, behavioural and psychodynamic approaches. In this staged model, in the first stage (initial behaviour modulation), individuals who engage in compulsive sexual behaviour learn how to modulate their behaviour through a combination of inner motivation, psychological support and affect-regulating medication; the second stage (stabilization of behaviour and affect) addresses the question of relapse preven-

tion, with a distinction between high- and low-risk forms of sexual behaviour. Patients are taught to engage in 'healthier' forms of sexual behaviour.

70.7 Conclusion

'Sex addiction' as a concept carries a lot of controversy. There have been a number of attempts to define the features of 'sex addiction' in the last three decades. The inclusion of a Compulsive Sexual Behaviour Disorder diagnosis in the ICD-11 gives hope of providing a reference for clinicians in the recognition and treatment of this disorder and of furthering research in this field [40]. Although it has been noted that there is frequent comorbidity with attention deficit, and various substance use and personality disorders, there remains a paucity of research about the prevalence and incidence of the disorder [15]. Treatment of the disorder encompasses a variety of approaches, including psychotherapeutic models, involvement in 12-step programs, and pharmacotherapeutic interventions (especially for concurrent psychiatric disorders), alone or in combination. All of these approaches could benefit from more empirical research attention. In sum, the field is wide open for continued research efforts, whether in definition, nosology, incidence and prevalence, assessment and treatment.

Abstract

Obesity has become a worldwide pandemic with an estimated annual cost in related illnesses and loss of productivity over $100 billion and rising. Though not recognized as a psychiatric disorder, obesity has been linked to serious physical, psychological, and social consequences. Some forms of obesity are characterized by the compulsive consumption of food, inability to restrain from further intake despite negative consequences, a desire to cut back, and increasing amounts of food needed to reach satiety, resembling a form of tolerance.

These symptoms are remarkably similar to DSM criteria for substance use disorders: preoccupation, escalation, tolerance, denial, and a series of medical, psychological, and social consequences that relate directly to continued

use. Research in both animals and humans has demonstrated food-related changes in the brain itself that are very similar to changes caused by drugs of abuse leading to the hypothesis that some forms of obesity and a related contributing behavior, binge eating, may manifest secondary to or along with a "food addiction." This chapter seeks to describe the common elements and possible intersection of binge eating disorder, obesity, and addiction.

Keywords

Obesity · Binge eating · Food addiction · Overweight · Overeating · Eating disorder

71.1 Introduction

This chapter seeks to describe the common elements and possible intersection of binge eating disorder, obesity, and addiction. The Diagnostic and Statistical Manual of Mental Disorders-V (DSM-V) currently recognizes anorexia nervosa, bulimia nervosa, binge eating disorder (BED), avoidant/restrictive food intake disorder, other specified feeding or eating disorder, and unspecified feeding or eating disorder due to the serious impairments and severe negative outcomes associated with these conditions [4]. While these recognized eating disorders largely pertain to restriction of food intake or behavioral compensation for overconsumption, persistent excessive caloric intake resulting in obesity is not currently recognized as a psychiatric disorder. However, obesity has been linked to serious physical, psychological, and social consequences.

Obesity and overeating may represent an addictive process. Some forms of obesity are typified by the compulsive consumption of food, cravings, requiring increasing amounts of food to reach satiety (resembling a form of tolerance), a desire to reduce consumption, and significant difficulty curbing further intake despite negative consequences, including potentially serious medical and psychological issues [59, 61]. These symptoms are remarkably similar to DSM criteria for substance use disorders: preoccupation, cravings, escalation, tolerance, denial, and a series of medical, psychological, and social consequences that relate directly to continued use [4, 31], supporting the hypothesis that some forms of obesity and a related contributing behavior, binge eating, may manifest secondary to or along with a "food addiction."

The concept of food addiction is a highly debated one [5–7]. One argument against the notion that food is addictive is, of course, that everyone eats. How can something that sustains life be considered addictive? A recent systematic review assessed the evidence around "food addiction" and found that certain foods, such as processed foods with high added sweeteners and fats, have greater addictive potential [32]. This fits with prior hypotheses suggesting that only certain foods should be considered addictive, specifically those high in sugars and fats. Foods associated with "addictive" properties tend to be typically calorie dense and highly palatable and foods that people tend to overconsume the most [19]. Studies using animal models have provided a great deal of empirical support for the concept of food addiction. These studies found that, similar to substance addictions, the consumption of such food types increases dopaminergic activity in the brain's mesolimbic reward circuits which leads to increased intake over time. Furthermore, when animal subjects consumed these foods for significant periods of time and were then deprived of them, they experienced symptoms of withdrawal [8]. More recently, tools have been designed to assess food addiction in humans, and studies incorporating such tools are beginning to provide additional evidence of this construct. For example, more than half of obese individuals with binge eating disorder included in one study met the criteria for food addiction [27]. Using fMRI scanning, individuals with greater food addiction scores have also been shown to have greater activation in motivation-related brain regions when anticipating highly palatable food – similar to drug-addicted individuals when viewing cues associated with a drug [28].

Disordered eating, such as that seen in binge eating disorder, bulimia nervosa, and some cases

of obesity, poses a number of complications for the medical community. First, these conditions can be physically compromising; secondary side effects including type II diabetes, high blood pressure, and associated arthritis (from heavy-weight load) are particularly important consequences of disordered eating and weight gain, as well as public health concerns. Furthermore, disordered eating can, in some cases, even be fatal; however, their etiology is not well characterized. Expert speculations regarding the underlying risk factors for the development of disordered eating include a range of psychological, biological, and societal influences. Given the growing evidence of neurochemical and behavioral similarities between overconsumption of certain foods and substance addiction and the urgent need to develop effective treatments to combat obesity and overeating, it may be time to consider food addiction as a possible contributing factor to these issues, as well as a target for treatment.

71.2 Neurobiology

71.2.1 Feeding and Reward

Feeding behaviors are controlled by more than homeostatic mechanisms. As it has been pointed out, "if feeding were controlled solely by homeostatic mechanisms, most of us would be at our ideal body weight, and people would consider feeding like breathing or elimination, a necessary but unexciting part of existence" [54]. The fact that this is not the case suggests that there is a role for the reward systems in the brain in promoting motivational, hedonically driven feeding. Thus, excessive food intake may be explained more by dysfunction in the reward circuitry than strictly dysfunction in the homeostatic mechanisms controlling feeding habits. Studies in both humans and animals have supported the hypothesis that brain reward circuitry may be dysregulated in cases of obesity, disordered eating, and, more recently, food addiction.

The neurocircuitry underlying eating behaviors is quite complicated. Of the multiple regions of the brain involved in the processes of food procurement and ingestion, there are four regions that stand out as also being implicated in substance use disorders and drug addictions: the amygdala/hippocampus, insula, orbitofrontal cortex, and striatum. These areas of the brain play key roles in learning the rewards associated with food, allocating attention and effort toward procuring food, setting incentive for food, and integrating internal homeostatic information about energy stores and gut contents [11].

Sensory input from the mouth is relayed to the same cortical areas of the brain that receive satiety signals from the gut [53]. The gut hormones ghrelin, leptin, insulin, and peptide YY interact with limbic structures and the thalamus to integrate hypothalamic energy control signals [45]. The hypothalamus has direct connections to the nucleus accumbens, which is the control center for reward behaviors such as exercise, sex, and feeding. Mesolimbic dopamine (DA) directly acts upon the nucleus accumbens, thereby controlling motivational and hedonic feeding as well as serving as the point of action for endogenous opioids, serotonin (5-HT), and acetylcholine (ACh). (It should be noted that these are some of the same neurotransmitters and pathways that control motivation and reinforcement of behaviors typically associated with substance addictions.) The endogenous opioids modulate DA release, thereby affecting the reward process. Similarly, ACh in the nucleus accumbens has been associated with satiety, though the precise mechanism of action needs further investigation [9]. 5-HT is also associated with the sensation of satiety and can be associated with weight loss and fat intake [36]. Given the interplay between all of these neurotransmitters and the nucleus accumbens, it is possible that dysfunction at any of these key points could result in disordered eating. This also explains why many of the pharmacological therapies for eating disorders frequently target these neurotransmitter systems.

71.2.2 Obesity

Obesity, defined as a body mass index >30, has increased dramatically over the last three decades and was estimated to affect over 39% of the US population as of 2016 [35]. Obesity is classified

as a medical condition as it places a patient at increased risk for cardiovascular disease, diabetes, cancer, and other diseases. By conservative estimates, the health sequelae from obesity result in a 5–20-year reduction in life expectancy, as well as accrue healthcare costs totaling $147–$210 billion annually [15]. The seriousness of these health consequences highlights the urgent need for strong prevention efforts and the development of effective treatment approaches for individuals with this condition [61].

The cause of obesity remains largely unknown but, similar to eating disorders, is likely multifactorial (Fig. 71.1). It has been suggested that the behavioral phenotype of overeating may be influenced by an interplay of genetics, development, and environmental factors [14]. While separable in theory, the interplay of one's genes; the time, place, and culture in which one lives; and the development of one's obesity through non-homeostatic mechanisms are likely all simultaneously involved and thereby relevant to the problem [21].

Within genetic theories, the "thrifty genotype" hypothesis suggests that the neurocircuitry underlying food procurement and bodily storage evolved at a point in human history in which food was scarce as a means of promoting survival in times of famine [61]. However, recent advances in technology have allowed for the creation and modification of foods, which artificially enhance palatability beyond what would be found in nature, especially with regard to sugar, fat, and caloric value [23, 59] [23]. Foods that are both high fat and high sugar do not exist in nature, but calorie for calorie, these foods are valued more than foods containing only fat or carbohydrate resulting in supra-additive responses in the striatum during food valuation and are associated with greater recruitment of central reward cir-

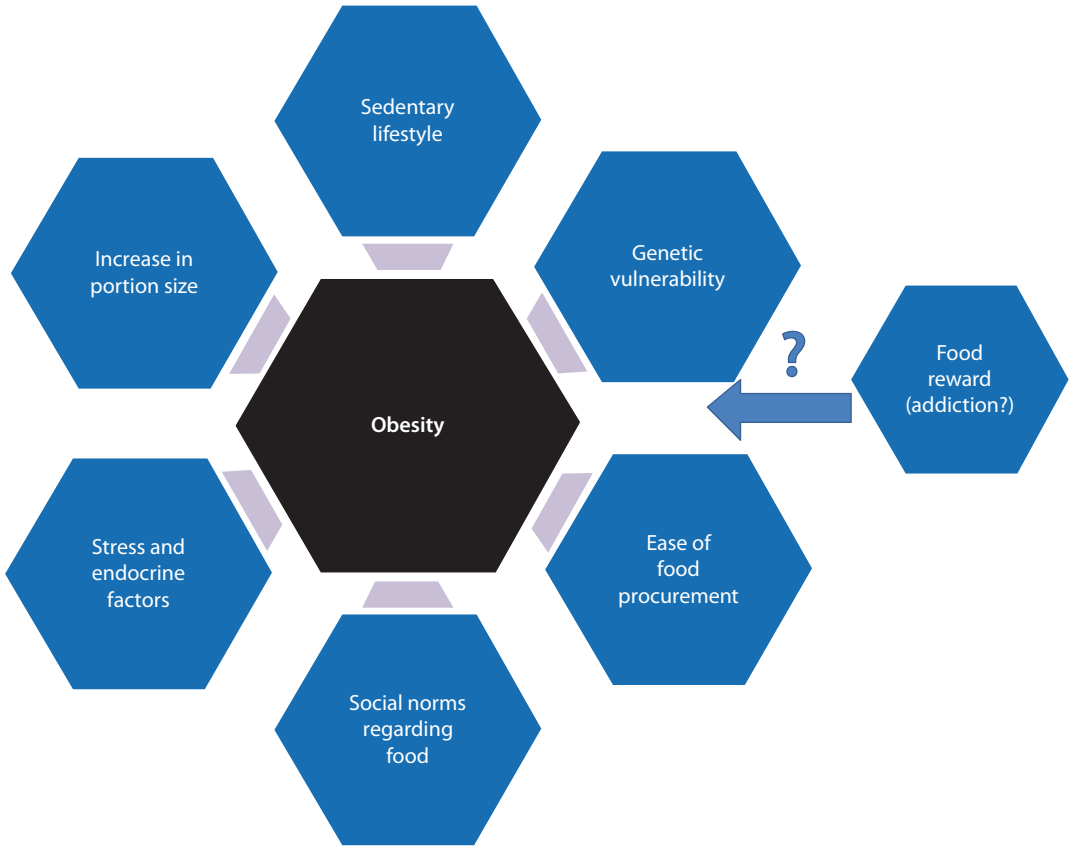

Fig. 71.1 Theorized contributions to the obesity epidemic

cuits [23]. Moreover, these calorie-rich, highly palatable foods are abundant and easily accessible in the typical Western diet. This combination of factors may lead to the activation of reward circuitry, which evolved to reinforce feeding behavior and desires to engage in pathologic overconsumption, which would have been advantageous in a time of famine but now, in a context of abundance, appear maladaptive [14].

In contrast, the "developmental origin" hypothesis suggests that our exposure to certain nutrients and calorie contents in utero may imprint upon our developing brain and influence food choices when outside of the womb. Evidence to support this hypothesis comes from studies investigating the effects of consuming certain diets during gestation on various outcome measures in the offspring. For example, recent research has found that the offspring of animals fed with a high-fat diet during gestation are more likely to weigh more and consume more of a high-fat diet compared to controls [13]. While one hypothesis takes into account an evolutionary perspective and the other a more developmental view, both of these hypotheses may have value for understanding the current issues of obesity and disordered eating.

In regard to possible cultural and environmental influences of obesity, the past several decades have seen five major developments that are thought to have tipped the balance between caloric intake and energy expenditure to an unfavorable disproportion: (1) expanding labor market opportunities for women, (2) increased consumption of food outside of the home, (3) rising costs of healthy foods relative to unhealthy foods, (4) increasing quantities of caloric intake with declining overall food price, and (5) decreased requirements of occupational and environmental physical activity (J [30].). General food accessibility issues and an inability to find healthy food options in certain areas, the so-called food deserts, are also an important factor which disproportionately affects minorities and individuals of a lower socioeconomic status [17]. Other environmental factors implicated in the development of patterns of overeating include advertisements, sights, smells, and sounds, which have all been shown to induce food cravings and can result in overeating [11]. Indeed, eating is more than a physiologic response; it can serve as a social lubricant, facilitating both personal and professional interactions, and is a prominent centerpiece for most individuals at holidays and celebrations (M. S [31]); food also plays a major role in many religions, cultures, and communities [24]. Stress and the difficulties of modern life may also lead to patterns of overeating [29], potentially through the production of the neurohormone corticotropin-releasing factor [50].

These factors highlight the cultural aspect of obesity, but with them come a new set of challenges. During the Coronary Artery Revascularization in Diabetes (CARD) trial, which followed a population of 18–35-year-old patients over 10 years, the average patient showed a weight increase of at least 7 kg regardless of race and sex. This study demonstrated that significant weight gain over the course of adult life is now normative, suggesting a strong cultural component [49]. In order to be classified as a disease, however, a condition must clearly differ from the norms of society. This conundrum has led some to refute claims that obesity should be included in the DSM-V as it may simply be a behavioral disturbance with an adverse medical outcome, not necessarily a psychiatric condition [21]. While not all individuals who are obese may fit the existing criteria for food addiction, it is possible that individuals who do may represent a subcategory of obesity that is characterized in part by significant distress due to their thoughts and behaviors regarding food and/or exhibit compromised functioning as a result of these thoughts and behaviors. As such, these individuals may be recognized as having a psychiatric condition despite being within a weight range that may be considered relatively "normal" based on current trends within society. In fact, over- and/or normal-weight individuals can meet the criteria for food addiction.

Obesity is often described as an imbalance between caloric intake and energy expenditure. This simplified view has led some to suggest that obesity is the fault of the person due to excessive consumption, inadequate activity, or a combina-

tion of the two, resulting in much of the stigma that is associated with this condition [21]. While decreased caloric consumption and increased physical activity can be effective in normalizing weight, these lifestyle modifications have proven very difficult to sustain [61]. The failure of many lifestyle modifications to reduce obesity over the long term suggests that obesity may not be entirely a metabolic disorder, but likely has a neuropsychogenic component [61]. While food addiction certainly does not explain all cases of obesity, the prevalence of people who eat for reasons other than obtaining energy suggests that other factors may play a role in motivating and/or reinforcing feeding behaviors.

With the rapidly increasing number of cases of obesity, it may be time to consider new ways of understanding and approaching this problem. Some hypothesize that obesity, at least in certain cases, is related to dysregulation of the brain's reward system. The hypothalamus is accepted as the primary brain region responsible for managing signals that regulate the intake of food, primarily through hormones such as ghrelin, leptin, and insulin which effect both the hypothalamus and the reward neurocircuitry in such areas as the caudate nucleus, hippocampus, and insula [59]. Food, especially when it is rich in fat and sugars, stimulates brain reward circuitry, in part, through the release of endogenous opioids, cannabinoids, and DA [1, 23]. Since these are some of the same neuropathways and neurotransmitters associated with drug addiction, as mentioned earlier, some have suggested that repeated exposure to certain foods in vulnerable individuals may result in compulsive food consumption, poor control, conditioning to food stimuli, and ultimately excess weight gain [61]. Further evidence of neurochemical similarities between substance addiction and obesity comes from studies showing that like individuals with drug addiction, obese individuals have decreased striatal D2/D3 receptor availability and demonstrate elevated levels of DA metabolism [19, 63]. Such findings suggest dysfunction within the brain reward mechanisms of individuals with obesity.

The addictive behaviors underlying some cases of obesity may be hardwired. There have been reports of a subset of patients who have undergone bariatric weight loss surgery for obesity (and, therefore, are less likely to be able to consume food in excess) later developing other addictive behaviors such as gambling, substance abuse, and impulsive spending [18, 64]. Interestingly, sweet preference has also been shown to correlate with a paternal history of alcoholism. In fact, one study found that having a family history of alcoholism increased the chance that one preferred a stronger sweet taste by five times [42]. Though this association requires further investigation, the implication of these findings is that the tendency toward increased reward sensitivity – which may lead to addiction – could be intrinsic [59].

There is a wide range of treatments for obesity. Stimulant drugs such as methamphetamine or cocaine are known to curb appetite presumably by affecting the reward circuitry, while partial blockade of these same pathways by antipsychotics has been associated with overconsumption, thereby increasing the risk for obesity and metabolic syndrome [61]. Taken together, current evidence suggests that similar neurological pathways are associated with both addiction and obesity. Thus, medications used to treat drug addiction, including cannabinoid antagonists; opioid antagonists, such as naloxone; GABA agonists, such as baclofen; and corticotropin-releasing hormone antagonists, such as CRF-1, have been suggested for the treatment of obesity, as have some of the same behavioral interventions, including cognitive behavioral therapy (CBT), cognitive behavioral therapy with guided self-help (CBT-gsh), dialectical behavioral therapy (DBT), interpersonal therapy (IPT), incentive motivation, and 12-step programs [50, 61, 66].

71.2.3 Binge Eating

Binge eating disorder is now listed in the DSM-V as a stand-alone diagnosis. Binge eating is characterized by eating rapidly, eating more than was intended, eating alone, and feelings of disgust, guilt, or depression secondary to these binges. It has been reported that 3.5% of adult women and 2% of adult men within the US population suffer

from binge eating disorder, making it the most prevalent eating disorder. These numbers are reported to be slightly lower for adolescents (2.3% females, 0.8% males) [55].

Bingeing has long been associated with bulimia nervosa, as binge eating is one of the major diagnostic criteria for this disorder, but it is also associated with obesity [4]. The key difference between binge eating and bulimia nervosa is that binge eating disorder patients do not engage in compensatory behaviors (i.e., vomiting, laxative use, excessive exercise) to expel calories after consumption. Thus, the excess caloric intake is not compensated for, which may result in weight gain. Indeed, one study found that nearly 70% of participants with binge eating disorder were obese and 20% were overweight [33]. A larger, national study found obesity to have a lower prevalence rate among individuals who ever had binge eating disorder. However, this number was still relatively high, with approximately 40% of these individuals considered either obese or severely obese [38].

Many studies have attempted to elucidate the relationship between binge eating and obesity. Longitudinal studies have demonstrated a correlation between binge eating and significant non-developmentally appropriate weight gain in adolescents and young adults [58]. Further, one study demonstrated a correlation between binge eating and both being obese and gaining weight over a 20-year span [37]. Another study also shows that cessation of binge eating is associated with weight loss, while continued binge eating is associated with ongoing weight gain [22]. Studies such as these strongly suggest a connection between uncompensated binge eating and weight gain and suggest that binge eating could ultimately contribute to obesity [21, 56]. It is thus reasonable to suggest that normal-weight individuals with binge eating disorder may be at risk for obesity.

In addition to the association between binge eating and obesity, binge eating has several similarities to addiction. Some of the criteria used to identify disorders characterized by binge eating are remarkably similar to those used to assess substance dependence. These include (1) binge-type intake, defined as consuming a larger amount of food than typically considered normal in a discrete period of time, (2) a sense of lack of control over eating during a binge episode, and (3) marked distress regarding binge eating. In fact, binge eating has been described as including "compulsion, marked change in affect, and long-term harm," and it is noted that "physiologically based satiety tolerance enables escalation of food 'dose'" [52].

The types of foods consumed during binge episodes are typically those that should be consumed in moderation due to their high-fat, high-calorie, and high-sugar content [41]. Consuming foods rich in sugar and fat activates the reward circuitry of the brain, as mentioned earlier. Bingeing on both high-sucrose and high-fat foods has been shown to elicit DA release in the nucleus accumbens in animals [5–7] and together to have supra-additive effects on the reward system [23]. Animal models have also shown that bingeing is associated with downregulation of D2 receptor mRNA and an increase in D3 receptor mRNA in the nucleus accumbens [57]. Interestingly, these dopaminergic changes seen in response to bingeing are the same as those observed in obesity and drug dependency [40, 43]. This has led some to speculate that binge eating of palatable foods may result in neurochemical changes and subsequent addictive-like behaviors ([13]).

Studies such as these have also led some to wonder if the dopaminergic system could provide a target for pharmaceutical intervention of bingeing behaviors. Indeed, one study using an animal model of binge eating found the D2 antagonist, raclopride, reduces binge intake of high-fat foods while having no effect on ad libitum consumption [20]. Similarly, studies suggest that naltrexone, an opioid antagonist, can suppress bingeing behaviors [20]. Further, single-photon emission tomography (SPECT) studies have demonstrated that when compared to obese controls, decreased 5-HT transporter binding was found among obese binge eaters, suggesting that this may be another potential pharmaceutical target [44]. Currently, the stimulant prodrug lisdexamfetamine is the only medication approved for the treatment of BED [12].

Within the brain, the ventral limbic circuit and the orbitofrontal cortex are important in the regu-

lation of feeding behaviors as well as identifying emotional stimuli and facilitating a subsequent response, and atrophy or deregulation within these regions has been noted in persons with bingeing behaviors [46]. This suggests a link between emotions and binge eating. Indeed, one study found that 100% of participants, all of whom were obese women who binge eat, reported that mood contributed to binge behavior, 68% reported depression or sadness, and 55% reported boredom preceding a binge episode [16]. It is not surprising, therefore, that the teaching of affect regulation skills through the use of dialectical behavioral therapy (DBT) has yielded promising results in this population [60].

71.2.4 Screening Individuals for Food Addiction

Given the potential magnitude and severity of food addictions, efforts have been made to develop screening tools for addictive-like eating. Gearhardt et al. [25] created the Yale Food Addiction Scale (YFAS), which consists of a series of questions based on the substance addiction criteria as outlined in the DSM-IV [25]. This tool is designed to identify and better characterize signs and symptoms consistent with food addiction. Respondents use a yes/no format and 5-point Likert scale for questions regarding frequency. In early testing, the YFAS exhibited adequate internal reliability, good convergent validity with other measures of disordered eating, and good discriminant validity relative to related yet dissimilar conditions such as alcohol consumption and impulsivity [26]. A recent study has shown a link between YFAS scores and mood disorders among obese patients with binge eating disorder. The YFAS has also been shown to be a good predictor of the frequency of binge eating episodes in this patient population [27].

As noted by the authors, the YFAS may help clinicians better identify disordered eating habits in their patients as well as allow researchers to better identify potential candidates for future studies. Additional screening tools that might aid in the diagnosis of addiction-like disordered eating include the Eating Disorders Inventory, Eating Disorder Diagnostic Scale, Eating Disorder Examination Questionnaire, Bulimia Test-Revised, Binge Eating Scale, Night Eating Symptoms Scale, and Eating Behaviors Questionnaire [47]. Future studies in this area may facilitate the development of screening tests for addiction to specific food ingredients, such as fat or sugar, which may lead to a better understanding of the types of foods that may be associated with food addiction, as well as the development of more specific approaches to treatment.

71.2.5 Management of Food Addiction

The study of food addiction is relatively new, and specialized treatment approaches have not yet been developed. However, because of overlaps between binge eating, obesity, and food addiction, it is possible that strategies that are effective for treating binge eating and obesity may also prove helpful in the treatment of food addiction. Certain types of psychotherapy, including cognitive behavioral therapy (CBT), cognitive behavioral therapy with guided self-help (CBT-gsh), and interpersonal therapy (IPT), have shown success in the treatment of binge eating disorder [22, 39]. As mentioned earlier, DBT has also been shown to be effective in treating binge eating behavior [60]. Aside from lisdexamfetamine, fluoxetine, desipramine, imipramine, and topiramate have been suggested to be effective in the treatment of binge eating disorder [62], and phentermine, diethylpropion, and orlistat are often provided for obesity [51], as has the combination of naltrexone and bupropion [34], which can also be used for BED combined with depression. Duloxetine has also been shown to help curb hunger and reduce weight gain [2]. For some, binge eating may become an ingrained behavior that serves as a form of self-medication in response to negative emotional states such as depression, anxiety, loneliness, boredom, anger, and interpersonal conflict. This highlights the role of behavior modification, in addition to pharmacological interventions, in the treatment of food addictions [59]. It should be noted that treat-

ment of disordered eating can be a long and arduous process marked by alternating periods of relapse and recovery.

With regard to obesity, some patients turn to invasive procedures such as bariatric surgical treatments including gastric bypass and gastric banding. While these procedures do result in dramatic weight loss, they can be expensive and can have significant risks, including the development of gastric dumping syndrome and increased risk of bone fractures [48]. As a result, much attention today is focused on developing better treatment options. Given the rise of obesity not only in the USA but around the world [65], a number of pharmaceutical companies are looking to develop new treatments for obesity based on the addiction hypothesis [11]. Indeed, a number of new treatments are in both phase II and phase III clinical trials [3]. The majority of these potential treatment options target the neuropathways and neurotransmitters discussed in this chapter, including raclopride, bupropion, and antipsychotics which target dopamine; naltrexone, naloxone, and nalmefene which target the opioid system; baclofen and topiramate which target the GABAergic system; SR141716, AM 251, and rimonabant which target cannabinoid receptors; and several new pharmaceuticals [10, 66]. However, these medications are not without risk; many of these drugs carry significant side effects including increased risk for depression, anxiety, obsessive-compulsive disorder, seizures, suicide, confusion, or memory deficits [11]. Given the risks and side effects associated with these drugs, physicians will need to exercise great care when considering whether to prescribe these treatments and should carefully select their population base prior to prescribing [11].

71.3 Conclusion

As it stands, obesity and binge eating behaviors continue to be a threat to global health [5–7]. As such, more research is needed to better describe and understand the early signs and risk factors for BED and obesity. It is perhaps also time to reevaluate the current food environment from many aspects while taking into consideration both the individual's perspective and society as a whole. Societal measures may, in fact, be required at this time as dysfunctional eating behaviors affect not only the current generation but also its offspring due to the effects that consuming certain highly palatable foods may have on the developing brain in utero.

Given that some of the cultural factors discussed in this chapter are driven by economic factors that lie outside the control of the individual, the topic of obesity cannot simply be relegated to the domain of personal responsibility. Rather, economic incentives that may encourage people to make unhealthy food choices may need to be reevaluated on a larger scale. Indeed, any plan to combat the rise in obesity will need to address the economic, political, social, psychological, and biological factors that contribute to obesity, as well as factors such as taste, accessibility, convenience, cost, and level of promotion [65]. Moreover, society may need to closely reevaluate the current state of food marketing. As mentioned earlier, one study has found that food-addicted persons respond at an even higher level to food cues than their nonaddicted counterparts [28]. This finding suggests that advertising cues may contribute, at least in part, to compulsive eating in at-risk persons. Further, societal changes such as reevaluating where government subsidies are allocated, taxation, publicly enforced well-care programs, and corporate-driven employee well-being programs may also be needed to address the issues of disordered eating and obesity. While these efforts are not expected to cure obesity, binge eating, or food addiction, they may help to reduce their prevalence and aid prevention efforts.

Substance misuse

Multimorbidity is characterised by distinct clustering of multiple concurrent health conditions. Multimorbidity is a growing concern worldwide particularly amongst certain 'at-risk groups', such as drug and alcohol users and/or individuals with mental health problems [1, 14]. Some clusters are particularly common and often share a mechanistic basis (concordant conditions). Mechanistically distinct (discordant) morbidities [7, 9] may sometimes be a secondary consequence of ill-health (e.g. depression), whereas adverse reactions to treatment may also underlie some common clusters. Importantly, some clusters show no obvious connection, hinting at currently unknown risk factors or causal linkages.

Multimorbidity shows a non-random geographic distribution, but it is particularly common in rural and semirural areas, in part reflecting the age distribution as well as areas of deprivation. In many countries, the high burden of infectious disease is a major contributor: HIV/AIDS, hepatitis B and TB are highly prevalent, and chronic infections often coexist with other morbidities. Furthermore, epidemiological, demographic and nutritional transitions significantly affect patterns of ill-health [13]. Migration to cities and increased exposure to more affluent diets and lifestyles are shifting risk exposures and contributing to a marked rise in cardiometabolic diseases. Furthermore, many LMICs are facing the simultaneous challenge of widespread undernutrition, particularly in children coexisting with growing rates of obesity later in life, both of which have implications for the development of multimorbidity. As access to treatments in many countries improves, people with chronic medical conditions are living longer with additional morbidities and

with health consequences triggered by slowed disease progression and long-term treatment.

Multimorbidity affects all ages but is likely to be experienced differently at different stages of life. While multimorbidity is most common in older people, it is also common in younger age groups and affects substantial numbers of middle-aged people. Life expectancy is continuing to rise globally leading to larger numbers of older people with multiple health conditions. Further, modelling studies suggest that complex multimorbidity in old age will increase significantly over the next 20 years (The [15]). Indeed, it appears that the growing complexity of multimorbidity is contributing to a falling life expectancy in some countries including the UK and the USA.

It has been suggested that there is a need to understand common clusters, risk factors (biological and social) and disease mechanisms at different life stages, to inform prevention and models of care, including continuum of care as individuals transition into and out of care pathways (e.g. from juvenile to adult care) [2, 4]. As is the case with many individual chronic conditions, considerable social patterning is evident for multimorbidity. Young and middle-aged adults living in the most socioeconomically deprived areas have similar rates of multimorbidity to those 10–15 years older in the most affluent areas [1]. A 2017 study indicated the contribution of known risk factors, such as smoking and diet, to socioeconomic inequalities in multimorbidity across the life course [6]. The life-course perspective also emphasises that, as is clear from individual non-communicable diseases, the roots of multimorbidity may lie in much earlier influences.

A focus on multimorbidity across the life course, together with mechanistic studies, could reveal early predictors and biomarkers of multimorbidity and whether the impact of early influences relates solely to their effects on individual conditions or whether they have a more complex relationship with multimorbidity. This understanding could support the use of targeted interventions at different points in the life course, to influence long-term disease trajectories. Again, it will be important to determine the impact of these interventions on multimorbidity as well as individual conditions. One particular concern is multimorbidity that involves both physical and mental health conditions, as existing healthcare structures are not well aligned to deal with this, and outcomes for those with multimorbidity comprised of physical and mental health conditions tend to be worse [11]. Outcomes for mental/physical multimorbidity are particularly poor for those in the most socioeconomically deprived areas [8]. Reasons include poor general health, poor engagement with healthcare, lower rates of treatment uptake and higher rates of treatment dropout. Furthermore, the financial burden of multimorbidity in the healthcare system is higher when there is mental/physical comorbidity [3].

A particularly vulnerable group of the population, a high proportion of whom have multimorbidity, are people who use drugs [10]. The health consequences of drugs are major problems throughout the world with billions of people using legal (tobacco and alcohol) and illegal drugs (amphetamines, cocaine, opiates, hallucinogens and marijuana). Drug use is associated with burdensome social, economic and health consequences, the latter involving almost every physiological/biochemical system. These may include psychiatric, neurocognitive, cardiovascular, metabolic and hepatic complications and infectious diseases. Infectious diseases form the focus of several chapters in this section. An estimated one-third of the global population of 7 billion is living with one or more bacterial or viral infections (United Nations AIDS (UNAIDS) [16]). There are an estimated 500 million people who use illegal drugs regularly [17] in the world, and this population is at increased risk of bloodborne viruses and other infections.

Drug-related deaths (DRD) are a significant and increasing public health concern. Deaths attributed to the use of illegal or prescription drugs in 2016 showed an increase of 106% compared to 2006 in Scotland [12]. From the review of the literature, the increased mortality risk is clear—approximately six times higher for opioid users than for the general population—but the relative contribution of a range of factors is not

proven. The majority of opioid users die from causes other than overdose. Amongst opioid users in England, increased mortality has been shown for all causes using standardised mortality ratios (SMR), e.g. infectious disease (SMR 12.6), respiratory (SMR 9.2) and mental and behavioural (SMR 4.3) conditions. Predicted hospital admissions in Scotland for cardiorespiratory, hepatic and mental health conditions in drug users are anticipated to rise. Recent analysis of all-cause mortality in people prescribed with methadone identified circulatory disease as a leading cause of death [5].

Although there is a myriad of problems related to drug use, it is the medical consequences that are the leading causes of death, and consequently, these are of great medical concern. It is evident that this section on medical consequences of drug abuse is an important component of a comprehensive textbook of addiction medicine that should describe, most if not all, these health effects and their clinical management. In general, the principles of assessment and management of these disorders are no different from people who do not abuse drugs or alcohol, but this section of the textbook describes particular patterns of morbidities and approaches to management that distinguish this population.

This second edition reflects the increasing medical morbidities present to people with substance use. The complications and management of liver-related disorders including viral hepatitis in drug- and alcohol-using populations have been addressed by John Dillon et al. Additionally Dr. Brian Conway focused around co-occurring infections beyond HIV treatment. Neuropsychiatric and neurocognitive complications due to alcohol and drug use have been separated and addressed by Thomas Gilbertson et al. and Antonio Verdejo Garcia et al., respectively, acknowledging the increasing knowledge base that clinical neuroscience in addiction medicine is offering us.

The cardiopulmonary complications of alcohol and other drugs have been addressed by Peter Moore et al. and Stephen McNamara et al. This group has provided an overview on the broad range of cardiopulmonary issues including both the pathophysiological approach and practical approach for clinicians. Acute pain issues have been comprehensively reviewed by Michael Dinh et al. around trauma emergencies and by Steven Gilbert et al. around perioperative issues.

Gastrointestinal, endocrine and renal disorders are commonly seen in the substance-using population and addressed by Paul Haber et al., Anna Quirk and Annemarie Hennessy et al., respectively. Sexual dysfunction is another clinical problem that may be overlooked in clinical practice. This has been addressed by Richard Hallinan. Tim Roehrs et al. describe sleep disorders and present a clinical approach to their management. Finally, we expanded the chronic pain and dependence chapter addressed again by Steven Gilbert et al. and also introduced oral health issues in addictions addressed by Ruth Freeman et al.

In summary, this section provides the necessary knowledge base and core competencies to manage medical conditions that present as either comorbidities associated with drug and alcohol use and often as multiple morbidities. These conditions will need the best of care and interventions. The addiction medicine specialist of tomorrow needs to be well placed to coordinate and/or manage such complex care.

Abstract

Drugs of abuse often have important effects on the cardiovascular system, some of which are life threatening. An understanding of the intersection between addictive and cardiovascular disorders is increasingly relevant to general practitioners, emergency physicians, and psychiatrists. The effects of these drugs vary

depending upon the agent, dose, route of administration, and potential interactions with other medications. Cardiovascular consequences can range from innocuous side effects, such as mild tachycardia and hypertension, to life-threatening ventricular arrhythmias and myocardial infarction. Hemodynamic alterations are common with both active drug abuse and withdrawal and are frequently mediated by the autonomic nervous system.

The relationship between alcohol use and cardiovascular health is complex. Alcohol is one of the leading causes for systemic hypertension and often overlooked. Alcohol is also a common cause for atrial fibrillation and cardiomyopathy. Moderate alcohol use is linked to reduction in myocardial infarction but increased rates of stroke. Sympathomimetic drugs including amphetamines and cocaine result in an expected increase in blood pressure and heart rate. However, they may also cause substantial cardiotoxicity including ventricular arrhythmia, stroke, myocardial infarction (MI), heart failure, and death. Moreover, chronic stimulant drugs are atherogenic. Some of this is mediated by increases in blood pressure and lipids, but may also occur due to proinflammatory effects or increased hypercoagulability. By contrast, some drugs such as opioids lead to small reductions in pulse and blood pressure. Most naturally occurring opioids do not alter cardiac repolarization; however, synthetic opioids, such as methadone, may result in QTc-interval prolongation and torsade de pointes (TdP), a form of life-threatening ventricular arrhythmia. In this chapter, we review the cardiovascular effects of common drugs of abuse.

Myocardial infarction · Cardiotoxic · Arrhythmia · Sudden death · Heart failure

73.1 Introduction

Drugs of abuse have a myriad of cardiovascular effects. Depending on the drug, dose, and route of administration, cardiovascular consequences can range from innocuous side effects, such as mild tachycardia and hypertension, to life-threatening ventricular arrhythmias and MI (Table 73.1). Hemodynamic alterations are common with drug use and most often are mediated through interactions with the autonomic nervous system [35]. Sympathomimetic drugs like amphetamines and cocaine increase the release and inhibit the reuptake of peripheral catecholamines stimulating increases in heart rate, systemic vascular resistance, and cardiac contractility, thus resulting in augmentation of cardiac output and blood pressure. In contrast, several drugs are directly cardiodepressant in the acute setting, and many drugs of both types are cardiotoxic causing cardiomyopathy and congestive heart failure with long-term use.

Changes in the balance of myocardial oxygen supply and demand with drug use can lead to myocardial ischemia [35]. For example, cocaine augments oxygen demand in the myocardium by increasing heart rate, afterload, and contractility, while simultaneously decreasing supply by inciting epicardial coronary vasoconstriction. Modulation of lipid profiles, coagulation factors, platelet function, and inflammation further heighten the risk of cardiac ischemic events in patients using these drugs.

Table 73.1 Clinical cardiovascular effects of drugs of abuse

Drug	Cardiovascular effect
Ethanol	Hypertension
	Arrhythmias
	Dilated cardiomyopathy
	Stroke
Cocaine	Tachycardia
	Hypertension
	Accelerated atherosclerosis
	Chest pain
	Angina pectoris
	Myocardial infarction
	Ventricular and atrial arrhythmias
	Left ventricular hypertrophy
	Dilated cardiomyopathy, myocarditis
	Aortic dissection
	Infective endocarditis
	Stroke
	Mesenteric ischemia

Table 73.1 (continued)

Amphetamines	Tachycardia
	Hypertension

	Hypertension
	Dyslipidemia
	Myocardial infarction
	Ischemic stroke
	Ventricular hypertrophy

Many recreational drugs are arrhythmogenic in the acute setting or during abstinence/withdrawal. Mechanisms of arrhythmias are complex and likely result from interplay between the direct effects of drugs, electrolyte derangements, sympathetic nervous alterations, and cardiac ischemia. Of particular importance is the interaction of several drugs, especially the synthetic opioids, with a subunit of a voltage-gated potassium channel coded by the human Ether-à-go-go-related gene (hERG) [45]. Inhibition of this subunit causes alterations in repolarization during phase 3 of the action potential, which can lead to acquired prolongation of the rate corrected QT (QTc) interval, augmenting the risk of the ventricular arrhythmia torsade de pointes (TdP), and sudden cardiac death (Fig. 73.1)

Stress cardiomyopathies are also an increasingly recognized entity. In addition to extreme physical or emotional stressors, stress cardiomyopathy can develop from the abuse of sympathomimetic drugs or withdrawal states from depressant drugs (including alcohol and opioids). These patients often present with signs and symptoms of heart failure, elevated troponin, and ST-segment elevation on EKG, often resulting in initial treatment as an acute coronary syndrome. On echocardiography, the classic findings are that of apical "ballooning" with spared myocardial function at the base and no coronary obstruction on angiography.

This overview highlights the variety of short-term and long-term cardiovascular consequences of drugs of abuse, with a particular focus on alcohol, cocaine, and opioids employing a clinical vignette format.

Fig. 73.1 (**a**) Prolonged rate corrected QT interval (QTc). (**b**) Torsade de pointes (TdP), a type of polymorphic ventricular tachycardia

73.2 Main Text

73.2.1 Alcohol

Light-to-moderate alcohol consumption has been associated with a reduced risk of vascular events, but chronic heavy alcohol use is associated with hypertension, atrial fibrillation, stroke, and cardiomyopathy. Adverse cardiovascular effects begin to appear clinically with consumption of two to three standard drinks/day or more and increase thereafter in a dose-dependent fashion, though there may be subclinical evidence of echocardiographic dysfunction with even mild consumption [41, 56]. Alcohol is toxic to cardiomyocytes, in addition to increasing sympathetic tone, activating the renin-angiotensin-aldosterone system, and is associated with endothelial dysfunction [37, 56, 76].

Abstinence often results in rapid improvement in many of cardiovascular consequences and in some cases may the only intervention necessary in the long term to address alcohol-associated cardiovascular risk. However, acute alcohol withdrawal, delirium tremens in particular, can precipitate fatal cardiovascular collapse. Hypertension and tachycardia are classic symptoms of acute alcohol withdrawal, and though they improve within 3–4 days of alcohol cessation, they may precipitate ischemic or hemorrhagic stroke, acute decompensated heart failure, or cardiac ischemia. Fatal arrhythmias may also be precipitated by adrenergic surge, electrolyte deficiencies, and QT-interval prolongation. There is little direct evidence regarding management of cardiovascular complications of acute alcohol withdrawal in the setting of specific cardiac conditions, but propranolol and clonidine are most commonly suggested to treat withdrawal-related autonomic instability as well as aggressive replacement of potassium, magnesium, and phosphate. Intravenous dexmedetomidine, a central alpha-2 agonist, is increasingly used as an adjunct to benzodiazepines in treating withdrawal-associated agitation in the intensive care unit (ICU) setting. This medication may be particularly effective at reducing sympathetic outflow in the withdrawal state, but its use can cause bradycardia or hypotension and should be avoided in patients with pre-existing heart block [92].

Vignette

A 48-year-old man is evaluated in the emergency department for intermittent palpitations and chest pressure over the preceding 48 h. He does not regularly receive medical care and takes no medications. He smokes cigarettes, but uses no other drugs. He reports drinking a 12-pack of beer daily and consumed double his normal amount the week prior to presentation. He has an irregular heart rate of 130 bpm, a blood pressure of 140/90 mmHg, and pedal edema. The clinical diagnosis was alcohol withdrawal complicated by atrial fibrillation and was confirmed by ECG.

73.3 Atrial Fibrillation

Atrial fibrillation (AF) was identified in 1978 as the "Holiday Heart Syndrome" defined as dysrhythmia immediately following binge drinking, classically following a weekend, vacation, or year-end holiday [27]. Since then, moderate-to-heavy drinking has been associated with both new onset AF as well as exacerbation of existing paroxysmal AF, and it is suspected that alcohol is a causative factor in up to two-thirds of patients ≤65 years of age presenting with AF [18] (Fig. 73.2).

Acute AF related to alcohol and/or drug use often reverts to sinus rhythm without requiring electrical cardioversion in young patients [53]. However, if the patient is likely to continue to use alcohol, they will remain at an elevated rate of future episodes of paroxysmal AF that may become persistent. There are no specific recommendations regarding management of AF related to alcohol use. β-blockers have a theoretical advantage over calcium channel blockers for rate control in light of the adrenergic excess thought to contribute to alcohol-related AF. Alcohol and

Fig. 73.2 Atrial fibrillation. Note, the rhythm is "irregularly irregular"

drug abuse have been associated with a lower likelihood of treatment with guideline-directed antithrombotic therapy, and it remains important to risk stratify all patients using a validated risk score such as the $CHADS_2$ or CHA_2DS_2-Vasc score when deciding whether to initiate prophylactic antiplatelet or anticoagulation therapy [21]. However, heavy drinkers (>20 drinks per week for men, >13 for women) are at increased thromboembolic risk than lighter drinkers, even when controlling for anticoagulation or CHA_2DS_2-Vasc score [72]. Unlike warfarin, newer direct oral anticoagulants offer the advantage of not requiring routine monitoring and have been associated with lower rates than warfarin of intracerebral hemorrhage and gastrointestinal bleeding (particularly apixaban), both of which occur more frequently in alcoholics than nonalcoholics [62]. Nonetheless, very heavy drinkers are at high risk of fall and bleeding, limiting the safety of systemic anticoagulation.

73.3.1 Hypertension and Vascular Disease

Alcohol is associated with dose-dependent increases in blood pressure both acutely and chronically in men and women [65]. Abstinence has been associated with clinically meaningful reductions in blood pressure comparable with effects of antihypertensive medications [26]. In moderate or heavy drinkers, reduction in alcohol consumption can significantly improve systolic blood pressure, but no improvements were seen in hypertension when light drinkers abstained [88]. Therefore, abstinence or at least reduced consumption remains a primary recommendation for all patients with hypertension who misuse alcohol.

The association between alcohol and cardiovascular mortality is J-shaped, with small to moderate amounts of ethanol producing reductions in vascular events [99]. However, heavy alcohol use is associated with increases in coronary artery disease, ischemic stroke, and cerebral hemorrhage compared with moderate drinkers [59, 89]. The mechanism of this association remains controversial, but is likely due in part to increased serum triglycerides, hypertension, decreased nitric oxide synthesis, and increased inflammation [12]. Binge drinking may cause an acute increase in stroke risk within 1–24 h of abuse [89]. This may be due to reactive thrombocytosis and increased platelet aggregation during alcohol withdrawal, and we speculate that increased adrenergic activity may also play a role. The increased risk of stroke and MI returns toward baseline in former heavy drinkers, and apart from abstinence, there are no risk reduction strategies recommended [87].

73.4 Cardiomyopathy

Although light-to-moderate alcohol consumption has been associated with a lower rate of heart failure than nondrinkers, chronic heavy alcohol use is a well-known cause of left ventricular (LV) systolic dysfunction. Most men who develop alcoholic cardiomyopathy have consumed ≥5 standard drinks per day for ≥5 years [70]. Women appear to be more sensitive to the cardiotoxic effects of alcohol and may develop cardiomyopathy with a smaller comparative exposure [28]. Evidence of cardiotoxicity may be apparent on

echocardiography long before the emergence of symptoms, even in light or moderate drinkers [41]. Direct myocardial damage may be mediated by acetaldehyde, the first metabolite of ethanol. Acetaldehyde levels are particularly elevated in heavy drinkers, in part due to reduced hepatic aldehyde dehydrogenase activity [100]. Chronic activation of the renin angiotensin aldosterone system and sympathetic nervous system and nutritional deficiency (especially thiamine) may also contribute to progression of myocardial dysfunction by potentiating alcohol and acetaldehyde-induced cell death.

Abstinence can result in significant improvement in LV systolic function if achieved early during the progression of myocardial dysfunction. Long-term survival in patients with alcoholic cardiomyopathy who achieve abstinence is the same or better than patients with idiopathic dilated cardiomyopathy, whereas patients who continue to drink have a lower survival [78]. In addition to standard heart failure therapies, additional considerations in the setting of alcoholic cardiomyopathy are nutritional and vitamin supplementation, particularly vitamin B12 and folate.

73.5 Sudden Cardiac Death

Large studies have demonstrated an elevated risk of sudden death associated with heavy drinking, even in patients without pre-existing ischemic or structural heart disease [75]. Sudden death may also occur during periods of abstinence or withdrawal [17]. The QTc interval may be prolonged in up to 63% of cases during alcohol withdrawal and normalizes with remission of withdrawal symptoms. Electrolyte abnormalities, catecholamine excess, impaired vagal control of heart rate, myocardial fibrosis, and sleep apnea may also contribute to a heightened risk of arrhythmia [57].

In addition to correction of electrolyte abnormalities, particularly hypokalemia and hypomagnesemia (which prolong the QTc interval), it is essential to provide cardiac telemetry monitoring during the early stages of withdrawal, particularly in the setting of underlying structural heart disease and severe symptoms including delirium tremens. Furthermore, administration of QTc-prolonging medications such as antipsychotics must be used cautiously, as there appears to be acute, transient prolongation of the QTc interval and increased QT variability during alcohol withdrawal. There is currently no recommendation for prophylactic antiarrhythmic therapy or continuing therapy after alcohol withdrawal has subsided, although β-blockers to treat hypertension and tachycardia are often used.

73.6 Cocaine

Vignette

A 44-year-old man presents to the emergency department with complaints of midsternal chest discomfort of moderate severity, which has been unremitting for the past 3 h and radiates to his shoulders. He denies illicit drug use but became more agitated when this line of questioning was pursued. Blood pressure is 178/90 mmHg, pulse rate is 95 beats per minute, while respiratory rate, temperature, and oxygen saturation are within normal limits. Urine toxicology is positive for cocaine metabolites. Upon sharing these results, the patient confides that he and his girlfriend consumed an "eight-ball" (3.5 grams) of cocaine by intranasal route. His electrocardiogram (ECG) demonstrates ST-segment elevation in leads V2-V5 with peaked T-waves. QRS duration and rate corrected QT (QTc) intervals are prolonged. Chest X-ray and serum chemistries (including cardiac troponin) are unremarkable.

Cocaine incites a wide array of cardiovascular consequences ranging from acute alterations in hemodynamics to myocardial ischemia, ventricular arrhythmias, and dilated cardiomyopathy (Table 73.1). The extensive effects on the cardiovascular system result from its numerous mecha-

nisms of action. Cocaine is a potent sympathomimetic that augments central sympathetic outflow and has the ability to increase peripheral catecholamine concentration. Cocaine also exhibits inhibition of voltage-gated sodium channels and potassium channels and has complex, poorly understood interactions with L-type calcium channels [80].

73.6.1 Hemodynamic Effects

Sympathomimetic activity dominates at low-to-moderate doses resulting in tachycardia, systemic vasoconstriction, and coronary vasospasm. When taken at low doses (~0.35 mg/kg) through the intranasal route, cocaine results in slight elevation of systolic blood pressure. Higher doses (~1.3 mg/kg) will cause an increase in systolic and diastolic blood pressure (~30/15 mm Hg) and elevation of the heart rate (~20 bpm). The onset of these alterations occurs at 2 min and peaks at 5–10 min [81]. Moderate cocaine doses (2–3 mg/kg) have a positive inotropic effect, resulting in an increase in LV contractility and cardiac index [10].

Tachycardia is mediated through β-adrenergic receptor stimulation as β-blockade with propranolol abolishes the increase in heart rate caused by cocaine [47]. Hypertension is partially mediated through α-adrenergic receptors as α-blockade with prazosin experimentally prevents vasoconstriction [23]. However, positive inotropic effects facilitated through β-adrenergic stimulation contribute to hypertension caused by cocaine, as propranolol attenuates the rise in mean arterial pressure by diminishing the cocaine-mediated rise in LV contractility. Combined α- and β-blockade with labetalol eliminates cocaine's chronotropic effect on the heart and significantly blunts the increase in blood pressure [47].

73.6.2 Myocardial Ischemia

Cocaine-related chest pain is typically described as pressure-like in quality and is frequently associated with dyspnea, diaphoresis, nausea, palpitations, and anxiety [68]. The reported incidence of acute MI in patients with cocaine-related chest pain ranges between 0.7% and 6%. There is a 24-fold increased risk of acute MI within the first hour of cocaine use. However, myocardial injury can also occur hours after use, presumably due to cocaine metabolites [68]. Cocaine is estimated to play a role in 25% of MIs in patients between the ages of 18 and 45, and half of patients with cocaine-related MIs have no evidence of atherosclerotic coronary artery disease on angiography [55, 79]. The diagnosis of MI in those with recent cocaine use is difficult. There are no historical factors useful for distinguishing MI from chest pain without myocardial injury in this population. Specific characteristics of pain such as onset, location, quality, and duration are not predictive, nor are histories of chest pain, MI, or risk factors for atherosclerotic coronary artery disease [40]. ECG data is equally challenging: Presenting ECGs are abnormal in approximately 55–85% and up to 43% of patients with cocaine related chest pain meet diagnostic criteria for ST-elevation MI (as defined by >0.1 mV elevation in contiguous leads) [15]. The positive predictive value of ECG for MI in this population is reportedly only 18% with a sensitivity of approximately 36% [40]. Serum troponin assays remain effective in detecting myocardial injury in cocaine users [55].

The sympathomimetic actions of cocaine augment myocardial oxygen consumption by increasing heart rate, blood pressure, and myocardial contractility, while also leading to vasospasm [55]. In addition to α-adrenergic stimulation, cocaine causes vasospasm by increasing the expression of the potent vasoconstrictor endothelin and decreasing levels of nitric oxide [71, 96]. In several studies employing a recreational dose of cocaine (2 mg/ml) intranasally in humans, coronary artery caliber is reduced [8]. In a study of patients with and without coronary artery disease undergoing diagnostic catheterization, coronary diameter decreased more than twice as much in diseased arteries (>50% stenosis) versus normal arteries [31]. The time course of coronary vasospasm does not simply follow peak serum levels of cocaine and

occurs at a greater magnitude at 90 min post-administration versus 30 min when serum levels peaked [11]. The degree of vasospasm is augmented by concurrent cigarette smoking. Aside from vasospasm, habitual cocaine use has been linked to premature coronary artery disease in postmortem studies, which is thought to result from increase vascular permeability to low-density lipoprotein (LDL) cholesterol [55]. Acute cocaine use is also associated with intracoronary thrombus formation, by triggering platelet aggregation [55].

Those with chest pain in the setting of cocaine use should receive IV benzodiazepines promptly, which relieves chest pain and mitigates hemodynamic alterations. Nitroglycerin reverses cocaine-associated coronary vasoconstriction and calcium channel blockers are recommended after benzodiazepines and nitroglycerin have failed. Phentolamine, an α-adrenergic blocker, may also be administered as a second-line agent among hypertensive patients, as it reverses coronary vasoconstriction.

Recent guidelines for unstable angina and non-ST-elevation MI recommend treating patients with cocaine-related acute coronary syndrome like patients with no history of cocaine abuse, unless signs of acute intoxication are present (hypertension, tachycardia, and euphoria). If these signs are present, then the use of benzodiazepines is supported and β-blockers should be used cautiously unless vasodilators (e.g., nitroglycerine) are being co-administered, because unopposed α-adrenergic stimulation can potentially exacerbate coronary vasoconstriction and worsen arterial hypertension [3]. Several retrospective studies have evaluated outcomes in patients with cocaine-related chest pain who were given β-blockers prior to the discovery of their recent cocaine use. It was found that β-blocker therapy was associated with a lower incidence of MI without change in the rate of adverse outcomes or peak levels of troponin [42]. More recent systematic reviews have suggested that use of combined α- /β-blockers such as labetalol or carvedilol are safe and efficacious at mitigating the tachycardia and hypertension of acute intoxication, though this finding will need to be confirmed in larger trials [84].

Due to the risk of coronary thrombus formation, patients should be given aspirin, and those with proven MI should receive unfractionated heparin or low molecular weight heparin if there are no contraindications [68]. Fibrinolytics should be used with caution, as there are reports of devastating complications in cocaine users and the diagnosis of STEMI is challenging in this population due to baseline ECG abnormalities [55, 68]. Percutaneous coronary intervention is the preferred management of intracoronary thrombus [3].

Outcomes are generally better in cocaine-related MI compared to MI not related to cocaine [68]. The incidence of ventricular arrhythmias, congestive heart failure, and death are 4–17%, 5–7%, and < 2% respectively [55]. Improved outcomes are presumably due to the overall younger age of patients experiencing MI while using cocaine. However, those who experience cocaine-related MI are at high risk for recurrent ischemic events as more than half will continue to use cocaine and up to 58% will have recurrence of ischemia [68].

73.6.3 Cardiac Conduction and Arrhythmia

Cocaine can cause a wide range of electrocardiographic alterations [80]. Cocaine acts similar to Vaughan Williams Class I antiarrhythmics by blocking voltage-gated sodium channels (I_{Na}) in the inactive state. Cocaine also blocks the *hERG* coded voltage-gated potassium channel responsible for the rapid delayed rectifier potassium current (I_{Kr}) that allows for repolarization. Together, the inhibition of I_{Na} and I_{Kr} slow the rapid upstroke of the action potential during phase 0 and prolong the action potential duration by delaying phase 3. Electrocardiographically this can result in *both* widening of the QRS complex and prolongation of the QTc interval.

Clinically, cocaine use is associated with a variety of arrhythmias and ECG abnormalities (Table 73.2) [55]. The most common alteration is sinus tachycardia, but an assortment of rhythm disturbances have been temporally related to cocaine use, including non-sustained supraven-

Table 73.2 Arrhythmias and ECG abnormalities associated with cocaine

Arrhythmia	ECG abnormality
Sinus tachycardia	PR interval shortening
Sinus bradycardia	PR prolongation (first degree AV block)
Supraventricular tachycardia	QRS widening:
Atrial fibrillation	Nonspecific intraventricular block
Atrial flutter	Right bundle branch block
Second and third degree AV block	Left bundle branch block
Accelerated idioventricular rhythm	Left anterior fascicular block
Torsade de pointes	QTc-interval prolongation
Ventricular tachycardia	ST-segment elevation/ depression
Ventricular fibrillation	T-wave peaking, flattening, inversion
Asystole	Acquired Brugada pattern
	ST elevation, down-sloping ST-segment and T-wave inversion

tricular tachycardia, atrial fibrillation, and sinus bradycardia [80]. Excluding cocaine-related TdP, prospective studies have not consistently demonstrated an increased risk of ventricular arrhythmias other than frequent premature ventricular complexes. However, the literature contains frequent case reports of monomorphic ventricular tachycardia and ventricular fibrillation in cocaine users. These associations are often confounded by polysubstance use and electrolyte derangements, especially acidosis.

A retrospective report found that QTc-interval prolongation is present in approximately 4% of chronic cocaine abusers, 26% of patients treated for cocaine toxicity in the ED, and 75% of cases of cocaine-related mortality [15]. In addition to its ability to prolong the QT interval, cocaine has been shown to induce early afterdepolarizations, further increasing the risk of the ventricular arrhythmia TdP [48]. In the case report literature, QT prolongation is frequently reported, and associated TdP occurred in almost half of these cases [80].

Cocaine has seemingly contradictory interactions with atrioventricular conduction [80]. Several small observational studies have shown that cocaine use is associated with PR segment shortening, which would suggest that cocaine enhances conduction through the AV node. However, the case report literature is incongruent with these results and contains several cases of PR prolongation with various degrees of AV block. QRS interval widening reportedly occurs in up to 6% of patients using cocaine, which is most commonly due to nonspecific intraventricular conduction delay or right bundle branch block. It is important to note that many of these cases may be confounded by electrolyte derangements and concomitant ingestion of other substances.

There have been cases of acquired Brugada pattern associated with cocaine use [80]. However, electrophysiological testing did not induce sustained ventricular arrhythmias in any of these cases, and it is unknown if cocaine-associated Brugada pattern confers any additional risk of sudden cardiac death.

73.6.4 Other Effects: Cardiomyopathy, Endocarditis, Aortic Dissection, and Stroke

Cocaine can cause LV hypertrophy and can be a myocardial depressant resulting in LV systolic dysfunction [55]. There are reports of dilated cardiomyopathy in long-term cocaine users as well as acute, reversible, profound LV dysfunction after binge use [55]. One study found that LV dysfunction is present in 7% of apparently healthy, asymptomatic cocaine users [9].

In those with congestive heart failure, stimulant use (cocaine and amphetamines) is associated with an increased incidence of hospitalization and reduced ejection fraction [20]. Cocaine cessation leads to improved myocardial function, and cocaine relapse can cause recurrence of decompensated heart failure [93]. The possible mechanisms of cocaine's reduction in systolic function include myocardial ischemia/infarction, repetitive sympathetic stimulation (similar to cardiomyopathy associated with pheochromocytoma), hypersensitivity to adulterants or infectious agents leading to myocarditis, alteration of intracellular calcium concentration, and stimulation of cytokine production resulting in remodeling and myocyte necrosis [55].

As with any substance used by the intravenous route, there is a risk of bacterial endocarditis with IV cocaine use [55]. For unknown reasons, cocaine seems to increase the risk of endocarditis compared to other drugs. Left-sided valves are more frequently involved with cocaine than other IV drugs.

Aortic dissection is well described in the setting of cocaine intoxication [22]. The mechanism of cocaine's association with aortic dissection is thought to involve hypertension and tachycardia with a resulting increase in arterial wall shear stress. Cocaine is associated with decreased aortic elasticity, increased smooth muscle cell apoptosis, and premature atherosclerosis, all of which play a role in increasing the risk for aortic dissection [49].

Cocaine use confers a twofold increase in the risk of ischemic and hemorrhage stroke [93]. Subarachnoid hemorrhage most commonly results from rupture of arterial aneurysms, and intracerebral hemorrhagic strokes are thought to result from large spikes in blood pressure. Cocaine users with hemorrhagic strokes have worse functional outcomes and increased mortality [66]. Overall, cocaine is widely considered among the most cardiotoxic among drugs of abuse.

73.7 Amphetamines

Amphetamines cause an increase in catecholamine concentrations both centrally and peripherally by stimulating their release, blocking their reuptake, and inhibiting their metabolism by monoamine oxidase [30]. This section focuses primarily on three commonly abused amphetamines: amphetamine, methamphetamine, and 3,4-methylenedioxymethamphetamine (MDMA).

Amphetamines cause tachycardia, vasoconstriction, and hypertension, similar to the effects of cocaine [14]. The most common clinical presentations of amphetamine users requiring hospitalization are chest pain, tachyarrhythmia, palpitations, and hypertension. There are an abundance of reports of acute MI in amphetamine users [14]. The pathogenesis of coronary ischemia results from an increase in myocardial oxygen demand, chronotropy, wall stress, and afterload, with a simultaneous reduction in coronary blood flow secondary to vasoconstriction [14].

Amphetamines are also associated with sudden cardiac death due to malignant ventricular arrhythmias [14]. Methamphetamine has been shown to prolong the QTc interval in humans, increasing the risk of TdP. The mechanism is not well understood, but may relate to inhibition of transient outward potassium current, inward rectifying potassium current, and via the L-type calcium channel [60].

Aortic dissection has been strongly associated with methamphetamine intoxication in case reports [46]. In fact, one autopsy series found that after hypertension, methamphetamine use was the most common risk factor for fatal acute aortic dissection [94].

Like cocaine, amphetamines are linked to cardiomyopathy in the acute and chronic setting. In some cases the cardiomyopathy may reverse with abstinence. Additionally, Takotsubo cardiomyopathy has been described in the setting of acute amphetamine use [14]. As with other cardiomyopathies, the cornerstone of therapy is neurohormonal blockade. Similar to acute cocaine intoxication, β-blockers should be considered carefully in acute amphetamine intoxication. The available evidence would suggest that combined α- /β-blockers such as labetalol and carvedilol are safe and effective at treating the associated tachycardia and hypertension [82].

73.8 Amphetamine-Like Drugs

Synthetic "designer drugs" have gained increased popularity in recent years. These include "bath salts," [7] which typically contain 3,4-methylenedioxy-N-methylcathinone (methylone), 4-methylmethcathinone (mephedrone), and 3,4-methylenedioxypyrovalerone (MDPV), as well as alpha-pyrrolidinovalerophenone ("Flakka"). These drugs are synthetic cathinones; cathinone is found naturally in khat (*Catha edulis*) and exhibits amphetamine-like properties

[16, 19]. In addition to significant behavioral disturbances, the use of these drugs has been associated with sudden death, endocarditis, MI, and cardiomyopathy [7, 16, 19]. While no trials currently exist as to the optimal treatment of cardiovascular complications of cathinone derivatives, they should be approached similar to acute cocaine or amphetamine intoxication [85].

73.9 Opioids

Cardiovascular effects of opioids tend to be relatively mild, with no direct effect of most opioids on cardiac rhythm or myocardial contractility. However, orthostatic hypotension may occur, presumably secondary to histamine release and vasodilation of peripheral arteriolar vessels. In patients with acute coronary syndromes, opioids are often used intravenously for relief of chest discomfort. Intravenous morphine leads to mild venodilatation, which decreases preload and myocardial oxygen consumption in the setting of LV systolic dysfunction and pulmonary edema. Intravenous opioids also result in a small decrease in pulse and blood pressure in the acute coronary syndrome patient. Opioids may also improve myocardial energetics at the cellular level and have been associated with enhancement of "ischemic preconditioning." This phenomenon entails repetitive episodes of noncritical ischemia, which may provide myocardial protection to patients chronically treated with opioids, where a lower burden of coronary artery disease was noted relative to expected global risk (Framingham) score [64]. The authors found a lower burden of coronary artery disease among opioid users and postulated that this may relate to ischemic preconditioning.

By contrast to the potential protective effects of opioids regarding atherosclerotic risk, evidence suggests that synthetic opioids, such as methadone, may block the delayed rectifier potassium ion current known as I_{Kr}, which is encoded by the *hERG* gene, leading to TdP, a form of polymorphic ventricular tachycardia that occurs in the obligatory setting of QTc-interval prolongation. The pathobiologic sequence of events leading to sudden cardiac death in susceptible individuals receiving methadone is depicted in Figure 73.3. Blockade of the hERG potassium channel increases the action potential duration, which delays repolarization. This manifests as QT prolongation. If a premature ventricular complex occurs (early after depolarization or EAD), this triggers TdP, which may degenerate into ventricular fibrillation (VF) and death.

Vignette

A 34-year-old law school student presents to your psychiatry office with fevers, malaise, and rigors for 10 days. He has a 7-year history of intermittent recreational opioid

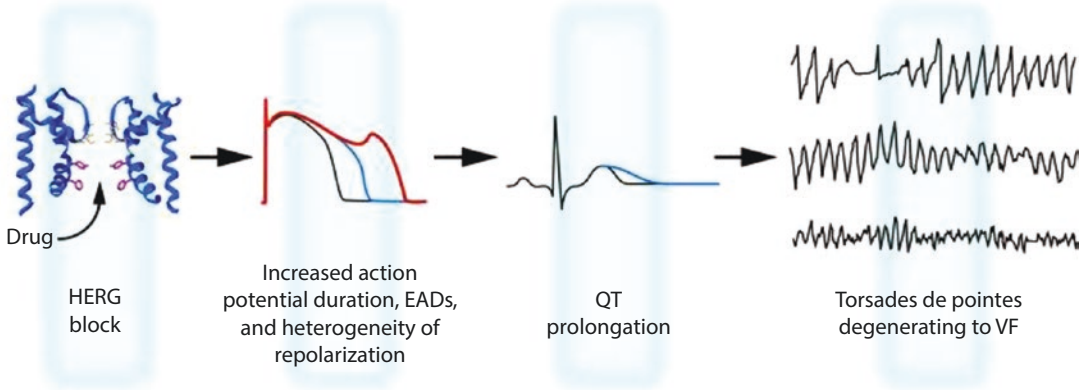

Fig. 73.3 Mechanism of drug induced TdP. From Roden and Viswanathan [101]

abuse. Over the past 6 months, he reports escalation in prescription opioid use including oxycodone and hydrocodone cough syrup with dextromethorphan. When he is unable to use opioids, he develops withdrawal symptoms and 2 weeks ago he admits to a period of heroin use. His last opioid consumption was 2 h ago. The patient is in no acute distress. Examination is notable for a temperature of 38.5 °C; blood pressure is 135/70 mmHg, and pulse is 112 bpm. Cardiovascular exam is notable for a grade III systolic murmur. He reluctantly rolled up his sleeves, revealing the presence of healed track marks and a small abscess in the left antecubital fossa.

73.9.1 Heroin

The effects of heroin on the cardiovascular system are not extensive, which may in part reflect its close derivation from the natural opium poppy. Heroin abuse is associated with acute pulmonary edema, but this is generally non-cardiogenic in origin. The typical hemodynamic findings include normal pulmonary-capillary wedge pressure and a normal or increased cardiac output suggesting the absence of direct myocardial toxicity [6]. Although moderately elevated pulmonary artery pressures have been described, this is most likely due to direct pulmonary toxicity in the setting of injected impurities or in overdose reflective of hypoxemia leading to subsequent increased pulmonary-capillary leakage akin to respiratory distress syndrome.

The most feared cardiovascular complication of intravenous heroin abuse is the development of infective endocarditis, often due to virulent pathogens such as *Staphylococcus aureus*. Heroin may also result in embolic stroke due to systemic embolization of valvular vegetations to the brain. Infective endocarditis of the right-sided heart valves (tricuspid and pulmonic) should always alert the clinician to the possibility of surreptitious intravenous drug abuse. Cases of potential endocarditis should be confirmed immediately by blood cultures and transthoracic echocardiography, which is often diagnostic particularly for right-sided valvular vegetation. If there is a high clinical suspicion, transesophageal echocardiography is increasingly utilized as it offers enhanced visualization, particularly of left-sided valvular structure [5].

Vignette (continued)
The patient is effectively treated for tricuspid valve endocarditis with 6 weeks of intravenous antibiotics with resolution of symptoms. He returns to school but eventually begins to relapse and abuse heroin. He asks for assistance and it's decided to induce him onto methadone maintenance therapy. He is initiated on 30 mg/day and he is up-titrated to 90 mg daily at which point he feels well and discontinues illicit opioids entirely. One month later he is at the opioid treatment center and develops the sudden onset of tonic-clonic seizures and loss of consciousness. He regains awareness and you refer him for neurologic evaluation. Computed tomography of the brain and electroencephalography are normal. Subsequently, magnetic resonance imaging is performed without focal lesion. He is started on low-dose antiepileptic therapy but one month later is involved in a motor vehicle accident after passing out while driving.

73.9.2 Methadone and Synthetic Opioids Used in Addiction Treatment

The most feared cardiovascular effect of methadone and synthetic opioids QTc prolongation and subsequent ventricular arrhythmia. The arrhythmic risk is primarily derived from the effects of these drugs on cardiac repolarization, which is the phase in the cardiac cycle where myocytes "reset" and is clinically characterized by the QTc interval on the surface ECG. The cardiac repolar-

ization changes associated with synthetic opioids were characterized in human cells stably transfected with the hERG gene which encodes the I_{Kr} current [45]. The ratio of the concentration of drug that blocks 50% of I_{Kr} channels (IC50%) was divided by the expected maximal plasma concentration (Cmax) in man for the individual drugs yielding the IC50/Cmax. This ratio predicts the likely occurrence of QTc prolongation, with higher numbers suggesting the greatest margin of safety. The IC50/Cmax observed with codeine and morphine (and by extension diacetylmorphine or heroin) was >400. These "naturally occurring" opioids therefore are not associated with QTc prolongation and TdP. By contrast, the synthetic opioids fentanyl, meperidine, and buprenorphine exhibited modest blockade with IC50/Cmax ranging from approximately 50 to 200. Notably, the most potent I_{Kr} blockade was observed with methadone and levacetylmethadol (LAAM), with ratios of 2.7 and 2.2, respectively. This creates a challenging paradox: while synthetic opioids clearly reduce the harm of injection drug use including the risk of hepatitis, HIV, and endocarditis, they also have a cardiac safety liability in susceptible individuals.

Methadone and buprenorphine are the only FDA-approved therapeutic choices for opioid-dependent patients. In 2002, a case series of TdP associated with high-dose oral methadone was first described [51]. In the case presented within the clinical vignette, it is likely that the patient's grand-mal seizures and syncope were manifestations of TdP. TdP is a self-terminating arrhythmia in most cases, though it may degenerate into ventricular fibrillation and lead to sudden cardiac death. A case of methadone-induced arrhythmia masquerading as epilepsy has been previously described [50]. This highlights the fact that ventricular arrhythmia may result in marked reduction of cardiac output and cerebral hypoxemia and subsequent seizures. Thus, seizures are not always due to epilepsy and should alert clinicians to the possibility of life-threatening arrhythmia.

Ventricular arrhythmia and cardiac arrest are now the most frequent FDA-reported class of methadone-associated adverse events, and reports of QTc prolongation and TdP have increased sharply [44]. Because methadone causes QTc-interval prolongation and TdP, a consensus guideline suggesting QTc-interval screening was developed [52]. The guideline emphasized five recommendations for physicians prescribing methadone (Table 73.3). Because the arrhythmia risk associated with methadone is a direct consequence of its effect on cardiac repolarization, the recommendations are applicable to patients either receiving current treatment with methadone or being considered for initiation of methadone treatment for addiction or pain management. Methadone is now considered an essential medication by the World Health Organization, and its utilization is expected to rise, highlighting the need to enhance its cardiac safety.

Table 73.3 Consensus recommendations for QTc-interval screening in methadone treatment [52]

Recommendation 1 (Disclosure)	Clinicians should inform patients of arrhythmia risk when they prescribe methadone
Recommendation 2 (Clinical history)	Clinicians should ask patients about any history of structural heart disease, arrhythmia, and syncope
Recommendation 3 (Screening)	Obtain a pretreatment ECG for all patients to measure the QTc interval and then a follow-up ECG within 30 days and annually. Additional ECG is recommended if the methadone dosage exceeds 100 mg/d or if patients have unexplained syncope or seizures
Recommendation 4 (Risk stratification)	If QTc interval is >450 ms but <500 ms, discuss potential risks and benefits with patients and monitor them more frequently. If the QTc interval exceeds 500 ms, consider discontinuing methadone or reducing the methadone dose; eliminating contributing factors, such as drugs that promote hypokalemia; or using an alternative therapy
Recommendation 5 (Drug interactions)	Clinicians should be aware of interactions between methadone and other drugs that possess QT interval–prolonging properties or slow the elimination of methadone

73.9.3 Nicotine

Cigarette smoking is the leading risk factor for developing cardiovascular disease, increasing risk of coronary artery disease by up 80–100% [58]. Secondhand smoke exposure is also harmful, potentially increasing risk of coronary artery disease by up to 30% [95]. The biologic effects of secondhand smoke have been well characterized and mirror those of direct tobacco exposure. In particular, coronary arterial plaque destabilization is triggered by nicotine in secondhand smoke; this stimulates the matrix metalloproteinase enzyme that degrades the fibrous cap in coronary plaques [13]. Secondhand smoke is also associated with impaired coronary endothelial function and increased aortic stiffness [63].

Nicotine acts in part by stimulating release of norepinephrine from sympathetic nerves and by release of epinephrine from the adrenal glands, which produce increases in heart rate and blood pressure shortly after exposure. Although the precise role of nicotine relative to other components of cigarette smoke is unclear, cigarette smoking is also associated with vasomotor dysfunction mediated by reduced availability of nitric oxide, systemic inflammation that increases adherence of leukocytes to endothelial cells, increases in serum low-density lipoprotein and triglycerides with decreases in high-density lipoprotein, platelet dysfunction, and alteration of thrombotic factors [2]. Consequently, cigarette smoking is associated with increased rates of all-cause and cardiovascular mortality, first MI, recurrent infarction or revascularization in patients with coronary artery disease, sudden death, and stroke [36, 86].

Cessation of smoking is associated with rapid decreases in cardiovascular events including MI, stroke, and sudden death, with rates returning to near that of nonsmokers within 3–4 years in many cases [34]. Although the increased risk of cardiovascular events associated with smoking appears to increase with age, the benefits of cessation are independent of age. Despite the clear risks of smoking and benefits of smoking cessation, smoking rates remain relatively stable, and the rate at which physicians in the USA advise patients to stop smoking has actually decreased over time [54]. Intensive support including structured behavioral modification counseling and pharmacotherapy with either nicotine replacement therapy and/or bupropion appears superior to one-time counseling in patients hospitalized for coronary disease or heart failure, although even a brief statement to outpatients of the risks associated with smoking can result in increases in smoking cessation [61]. Despite the stimulating nature of nicotine, large studies have failed to show an increased risk of cardiovascular events or death following initiation of nicotine replacement therapy in the setting of cardiovascular disease. There are very few drug-drug interactions between nicotine replacement therapy and cardiovascular medications. Bupropion appears safe to use in patients hospitalized for acute MI, but may not be as effective as in chronic, stable outpatients [24]. The use of varenicline in patients with cardiovascular disease has been controversial, but recent data indicate that varenicline use is both safe and efficacious even in the immediate post-MI setting [25]. As patients are most likely to quit immediately after having an MI, the use of prescription cessation medications in these patients may present a unique opportunity to augment their efficacy [74].

73.10 Cannabis

Cannabis (marijuana) is generally thought to be relatively benign by the community despite growing evidence that implicates it in several serious cardiovascular complications including MI and ischemic stroke. Cannabis is most commonly smoked and rapidly absorbed through the lungs with physiologic changes appearing shortly after use [35]. When consumed through the enteral route, absorption is slower and less predictable. The adverse cardiovascular effects of marijuana are thought to be mediated by the CB1 receptor, which is activated by tetrahydrocannabinol (THC) – the main psychoactive constituent of marijuana [73].

THC causes a biphasic autonomic response. The sympathetic nervous system is activated at

low-to-moderate doses, and the parasympathetic nervous system predominates at higher doses [35]. This results in tachycardia and augmented cardiac output at lower doses and hypotension and bradycardia at high doses. Even at low doses, cannabis can cause both hypertension and hypotension. Blood pressure alterations during cannabis use are often positional; blood pressure increases while in the seated or supine position and drops while standing. Hypotension can also occur during the act of smoking due to rapid changes in autonomic nervous system output, and orthostatic hypotension with resulting syncope is not an uncommon occurrence. Autonomic changes are generally well tolerated in healthy individuals, and cannabis-induced hypotension usually resolves spontaneously or responds to intravenous fluid boluses [35].

Cannabis use increases myocardial oxygen demand by increasing heart rate, wall stress, and sometimes blood pressure. Additionally, when smoked, it decreases oxygen supply through carboxyhemoglobin formation. Cannabis use has been shown to decrease the threshold for symptomatic angina pectoris [4]. Furthermore, in a systematic review of over half a million patients, cannabis users are at higher risk of acute MI shortly after using marijuana and continued use after MI was associated with an increased risk of death during the follow-up period [83].

In addition to cardiac ischemia, evidence is emerging that implicates cannabis use with other acute vascular emergencies, including aortic dissection, vasculitis, and ischemic stroke [67, 91, 97]. In a 2013 study, there were 59 reported cases of stroke associated with cannabis use [97]. All but one were ischemic in origin and the patients were often young. Cannabis use has been particularly strongly associated with two specific etiologies of ischemic stroke: reversible cerebral vasoconstriction syndrome (RCVS) and multifocal intracranial stenosis (MIS). In a prospective study evaluating cannabis' role in ischemic stroke, a single center enrolled every patient under 45 years of age that presented with ischemic stroke [98]. It was found that cannabis use was highly associated with ischemic strokes caused by multifocal intracranial stenosis. Caution must be taken with attributing these events solely to cannabis, as patients also smoked tobacco regularly and half of these patients had binged on alcohol shortly before their ischemic events. However, further study has demonstrated a 17% increased risk of ischemic stroke in cannabis users, even when controlling for comorbidities and abuse of other substances [90].

A number of arrhythmias have also been temporally related to cannabis use such as sinus bradycardia, atrial fibrillation, atrial flutter, premature ventricular contractions (PVCs), and second degree AV block [29, 77]. The onset of arrhythmias can begin within a few minutes of cannabis use, peaks at about 30 min, and can last as long as 90 min [43]. The majority of these arrhythmias revert spontaneously to sinus rhythm. There are two cases of cannabis-induced Brugada pattern, neither of which were associated ventricular arrhythmias [77].

Synthetic cannabinoids have gained increasing popularity in recent years; street names include "K2," "Spice," and "Black Mamba." The active compounds are often many times more potent than THC in activating CB1 receptors with some compounds reportedly 170 times more active than THC. There are numerous case reports of adverse cardiovascular effects associated with their use. The expected cardiovascular morbidity and mortality is likely higher with synthetic cannabinoids than cultivated cannabis, though the variation in active ingredients and lack of regulation make systematic study difficult [73].

Interestingly, there has been some research which suggests that certain cannabinoids may have cardioprotective effects. Cannabidiol (CBD), a non-psychoactive component of marijuana, has gained popularity with a wide range of reputed effects and uses including treatment of chronic pain. CBD has demonstrated anti-inflammatory properties which may result in plaque stabilization and has also been demonstrated in animal models to protect against doxorubicin-mediated cardiomyopathy [38, 73]. Further research is required to further evaluate the clinical efficacy of these cardiovascular effects in humans.

73.11 Anabolic Steroids

Anabolic steroids are associated with direct myocardial effects such as LV hypertrophy and myocardial fibrosis and indirect effects, including dyslipidemia, hypertension, arrhythmia, and MI [39]. It is likely that chronic exposure to these agents can result in significant alterations in the cardiovascular system, beyond the expected increase in salt and water retention leading to elevations in blood pressure in susceptible patients.

The most feared complication of anabolic steroids is acute MI. In addition to increasing thrombotic risk, there is further concern that anabolic steroids may accelerate the overall atherosclerotic process with ongoing abuse. A framework for understanding this risk has been put forward [69]. Four mechanisms are suggested:

1. Atherosclerosis-dyslipidemia model given marked reductions up to 70% in high-density lipoprotein (HDL) cholesterol, which is responsible for reverse cholesterol transport and > 20% increases in the atherogenic low-density lipoprotein (LDL) cholesterol.
2. Vasospasm model given alterations in the vascular nitric oxide system.
3. Thrombosis model involving alterations in platelet and clotting function including increases in plasminogen activator activity.
4. Direct myocardial injury model including impaired myocardial relaxation and diastolic dysfunction.

Another factor that enhances the risk of MI is polycythemia associated with anabolic steroids, which increases blood viscosity and thrombosis. As such, a complete blood count should be obtained in patients using anabolic steroids who present with ischemic complications. Beyond the risk of MI, these agents are associated with stroke as well as fatal arrhythmias [32, 33].

Surreptitious anabolic steroid use should be considered in young athletes with hypertension, very low serum HDL and elevated LDL cholesterol levels, or LV hypertrophy by ECG. The actual prevalence of significant coronary artery disease among anabolic steroid users is not known, and cardiovascular risk reduction should conform to standard age-appropriate guidelines until additional data is available. Blood pressure and lipid abnormalities will generally resolve after 6–12 months of abstinence, but there is evidence that pathologic LV hypertrophy may persist for years after discontinuation although this persistence may be due to sustained or ongoing strength training [1]. There is no clear evidence for pharmacologic treatment of LV hypertrophy, although dilated cardiomyopathy as a result prolonged steroid use and/or ischemic events should be treated in accordance with heart failure guidelines.

Key Points

Drugs of abuse have a variety of effects on the cardiovascular system. Alcohol may have beneficial effects in light-to-moderate drinkers, but heavy or binge drinkers are at risk for hypertension, heart failure, arrhythmia, and stroke. Sympathomimetic drugs, including cocaine and amphetamines, accelerate atherosclerosis, predispose to acute coronary events and arrhythmias, and lead to cardiomyocyte toxicity which can result in heart failure. Naturally occurring opioids may have a protective effect against developing ischemic heart disease and do not have clinically significant electrophysiologic properties; however, synthetic opioids such as methadone can lead to significant QTc prolongation and torsade de pointes. THC use has a number of adverse cardiac effects including arrhythmias and ischemia; CBD may be potentially cardioprotective but more research is necessary. Anabolic steroids have a number of negative effects including pathologic hypertrophy, accelerated atherosclerosis, increased risk of MI, and arrhythmia.

- Drugs of abuse s acute and chronic cardiovascular effects; given the prevalence of abuse, clinicians are surely to encounter these throughout their careers.
- Abstinence is the best remedy, but patients should also be treated according to established guidelines.

Respiratory Problems and Substance Misuse

74

B. Nanayakkara and S. McNamara

Contents

Abstract

Respiratory problems account for a significant proportion of the organ-related morbidity associated with substance misuse. Pulmonary injury may occur as a result of direct drug-related toxicity or through an indirect effect, and the spectrum of pulmonary complications from drug abuse is wide. The treating clinician must maintain a high degree of vigilance in considering whether illicit drugs could potentially be contributory – or even the causative factor – in any patient presenting with respiratory symptoms with or without associated chest X-ray and chest imaging changes. This chapter considers the common patterns of illicit drug–related pulmonary complications. After initially discussing the non-specific respiratory complications that are common to a range of different substances of abuse, a focused description of the range of respiratory pathologies that can occur in relation to specific drugs is provided.

Respiratory disease · Drug-related pulmonary toxicity · Pneumonia · Septic embolism · Pleuroparenchymal disease · Pulmonary vascular disease

74.1 Introduction

Drugs of abuse represent a worldwide health problem. These substances can cause both acute and chronic organ toxicity, with the potential for life-threatening consequences. Pulmonary involvement accounts for a significant proportion of organ-related morbidity. This is not surprising as the lung receives the entirety of the cardiac output, and is also the site at which gas exchange takes place. Pulmonary injury may occur as a result of direct drug-related toxicity, or through an indirect effect, such as inhalational thermal burns to the airway, or septic pulmonary embolisation. Therefore, the spectrum of pulmonary complications from drug abuse is wide (see Table 74.1). Furthermore, given the widespread prevalence of drug abuse, the treating clinician must exercise a high index of suspicion that illicit drugs could potentially be a contributory factor, if not a causative factor, in the patient presenting with a non-specific pulmonary infiltrate or other respiratory symptoms.

In this chapter the more common patterns of illicit drug-related pulmonary complications are discussed. Initially, the non-specific respiratory complications that are common to several different drugs are described, followed by a more focussed description of pulmonary insults related to specific drugs and commonly misused substances.

74.2 Non-specific Pulmonary Complications

74.2.1 Infective Complications: Pneumonia, Lung Abscess, Septic Embolisation, and Mycobacterium Tuberculosis

Infective complications, such as aspiration pneumonia and septic pulmonary emboli, are amongst the most prevalent of pulmonary complications in patients suffering from a substance abuse disorder. Any drug that can lead to an impaired level of consciousness and suppression of the gag and cough reflex can predispose an individual to aspiration and the development of pneumonia. Furthermore, concurrent smoking can impair local lung defences such as the mucociliary escalator, whilst bacteremia from injecting drug use can lead to hematogenous spread of infection to the lung. It is not surprising, therefore, that injecting drug users have a 10-fold higher risk of developing community-acquired pneumonia in comparison to the general population [1]. Left

Table 74.1 Spectrum of adverse pulmonary manifestations most commonly seen in specific substances of abuse

	Substance				
Pulmonary manifestation	Alcohol	Marijuana	Opioids	Amphetamines & Amphetamine-like substances	Cocaine
Pneumonia	+	+/–	+	+	+
Septic emboli	0	0	+	+	+
Airway injuries	0	+	+	+/–	+
Pneumothorax & pneumomediastinum	0	+	+	+	+
Acute lung injury	+	+/–	+	+	+
Non-cardiogenic pulmonary oedema	+/–	0	++	+	+
Foreign particle granulomatosis	0	+/–	+	+	+
Eosinophilic lung disease	0	+/–	+/–	0	+
Other parenchymal disease	0	+/–	0	0	+
Pulmonary vascular disease	0	0	+/–	+	+

untreated, suppurative complications such as lung abscess and empyema may also develop. The etiology and clinical presentation of pneumonia is similar to that of non-drug users [2]. Radiologically, aspiration pneumonia characteristically affects the dependent segments of the lungs – the posterior segments of the upper lobe and the apical segments of the lower lobes [3]. Treatment of pneumonia, pulmonary abscess and empyema should not differ from management outlined in current evidence-based guidelines.

If pneumonia does not respond to standard treatment, a high index of suspicion must be maintained regarding the possibility of fungal pneumonia. Several cases of pulmonary candidiasis have been reported in individuals who inject heroin [4]. Pulmonary tuberculosis (TB) should also be considered in the differential diagnosis in this patient group, as rates of latent tuberculosis infection are higher amongst the intravenous drug using community, with some patient cohorts being reported to have a prevalence of 59% [5]. This association is also true for alcohol use disorders. It is hypothesised that this increased susceptibility relates not only to socioeconomic factors more prevalent this group but also the detrimental impact of ethanol on the immune system [6].

Septic embolisation occurs through hematogenous seeding of micro-organisms, either from an infected vein thrombosis at the site of injection or from tricuspid valve endocarditis. Clinical presentations vary, but patients usually report fever, dyspnea, chest pain and cough, including haemoptysis. Chest CT scans may show multiple peripheral nodules with or without cavitation, focal or wedge-shaped infiltrates due to pulmonary infarction and pleural effusions [7] (Fig. 74.1). *Staphylococcus aureus* is the most

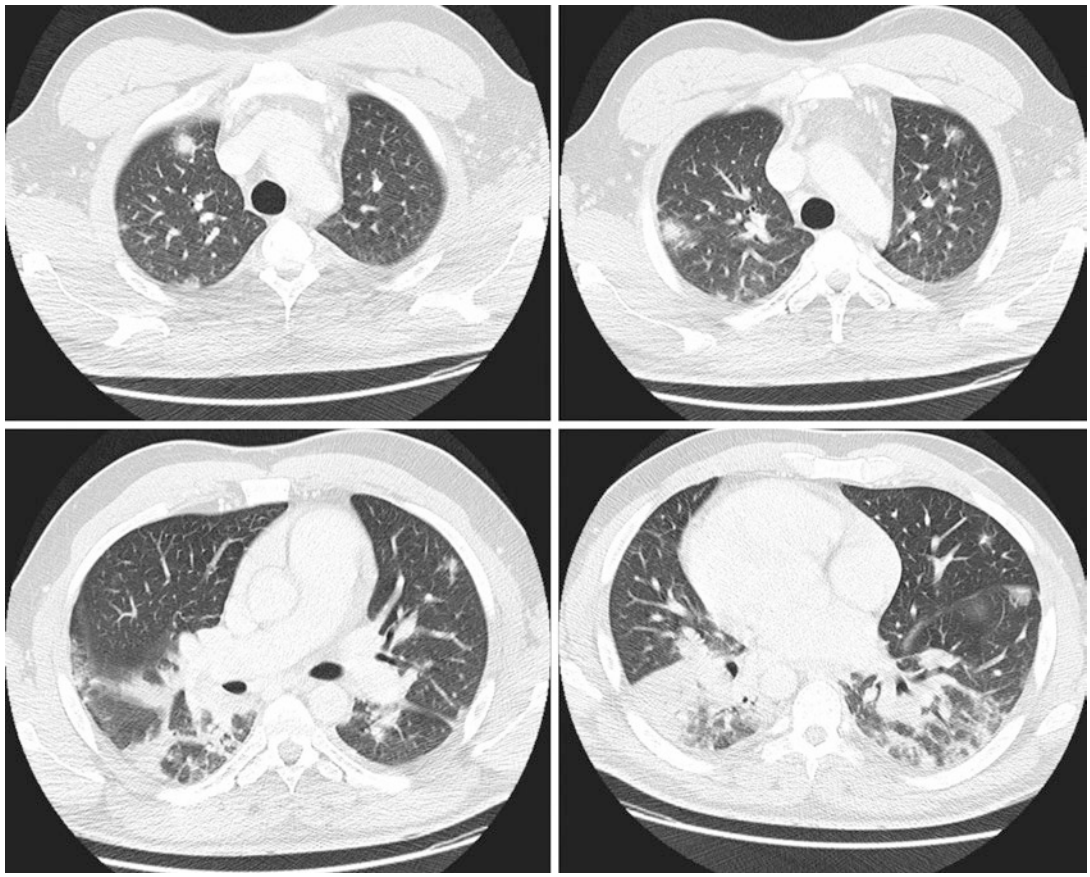

Fig. 74.1 Cross-sectional computed tomography (CT) scan views showing multiple ground glass septic emboli in a 38-year-old male patient with tricuspid valve endocarditis from intravenous heroin use

commonly isolated micro-organism from blood [8]. Transthoracic echocardiography is often sufficient to visualise tricuspid valve vegetation due to the proximity of this valve to the ultrasound transducer, largely negating the need to proceed to trans-esophageal echocardiography [9].

Occasionally, micro-organisms can be transmitted from contaminated media, such as the water used in an inhalational device. There is a case report of severe necrotising pneumonia due to *Pseudomonas aeruginosa* in a marijuana user. *Pseudomonas*, in this case, was isolated from sputum, pleural fluid and subject's water pipe [10].

74.2.2 Non-infective Complications

Magnesium silicate (talc), silicon dioxide (sand), glass beads, microcrystalline cellulose and corn starch are often used to increase the volume and weight of illicit drugs intended for oral use. Intravenous injection of these drugs, such as methylphenidate and methadone tablets, can lead to the deposition of foreign particles within the lungs. This initially leads to the development of an arteritis with rapid influx of neutrophils around the foreign body [11]. Following this, talc particles migrate through the vessel wall into the interstitium where they induce a granulomatous reaction [12]. This leads to discrete, small nodules – foreign body granulomas – that typically have a random distribution on chest CT images. These nodules may coalesce and lead to the development of significant interstitial lung disease including progressive massive fibrosis and, occasionally, diffuse interstitial fibrosis [13]. Emphysema has also been reported in patients who chronically inject crushed methylphenidate tablets [14]. In these patients, the distribution of the emphysematous changes is typically basal predominant and disproportionate to the degree of change that would be expected following tobacco exposure alone. The mechanism by which emphysema develops is thought to be secondary to small vessel occlusion causing alveolar wall necrosis [15]. Chronic pulmonary hypertension may also occur as a complication of pulmonary talcosis [16]. Whilst most patients present with non-specific pulmonary symptoms, occasionally individuals may present with acute hypoxemic respiratory failure [17].

74.3 Pulmonary Complications of Specific Substances

74.3.1 Alcohol

There are two main ways in which ethyl alcohol affects the lungs: through an increase in the risk of pneumonia and through acute lung injury. In 1985, Perlino and Rimland published a case series of patients with alcohol use disorders suffering from pneumococcal pneumonia associated with leukopenia, in whom the mortality rate was more than 80% [18]. Patients with a chronic alcohol use disorder who have pneumonia also suffer from a heightened risk of developing acute respiratory distress syndrome (ARDS), with a relative risk for this condition of 3.7 compared to non-alcoholic patients [19]. It has been hypothesised that disruption to the epithelial barrier and reduced antioxidant levels leads to the increased susceptibility to acute lung injury in these patients [20]. There has also been a case report of negative pressure acute pulmonary oedema that has developed in a young male who presented stuporous following acute alcohol intoxication. It is hypothesised that the development of pulmonary oedema in such cases relates to increased hydrostatic pulmonary capillary pressure from an increased venous return, which in turn is generated by the excessively negative intrathoracic pressures that occur during inspiration against a closed glottis [21].

74.3.2 Cannabis

Cannabis contains the active ingredient tetrahydrocannabinaol (THC) and is derived from the flowers, dried leaves and extracts of the hemp plant *Cannabis sativa*. Due to its high lipophilic-

ity, cannabis is mainly inhaled, but can be ingested, and very rarely injected.

Interestingly, in healthy habitual cannabis smokers, there is a decrease in airway resistance and increase in airway conductance occurring within minutes of inhalation, suggesting an acute bronchodilatory effect. This effect, which peaks between 15 and 20 minutes after exposure and lasts for approximately 60 minutes, has been directly attributed to the presence of THC [22]. Care must be exercised in interpreting this result as potentially therapeutic. Large doses (5–20 mg) of aerosolised THC have been shown to induce acute bronchoconstriction [23], in comparison to smaller doses (0.2 mg) that show bronchodilation [24]. Despite the bronchodilation effect, cannabis smokers suffer from similar respiratory symptoms to that of tobacco smokers, including chronic cough, recurrent bronchitis and wheeze. However, there may be an added burden of these symptoms if the individual smokes both substances [25]. A large epidemiological survey of US adults did not show an association between cannabis use (expressed in joint-years) with decline in forced expiratory volume in one second (FEV_1). Rather, the investigators reported that cannabis use was associated with an increase in forced vital capacity (FVC), an effect that is difficult to explain but has been postulated as being related to the effects of respiratory muscle training from breath holding during cannabis smoking [26].

There has been an association between apical bullous disease, spontaneous pneumothoraces and habitual cannabis smoking. However, these have only been reported in case series. The association is hypothesised to be a result of the increased depth of inhalation and occasional Valsalva maneuvre that many marijuana smokers employ when smoking, rather than from the toxic effects of marijuana itself [27] (Fig. 74.2).

Interstitial lung disease is a rare manifestation of marijuana smoking and has also only been reported in case series. These have included case reports of eosinophilic pneumonia and pulmonary alveolar proteinosis. Two cases of an acute pneumonitis have been described in patients smoking marijuana laced with other substances, such as formaldehyde and phencyclidine [28]. There is controversy surrounding the link between marijuana smoke and lung cancer. At present, no quality evidence exists to establish a causal link [29]. There has been a case report of pulmonary talcosis in a 29-year-old who inhaled marijuana adulterated with mineral substances [30].

Fig. 74.2 Frontal radiograph showing a left-sided pneumothorax in a 22-year-old male who reported the sudden onset of left-sided pleuritic chest pain whilst smoking marijuana from a water-pipe ("bong") device

74.3.3 Miscellaneous Inhaled Substances

Amyl and butyl nitrites are inhaled substances used for their aphrodisiac properties, including relaxation of rectal smooth muscle tone and prolongation of penile erection. This effect is mediated through the production of nitric oxide via an oxidation-reduction reaction of nitrogen dioxide with haemoglobin. This generates methemoglobin, and significant abuse can lead to severe methemoglobinemia. The clinical phenotype is characterised by the presence of slate-grey skin with cyanosis and normal arterial oxygen tension but reduced arterial oxygen saturation, as the standard oximeter cannot distinguish between deoxygenated haemoglobin or methemoglobin. Blood is characteristically chocolate brown in colour [31].

Whilst toluene sniffing, or glue sniffing, was rare prior to 1960s, it has now become the most commonly abused volatile substance. Because toluene is an excellent solvent for substances such as paint, lacquers, thinners, coatings and glues, it is widely available. The desired effects in individuals sniffing toluene include a sense of euphoria, excitation, delusions and distorted perception. Pulmonary consequences from this form of substance misuse include pneumothorax [32] and panacinar emphysema [33]. A case of Goodpasture syndrome bearing a close temporal relationship with glue sniffing has also been described in a 17-year-old girl [34].

Pulmonary effects from inhaling other volatile hydrocarbons include pneumonitis [35], diffuse alveolar haemorrhage [36] and airway angioedema [37].

74.3.4 Opioids

Opium, derived from the opium poppy plant *Papaver somniferum,* contains over 20 alkaloids including morphine and codeine [38]. Semi-synthetic opioids, such as heroin and hydromorphone, are derived from morphine as a precursor. Purely synthetic opioids are not derived from an opiate but still bind to the opioid receptor. These include fentanyl and methadone [39].

74.3.4.1 Airway Complications

As a result of chronic injection, a heroin user's veins become sclerosed. Many individual users will subsequently attempt high-risk sites of injection, including the approach described as a "pocket shot", which involves directly injecting into the veins of the supraclavicular fossa. One case of bilateral lung pneumothoraces has been reported due to two failed "pocket shots" in an individual [40]. Cervical injection of heroin has also been shown to cause vocal cord paralysis. In a case series of nine such patients, five required tracheostomies due to resultant vocal cord paralysis causing acute airway obstruction [41]. Nasal septum perforation has also been described in a case series of patients who inhaled crushed hydrocodone-paracetamol [42]. Acute bronchospasm may also occur; this is thought to be mediated by direct histamine release from mast cells [43].

74.3.4.2 Respiratory Drive and Respiratory Failure

The most immediate life-threatening acute toxicity of opioid administration is respiratory depression. This occurs due to both a reduction in central chemoreceptor sensitivity to hypercapnea and a heart block-like effect on the respiratory centre pattern generating neurons in the pre-Botzinger complex [44]. This central action of opioids also increases the risk of sleep-disordered breathing by increasing central apneic events during sleep [45].

Life-threatening truncal and laryngeal rigidity has also been reported after the administration of synthetic opioids such as fentanyl, with one case requiring intubation and administration of muscle relaxants [46].

74.3.4.3 Pleuroparenchymal Disease

Non-cardiogenic pulmonary oedema is a well-known complication of acute opioid overdose occurring after either inhalation or injection and has an estimated prevalence of 3% in the heroin overdose population seen in hospital [47]. Presentation with respiratory distress and a pulmonary infiltrate usually occurs within 4 hours, and, with supportive care, symptoms usually resolve within 24–48 hours [47]. The mechanism by which pulmonary oedema develops in this circumstance is debated, with various pathophysiologies proposed, including direct hypoxia-related epithelial damage, a direct toxic effect of opioids on lung parenchyma, the effects of excess negative intrathoracic pressure against an occluded upper airway, as well as the development of increased pulmonary capillary permeability [38]. Naloxone administration is a plausible contributor, and it is hypothesized that in opioid users, naloxone administration triggers a substantial catecholamine release with resultant acute cardiac dysfunction [48]. Management of non-cardiogenic pulmonary oedema in this

circumstance is supportive, most critically ensuring adequate oxygenation. Rare cases of acute eosinophilic pneumonia have been reported following inhalation of heroin, with complete remission occurring following treatment with corticosteroids [49].

74.3.4.4 Pulmonary Vascular Disease

Opioid abuse is not classically associated with the development of pulmonary hypertension. Traclet and colleagues performed a single centre registry analysis of 222 consecutive patients with Group 1 pulmonary arterial hypertension, amongst whom 10 patients had been exposed to heroin. Whilst there was no difference in baseline clinical characteristics between heroin and non-heroin-exposed groups, the patients who abused heroin were diagnosed with pulmonary hypertension 10 years earlier than the non-exposed group, raising a possible connection between heroin use and the development of pulmonary hypertension [50]

74.3.5 Amphetamines and Amphetamine-Like Substances

Amphetamines and amphetamine-like substances, including methamphetamine, methylphenidate and methyl-enedioxy-methamphetamine (MDMA) are sympathomimetic non-catecholamine compounds. Their mechanism of action is multifactorial. By blocking catecholamine re-uptake, inhibiting enzymatic degradation, and facilitating catecholamine release from the pre-synaptic terminals, amphetamines and amphetamine-like substances increase catecholamine concentrations at the synaptic cleft [51].

74.3.5.1 Airway Complications

Methamphetamine users frequently exhibit severe dental disease, predisposing them to respiratory tract infection. "Meth mouth" is characterised by severe dental caries, rotting and crumbling teeth and relates to a combination of factors including poor oral hygiene, increased oral cavity acidity, frequent craving for refined carbohydrates, bruxism, xerostomia and gastro-esophageal reflux disease [52].

74.3.5.2 Pleuroparenchymal Complications

Cases of pneumomediastinum have been reported following aggressive inhalation of crystal methamphetamine ("crystal ice") related to the barotrauma of negative pressure inhalation and subsequent Valsalva maneuvre, prior to exhaling against a pursed lip [53]. Case reports of MDMA pneumothorax and pneumomediastinum have also been reported. The mechanism is thought to be related to excessive physical exertion with wide swings in intrathoracic pressure, rather than direct drug-related effects [54].

Non-cardiogenic pulmonary oedema has been reported in case studies and should be considered in the differential diagnosis in patients taking MDMA and amphetamines who present with dyspnoea, hypoxia and a pulmonary infiltrate [55, 56]. Methamphetamine abuse may also mimic a systemic vasculitis, with one case report of a 27-year-old female presenting with a pulmonary-renal syndrome, in whom a chest computed tomography (CT) scan showed multifocal patchy ground glass opacities and brain imaging revealed changes suggestive of vasculitis [57]

74.3.5.3 Pulmonary Vascular Disease

There is a well-known association between methamphetamine use and pulmonary arterial hypertension. In comparison to a matched cohort of patients with idiopathic pulmonary arterial hypertension, patients with methamphetamine-associated pulmonary hypertension show a more severe disease phenotype characterised by worse 5-year and 10-year event-free survival [58].

74.3.6 Cocaine

Cocaine, an alkaloid derivative synthesised from the leaves of the *Erythroxylum coca* species, is a central nervous system stimulant and anaesthetic

[59]. It is often self-administered by nasal insufflation of the hydrochloride salt or by inhaling vapour from heating of the freebase form. The hydrochloride salt is water soluble, thus also allowing it to be injected. Cocaine is also lipophilic, enabling it to also be absorbed via the nasal mucosa [60]. Frequently, cocaine is adulterated with substances to dilute the active ingredient, often to increase the profit margin per unit sale of the product. One of the most frequently detected adulterants is levamisole, an antihelminthic drug [61].

The mechanism of action of cocaine is complex. The predominant mechanism, occurring both peripherally and centrally, is a blockade in the re-uptake of catecholamines. This causes an increase in the concentration of catecholamines in the synaptic cleft, leading to increased adrenoreceptor and dopamine receptor stimulation. Serotonin re-uptake is also inhibited centrally via its competitive inhibitory effect on the serotonin reuptake transporter [62]

74.3.6.1 Pulmonary Symptoms

Pulmonary symptoms from cocaine misuse are common, non-specific and often camouflaged because of the concurrent co-ingestion or inhalation of other substances such as tobacco and marijuana in the period prior to presentation. Symptoms can include wheeze, cough, haemoptysis, black sputum (melanoptysis), chest pain and dyspnea [63]. In a study of 192 cocaine smokers in Los Angeles, the prevalence of acute cardiorespiratory symptoms upon exposure to cocaine was high. Within 1–12 hours of inhalation, 43.7% of respondents noticed cough with black sputum, 38.5% reported chest pain, whilst 5.7% experienced haemoptysis [64].

74.3.6.2 Airway Complications

A variety of upper airway complications can occur in cocaine users. These include alterations in sensory perception of smell, epistaxis, mucosal irritation, persistent sniffing and sinus-related problems [65]. Velopharyngeal dysfunction, triggering nasal regurgitation of oral contents, hypernasal speech and alteration of speech intelligibility, has recently been reported in a case series of four patients snorting cocaine [66]. Severe disfiguring midline nasal destruction is also reported, including total nasal septal bony and cartilaginous vascular necrosis, saddle nose deformity and osteolytic sinusitis with involvement of the optic nerve [67]. This is thought to be secondary to the direct vasoconstrictor efects of cocaine on the nasal mucosa causing localised ischemia [68]. However, an autoimmune mechanism has also been postulated, given the disproportionately high rate of positive anti-neutrophil cytoplasmic antibody (ANCA) directed against human neutrophil elastase detected in patients with cocaine-induced midline destructive lesions [69]. Indeed, biopsy of these lesions often reveal pathological granulomatous changes indistinguishable from systemic vasculitis/granulomatosis with polyangiitis [70, 71].

Clinicians must also be wary of the potential for acute airway obstruction in cocaine users. Uvulitis and uvular angioedema have been reported in cocaine users [72]. Vocal cord paralysis from neck injections of cocaine have also been reported [41], as well as stridor related to oedema of the arytenoids, epiglottis and vocal cords in smokers of free-base cocaine [73]. Bilateral saccular cysts causing acute airway obstruction have been described in a cocaine user, necessitating an emergent tracheostomy [74].

There is also a plausible link between asthma severity and cocaine abuse. Asthma exacerbations, including episodes of severe bronchospasm requiring endotracheal intubation and mechanical ventilation, are more severe and more frequent in patients admitting to the prior use of cocaine (or identified as having recently used cocaine via identification with urine cocaine metabolites) [75–77].

74.3.6.3 Pleuroparenchymal Complications

Barotrauma causing pneumothoraces, pneumopericardium, pneumomediastinum and pneumoperitoneum have been noted to occur in users smoking cocaine. The mechanism probably arises from aggressive inhalation against a small

pipe, often followed by a Valsalva maneuver after inhalation – with or without violent coughing episodes – causing barotrauma [78]. The common practice of partners smoking cocaine forcefully exhaling into one another's mouths is another proposed mechanism by which this complication might occur. Pleural effusions have also been described but are rare [79]. The pleural effusion may appear macroscopically purulent and therefore masquerade as an empyema. However, on careful characterisation, the fluid contains abundance of eosinophils and markers of eosinophilic inflammation such as interleukin-5 [80].

Cocaine-induced acute interstitial pulmonary oedema is a well-known phenomenon. Cardiogenic oedema may occur because of acute myocardial infarction and left ventricular dysfunction [81]. Non-cardiogenic oedema, manifesting as diffuse pulmonary infiltrates with normal capillary wedge pressures, is a common manifestation of cocaine induced pulmonary toxicity. Mechanisms are likely related to direct cellular, epithelial and endothelial injury [82].

The frequency of cocaine induced interstitial and alveolar disease is worryingly high. In an autopsy series of patients with toxicology studies suggesting cocaine use, the prevalence of interstitial pneumonitis and fibrosis was as high as 38%. Furthermore, the rates of acute and chronic pulmonary haemorrhage were 58% and 40%, respectively [83].

"Crack lung" is a well-known entity. The term "crack" arises from the characteristic crackling sound that cocaine makes when it is heated and "crack lung" refers to the acute pulmonary syndrome that develops within 48 hours of inhalation after smoking "crack" cocaine or freebase cocaine. "Crack lung" is characterised by diffuse pulmonary infiltrates, fever, hypoxemia and sometimes haemoptysis. On biopsy, there is evidence of diffuse alveolar damage with hyaline membranes, pulmonary haemorrhage and eosinophilic inflammation, sometimes with the accumulation of immunoglobin E (IgE) deposition in lymphocytes and alveolar macrophages [84]. Pulmonary eosinophilia associated with cocaine use is also well described. This may manifest as an acute syndrome characterized by pulmonary infiltrates, bronchoconstriction and hypoxemia. Assessment of washings obtained from bronchoalveolar lavage in such patients can reveal an eosinophilia, whilst transbronchial biopsies can reveal a dense eosinophilic infiltrate [85].

There is an association between levamisole-containing cocaine and the development of ANCA-associated vasculitis [86]. The p-ANCA antibody is usually detected, although titres to myeloperoxidase (MPO) may be low. Atypical p-ANCA antibodies – such as lactoferrin, cathepsin G or human neutrophil elastase – may also be present [87].

74.3.6.4 Pulmonary Vascular Disease

The association between inhalational cocaine and the development of pulmonary hypertension is not strong [88]. Histopathological findings include pulmonary artery vascular abnormalities such as medial hypertrophy [89]. Vasoconstriction from cocaine can lead to pulmonary perfusion abnormalities, which on a ventilation-perfusion scan can be misinterpreted as "high probability" for pulmonary embolus [90]. Pulmonary infarction can also occur [91]. Pulmonary hypertension itself may be caused by the adulterant levamisole, which is converted to aminorex (a potent anorexigen associated with idiopathic pulmonary hypertension) [92].

74.3.7 Cigarettes

The harmful effects of cigarette smoke on the lungs are unparalleled by any other addictive substance. Pathologically, smoking combustible cigarettes leads to loss of cilia, mucus gland and goblet cell hyperplasia, inflammation, squamous metaplasia, mucus plugging, destruction of alveoli and reduction in pulmonary capillary density [93]. A complete discussion on pathophysiology and disease manifestations is beyond the scope of this review; however, we will focus on the most important aspects of pulmonary injury.

74.3.7.1 Respiratory Infections

The risk of acquiring a respiratory tract infection, including viruses, typical bacteria and

mycobacteria, is much higher in cigarette smokers than non-smokers [94]. For example, the risk of invasive pneumococcal disease in immunocompetent adults was highest in current smokers (odds ratio [OR] 4.1, 95% confidence interval [CI] 2.4–7.3) in comparison to non-smokers, with the risk only declining to that in non-smokers after 10 years smoking cessation [95]. Additionally, the risk of community-acquired pneumonia is almost twice as high in smokers compared to non-smokers [96].

74.3.7.2 Airways

The most well-known association between cigarette smoking and the lungs is its causal relationship with airways disease. Cough is a frequent symptom [97], irrespective of the presence or absence of chronic bronchitis, and is probably triggered by chronic cigarette smoke induced upregulation of the cough reflex [98], occasionally leading to cough syncope [93]. There is a clear and undisputed link between cigarette exposure and the development and progression of chronic obstructive pulmonary disease [99, 100]. Smoking cessation can reduce the rate of decline in FEV1 back to the level of non-smokers, but the loss of lung function cannot be regained [101]. Furthermore, smokers without spirometric obstruction (FEV_1/FVC >0.7) may also suffer with chronic respiratory symptoms, exacerbations and airway remodelling [102]. Whether current treatment strategies for COPD are applicable to these patients is currently under review. Carbon monoxide from cigarette smoke can also add to the burden of exercise intolerance as it binds avidly to haemoglobin reducing the oxygen carrying capacity of blood as well as peripheral oxygen release [103, 104]. There is a link between cigarette smoking and the development of asthma, with a large British national study suggesting that regular smoking was associated with a 4.4-fold increased risk of asthma [105], a result corroborated by a large Finnish study [106].

74.3.7.3 Pleuroparenchymal Complications

Less well known is the strong association between smoking and interstitial lung diseases (ILD). Robust associations are seen with respiratory bronchiolitis-associated interstitial lung disease (RB-ILD), Langerhans cell histiocytosis (LCHx) and desquamative interstitial pneumonitis (DIP). These three entities are commonly referred to as smoking related ILD [107]. If fibrosis is not established, smoking cessation may lead to resolution of interstitial changes and physiological abnormalities. However, immunosuppression with corticosteroids may be required for patients with significant impairment [108]. Smoking is also a well-known risk factor for idiopathic pulmonary fibrosis [109] and rheumatoid arthritis associated ILD [110]. A rare but important entity temporally associated with cigarette use is acute eosinophilic pneumonia, presenting with an acute interstitial infiltrate characterised by bilateral ground glass opacities [111]. Despite its name, peripheral blood eosinophilia may not be present, and bronchoalveolar lavage eosinophilia is needed to confirm the diagnosis [111]. Treatment includes supportive ventilatory strategies with prompt initiation of high-dose corticosteroids [112].

74.3.7.4 Malignancy

There is a strong association between lung cancer and cigarette smoking through the carcinogenic effect of cigarettes on the human genome [112, 113]. Interestingly, with the rates of smoking declining and an increase in the use of filtered cigarettes, there has been a corresponding increase in peripherally based adenocarcinomas in place of squamous cell carcinomas [114]. Patients should be counselled on smoking cessation as this has been a clearly established strategy to reduce the risk of developing lung cancer. Indeed, those who were abstinent from smoking cigarettes for more than 15 years had an 80–90% reduction in risk of lung cancer in comparison to current smokers [115].

74.3.7.5 Electronic Cigarettes (E-Cigarettes)

E-cigarettes have been marketed as a battery powered device that is less toxic than conventional cigarettes [116]. However, there has been an alarming increase in the number of reported cases of vaping-associated pulmonary injury. A recent publication in the New England Journal of

Medicine identified 53 cases of severe vaping-associated pulmonary injury, characteristed by respiratory, gastrointestinal and constitutional symptoms with bilateral pulmonary infiltrates revealed on pulmonary imaging [117]. The majority of these patients were young, not regular smokers who reported use of tetrahydrocannabinol products in their e-cigarette devices [117]. This epidemic may be attributed to poor regulation of the materials used in e-cigarettes

74.4 Conclusion

Pulmonary complications of illicit substance abuse are common amongst patients who suffer from a substance abuse disorder. The toxic effect of illicit substances may be direct and impact almost any part of the respiratory tract, from the nasopharynx through to the pleura. The effects may also be indirect, such as occurs with aspiration pneumonia and septic embolisation. Furthermore, patterns of injury may be specific to the route of drug administration, such as foreign particle granulomatosis in injecting drug users, or inhalational thermal injury to the airways.

Given the wide spectrum of polysubstance abuse, it is often difficult to attribute specific patterns of pulmonary toxicity to an individual drug in an individual patient. Clinicians should therefore be alert to and aware of the wide spectrum of pulmonary manifestations that may befall patients who use illicit substances and formulate a broad differential diagnosis when assessing this patient cohort. Apart from naloxone for opioid-induced respiratory depression, there is usually no specific management strategy, and treatment is dependent upon the specific pulmonary insult that has occurred and the provision of appropriate supportive care.

Key Points

- Respiratory complications are amongst the most common medical complications of drugs of abuse. Tobacco causes the greatest burden of disease.
- Infectious complications, whilst not specific to a certain drug class, are common and can progress to suppurative conditions such as empyema and pulmonary abscess. This is a result of decreased airway clearance mechanisms in conjuction with altered level of consciousness.
- The pattern of diffuse pulmonary infiltrates is relatively common. It may result from an interstitial infectious pneumonia, pulmonary talcosis (particularlarly if the infiltrate is nodular), septic embolisation, cardiogenic and non-cardiogenic pulmonary oedema, acute hypersensitivity pneumonitis, pulmonary vasculitis and pulmonary haemorrhage.
- Knowledge of the offending drug may help with the differential diagnosis. However, because the pattern of pulmonary involvement is common amongst a number of drug classes, the extrapolation of offending drug from the pattern of injury can often be difficult.
- Additive compounds may have an important effect on toxicity, for example, levamisole leading to an ANCA-associated vasculitis in cocaine users and pulmonary talcosis with massive progressive fibrosis from the intravenous injection of talc containing tablets.

Oral Health and Addiction: Consequences of Substance Use

75

Garima Arora and Ruth Freeman

Contents

Abstract

This chapter is a review of the effects of drugs and substance use upon oral health. It provides the latest WHO and FDI definition of oral health together with a brief description of the main oral diseases, i.e., dental caries and periodontal disease. It describes the effects of substance use and their physiological actions on teeth, oral mucosa and other oral diseases. Finally, it presents the dental treatment and oral health management for people with a history of substance use. The overall aim of the chapter is to present the effects of substance on oral health and therefore to illustrate the need for practitioners working in the addiction field to include an oral assessment and referral for dental treatment as part of their overall treatment strategy.

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment*, https://doi.org/10.1007/978-3-030-36391-8_75

75.1 Introduction

Oral health is considered as one of the non-communicable disease and contributes to the global burden of disease [37]. While dental caries and periodontal disease represent a considerable portion of disease burden, oral-health-related quality of life is now considered to play an important part when considering the totality of oral health. Therefore, the World Health Organization (WHO), in 2003, defined oral health in terms of physical and psycho-social well-being; however, by 2016, oral health was redefined by the International Dental Association (FDI). FDI described oral health not simply in terms of physical disease but also in terms of oral-health-related quality of life and function. Moreover, the FDI definition included the role of environment and circumstances as a major determinant of oral health. Therefore, social determinants of health were recognised as playing a significant role in the distribution, prevalence and severity of oral diseases. It is apparent that lifestyle factors, including substance use, affected people's oral health status.

Box 75.1 WHO [85] FDI [24] Definitions of Oral Health

WHO [85]: 'a state of being free from chronic mouth and facial pain, oral and throat cancer, oral infection and sores, periodontal (gum) disease, tooth decay, tooth loss, and other diseases and disorders that limit an individual's capacity in biting, chewing, smiling, speaking, and psychosocial wellbeing'.

FDI [24]: 'Oral health is multifaceted and includes the ability to speak, smile, smell, taste, touch, chew, swallow, and convey a range of emotions through facial expressions with confidence and without pain, discomfort, and disease of the craniofacial complex. Further attributes of oral health:

- It is a fundamental component of health and physical and mental well-being. It exists along a continuum influenced by the values and attitudes of people and communities.
- It reflects the physiological, social, and psychological attributes that are essential to the quality of life.
- It is influenced by the person's changing experiences, perceptions, expectations, and ability to adapt to circumstances'.

75.1.1 Dental and Oral Diseases

There are two main oral diseases which make up the greatest global burden of disease [37]. These are dental caries and periodontal disease. Other oral disease associated with mucosal disorders include oral cancers, HIV, oro-dental trauma, cleft lip and palate and noma [87].

Dental caries is caused by the action of free sugars upon the tooth surface. Free sugars contained in foods and drinks are converted into acids by *S. mutans* in the plaque. The acid attack, which lasts about 30 minutes after the ingestion of free sugars, causes a loss of calcium together with demineralisation which results in tooth decay or dental caries. While the acid attack and the effect upon the tooth surface is affected by the buffering effects of saliva and tooth morphology, it is the total daily calorific intake which is primarily responsible for tooth decay [86]. WHO [86] recommends that the consumption of free sugars should be limited to 5% (10 kg/person/year) of the total calorific intake to prevent dental caries. Therefore, the prevention of dental caries is firstly to reduce free sugar consumption to 5% of the total calorific intake and secondly to brush teeth to introduce and distribute fluoride toothpaste (1450 pmm) across the teeth to strengthen the tooth enamel against carious attack.

Periodontal disease and specifically gingivitis are associated with poor plaque control. Gingivitis presents as bleeding and swollen gums. Acute and chronic periodontitis are associated with destructive bone loss that supports the tooth. However, since the natural history of periodontal disease remains unknown, there is not necessar-

ily a natural progression from gingivitis to periodontitis. Chronic periodontitis and the loss of attachment of the gum to the tooth can lead to (i) a pocket formation between tooth and gum, (ii) cause bad breath, (iii) increase tooth mobility and (iv) in some cases eventual tooth loss [52]. Recognised aetiological factors in chronic periodontitis are tobacco smoking and to a lesser degree alcohol consumption [72].

Oral cancer as defined by the WHO includes the cancers of lip and all subsites of the oral cavity, and oropharynx [87] caused predominantly by tobacco smoking and alcohol consumption.

These tooth and mucosa-related dental diseases can be caused directly from the consumption of addictive substances or arise indirectly as a consequence. Currently, alcohol, tobacco and drugs are readily available. The apparently easy access to substances makes it crucial for the health care providers to be aware of the oral manifestations and respond in the best interest of any patient with a history of alcohol and drug use.

75.2 The Oral Health Effects of Substance Misuse

The oral health effects of the most commonly used drugs, and the implications to the dental treatment of a drug user, approach to dental treatment and management are presented in Tables 75.1, 75.2, and 75.3.

Table 75.1 Depressants and oral health

Substance	Physiological effect	Oral manifestations			Dental treatment and management
Depressant		Tooth	Mucosa	Other	
Alcohol	Inhibits saliva secretion, increases mucosal permeability, gastric reflux	Dental caries, tooth erosion associated with reflux and vomiting, periodontal disease	Oropharyngeal cancer, oral pigmentation, glossitis associated with Vitamin B1 and B6 deficiencies periodontal disease	Halitosis, xerostomia and bilateral enlargement of parotid glands (sialadenosis)	Haematological investigation before oral surgery Check for alcohol consumption before prescribing medication Arrange referral for alcohol counselling
Opiates Morphine Heroin Oxycodone Tramadol Methadone Buprenorphine	Increased consumption of free sugar, reduced saliva flow, immune suppression	Rampant caries	Periodontal disease, mucosal infections, e.g., candidiasis, dysplasia	Xerostomia, severe bruxism, taste impairment	Extreme dental anxiety associated with local anaesthetic injections, reduced responsiveness to local anaesthesia; increased pain tolerance: possibility of infective endocarditis Prevention includes dietary advice, fluoride mouthwashes (after methadone), varnish applications and improved toothbrushing with fluoride toothpaste; sugar-free gums, artificial saliva
Cannabis	Anticonvulsant, immune-suppressive properties	Dental caries	Gingivitis, destructive bone loss, oral cancer, candidal infections, leukoedema	Xerostomia, nicotinic stomatitis, uvulitis lesion	Dietary advice, use of fluoride toothpaste Patients to discontinue marijuana use 1 week prior to the dental treatment Local anaesthetic agent with adrenaline should not be used

Table 75.2 Stimulants and oral health

Substance	Physiological effect	Oral manifestations			Dental treatment and management
Stimulant		Tooth	Mucosa	Other	
Cocaine Crack cocaine	Decrease in salivary flow and pH, necrosis of nasal septum and surrounding tissue vasoconstriction	Greater prevalence of dental caries, attrition, glossy appearance of tooth surfaces, rapid tarnishing of gold crowns	Gingival lesions at the site of drug application, destructive periodontitis Crack cocaine increased prevalence of oral mucosal lesions, e.g., ulceration	Oro-nasal perforation, severe bruxism, orofacial pain, xerostomia, numbness	Local anaesthetic agent with adrenaline should not be used treatment postponed for 6–24 hours if cocaine use is assumed following a period of abstinence surgical closure of palatal defect or removable maxillary obturator
Amphetamines Methamphetamine	Reduction in salivary secretion hyper-metabolism causing increased sugar craving, increased motor activity, mild dysphoria	'Meth mouth': Rampant dental caries, erosion, attrition		Xerostomia, severe bruxism	Local anaesthetic without vasoconstrictor should be used for dental treatment Prevention includes fluoride mouthwashes, varnish applications and improved toothbrushing with fluoride toothpaste, sugar-free gums, artificial saliva
MDMA / Ecstasy	Muscle rigidity raising body temperature, dehydration, high consumption of sugary fizzy acidic drinks, dry mouth and low saliva buffering capacity	Enamel erosion, dental caries, attrition	Mouth ulcers	Xerostomia, severe bruxism, clenching and grinding, facial and TMJ pain, altered speech, tingling of lips	Sugar-free chewing gum, fluoride mouthwash, high-fluoride toothpaste Caution must be taken in administering a local anaesthetic agent containing epinephrine

Table 75.3 Other substances and oral health

Substance	Physiological effect	Oral manifestations			Dental treatment and management
Other		Tooth	Mucosa	Other	
Tobacco *(Nicotine)* Stimulant and depressant					
Smoked tobacco and reverse smoking	Oral microflora, immunity, periodontal inflammation, resorption of alveolar bone, impaired salivary function	Discoloration of teeth Discoloration of dental fillings and dentures, tooth abrasion, dental caries	Oral cancer, precancer: epithelial dysplasia, leukoplakia, erythroplakia Black hairy tongue, candidal infection, smokers' melanosis and palate Periodontal disease	Altered taste and smell, Halitosis, delayed wound healing, some evidence of increased prevalence of cleft lip and palate in infants	Brief intervention on smoking cessation (ask, advice, assist), referral to smoking cessation services, NRT Give clear post-operative instructions to prevent complications after surgical procedure
Smokeless tobacco	In addition to above: abrasive in nature	In addition to above: root caries, cervical abrasion	In addition to above: gingival recession		
Gabapentin (anticonvulsant)		Dental caries as a consequence of dry mouth and reduced saliva	Gingivitis	Xerostomia, dry throat	Prevention includes dietary advice, fluoride mouthwashes, varnish applications and improved toothbrushing with fluoride toothpaste; sugar free gums, artificial saliva

75.2.1 Depressants and Oral Health: Alcohol (Table 75.1)

75.2.1.1 Tooth-Related

Alcohol consumption has shown to affect oral health. Although the severity of tooth-related disease depends on the levels of alcohol consumption, higher levels of decayed tooth surfaces have been reported in those with a history of high alcohol use [36]. In addition to higher number of decayed teeth, as a consequence, people who consumed 24 g of alcohol per day were shown to have higher number of missing teeth when compared to social drinkers (subjects consuming ≤8 g of ethanol per day) [23]. Some findings, however, contradict the above evidence, indicating a preventive role for alcohol. For instance, in the UK, some beers contain fluoride that prevents tooth decay while others point to the inhibitory effect on cariogenic flora [22]. Since alcohol consumption is related to reduced salivary flow and dry mouth, dental caries in alcohol users is often attributed to salivary factors and poor dental health behaviours.

Enamel erosion or tooth wear is another complication of chronic alcohol consumption, typically affecting the palatal surfaces of the upper front teeth. Most alcoholic beverages have acidic pH or are consumed with acidic mixers such as carbonated drinks or fruit juices. Due to higher concentration of titratable acids, white wines are more corrosive than red wines for teeth [56]. The presence of dental erosion is related to duration of alcoholism and gastro-oesophageal reflux and vomiting [51].

Evidence suggesting the role of alcohol in staining the tooth is limited, red wine being the only alcoholic drink linked to tooth staining. Binge drinkers or those consuming high levels of alcohol are significantly more at risk of dental trauma.

75.2.1.2 Mucosa-Related

A systematic review from 2009 provided evidence to suggest that alcohol consumption could be considered as a risk factor for periodontitis [3]. A recent meta-analysis reported a dose-response relationship between alcohol consumption and periodontitis risk with risk of periodontitis increasing by 0.4% for each 1 g/day increment in alcohol consumption [81].

Chronic periodontitis is thought to have a systemic host mediated element associated with impairment of white cell and T-cell functioning. Since a link between alcohol consumption and periodontal disease has been proposed, and Tezal et al. [72] support this proposition having identified an important relationship between the number of drinks per week and destruction of the periodontal ligament supporting the tooth in the bone (clinical attachment loss).

Alcohol as a causative factor in oropharyngeal cancer is well established. While there is no clear explanation on how alcohol exerts its carcinogenic effect, possible explanations are, (i) 'genotoxic effect of acetaldehyde', (ii) 'role as a solvent for tobacco carcinogens', (iii) 'production of reactive oxygen and nitrogen species' and (iv) 'changes in folate metabolism' [13]. More recent research suggests that drinking more than 4 drinks per day increase the risk of oropharyngeal cancer by 5 times [50]. In their meta-analysis, Turati et al. [78] reported a dose-response relationship between alcohol consumption and oral cancer. They [78] stated that there was an increased risk of 1.32 among social drinkers and 2.54 among heavy drinkers (>4 drinks/day) of oral cancer. Moreover, they noted that smoking had a synergistic effect increasing the risk among smokers to 2.92 (social drinkers) and 6.32 (heavy drinkers), respectively.

75.2.1.3 Other

Presence of bad breath is associated with alcohol [62]. Halitosis is related to reduced saliva and sometimes xerostomia, which is associated with sialadenosis and reduced functioning of the parotid glands. This is particularly noticeable in those with alcohol cirrhosis of the liver. Glossitis and angular stomatitis are linked to Vitamin B1 and B6 deficiency observed in those with alcoholism.

75.2.2 Depressants and Oral Health: Opioids (Table 75.1)

Opioids commonly abused included in this review include morphine, heroin (diamorphine) and prescribed medications such as methadone, oxycodone, tramadol, etc. (Table 75.1).

75.2.2.1 Tooth-Related

People who use opiates have high prevalence of obvious dental caries experience with surface level data (tooth surfaces) revealing caries distribution predominantly on 'the smooth and cervical surfaces' [46]. This has been attributed to a complex, dynamic relationship between multiple factors. Therefore, irrespective of the economic status, it is the heightened craving for sweet carbohydrates [74], together with the neglect of personal care that has been observed in opioid users [1] which is thought to contribute to dental caries. The role of sugar-containing methadone prescribed to people on maintenance programme has been highlight as central in the causation of dental caries. This was first reported in 1978 [18] and has been supported by numerous researchers ever since. The effect of opioids and methadone are known to dry the mouth and reduce the buffering effect of the saliva upon the acid produced during the consumption of sugars resulting in tooth decay. However, Tripathee et al.'s [77] systematic review examining the link between sugar-containing methadone and dental caries showed no strong evidence to support a link and pointed to the role of other factors such as reduced salivary function.

75.2.2.2 Mucosal-Related

The increased experience of gingivitis and periodontal disease noted in those using morphine and heroin is associated with lack of toothbrushing and plaque removal [74]. Morphine in particular is known to inhibit the phagocytosis of *Candida albicans* and when this is coupled with xerostomia predisposes users to thrush [70].

75.2.3 Depressants and Oral Health: Cannabis (Table 75.1)

75.2.3.1 Tooth-Related

The role of saliva in buffering effects and preventing the acid attack on the teeth has been described. A study by Schulz-Katterbach et al. [65] aimed to clarify the role of reduced salivary function in dental caries among regular younger cannabis users. Regular cannabis users had more decayed tooth surfaces (smooth surfaces of anterior and molar teeth), stated that they brushed their teeth less, visited the dentist less and consumed greater amounts of sugar-containing beverages compared to non-cannabis users. It has been proposed, therefore, that the increased caries experience is due to the joint effects of reduced salivary buffering capacity and immediate desire to consume sweet foods and drinks after cannabis consumption.

75.2.3.2 Mucosal-Related

Cannabis has also been found to have a detrimental effect on the oral soft tissues, possibly due to a number of factors including the higher temperature at which cannabis burns compared with tobacco causing irritation to the oral mucosa together with the carcinogenic effect of tetrahydrocannabinol (THC).

Layman [38] and colleagues [6] were the first researchers to conclude an association between smoking cannabis and gingival enlargement. More recently a case report presented marijuana-associated gingival enlargement or swollen gums in men [54]. Since, phenytoin and cannabidiol (CBD) have common anticonvulsant properties [71], it has been suggested that the gingival enlargement observed in marijuana users could be caused by the same mechanisms to that of phenytoin [66].

Increased prevalence of leukoedema and density of *Candida albicans* has been reported in cannabis users [20, 80]. Leukoedema is thought to be a result of cellular damage due to local irritation of smoking cannabis, whereas it is the immunosuppressive effects of THC that are proposed to permit candida proliferation. Nicotinic stomatitis (smokers' palate) has been reported in marijuana smokers [20, 54]. Uvulitis has also been extensively reported in cannabis smokers whether acute or chronic [54].

Theoretically, a role of THC as a risk factor of oral cancer has been proposed; however, the evidence remains ambiguous. It is thought that the increased amount of carcinogenic hydrocarbons, such as benzo-alpha-pyrene, that is higher in marijuana tar compared to tobacco tar and that marijuana smoking involves inhaling three times more tar compared to tobacco smoking [33] increases the risk of head and neck cancer. Moreover, it has been suggested that it is through a dose-response relationship

between frequency and duration of cannabis smoking [91] that gives rise to an increased risk of oral cancer. In contrast, Rosenblatt et al. [63] and Lyewellyn et al. [39] found little evidence for an association between cannabis use and oral cancer.

75.2.3.3 Other

The experience of dry mouth immediately after cannabis use has been reported by nearly 70% of the people in Darling et al.'s study [20]. However, accuracy of the duration of having a dry mouth was not established by Darling [20].

75.2.4 Stimulants and Oral Health: Cocaine (Table 75.2)

Snorting and smoking cocaine are the main methods of use. In order to smoke cocaine, it must be converted into a smoke-able form and so sodium bicarbonate is added. Heating this produces a cracking sounding giving it the name 'crack'. A third form of use is rubbing of cocaine into gums or oral mucosa. Much of the oral health effects may be explained by the method of administration.

75.2.4.1 Tooth-Related

Bruxism, worn teeth [49] and tooth abrasion [27] have been observed in cocaine users. The resulting clenching and grinding of the teeth causes painful facial muscles and temporomandibular joints [27]. Cocaine hydrochloride can decrease salivary pH causing loss of calcium from the enamel, giving the smooth and occlusal surfaces of the teeth a smooth and glossy appearance [11]. Cocaine hydrochloride also causes tarnishing of gold crowns [17]. More recently, Cury et al.'s [19] work showed that crack cocaine or cocaine users had four times increased risk of dental caries.

75.2.4.2 Mucosa-Related

Gingival lesions at the site of cocaine application have been reported in a case report by Gandara-Rey et al. [28]. Of the four cases described, the patients used cocaine to relieve pain due to cluster headaches. Intraorally it was observed that they had erythematous lesions at the site of application, i.e., the alveolar gingiva and buccal mucosa. For a patient with history of 4 years of cocaine use, the patient had a necrotic lesion leading to bone exposure. These lesions have been attributable to the vasoconstrictive mechanisms of cocaine's pharmacodynamics.

Administration of local anaesthesia after recent cocaine use may induce an acute increase in blood pressure. Therefore, local anaesthetic without epinephrine should be used if cocaine use is suspected and dental treatment should be postponed for 6–24 hours to allow for its elimination [90].

75.2.4.3 Other

Other orofacial effects of cocaine addiction include perforation of nasal septum and palate. Nasal septum perforation is a complication observed in nearly by 5% of cocaine snorters [40]. This is explained by the vasoconstrictive action of cocaine, causing local ischemia resulting in the necrosis of the nasal septum and its surrounding tissues. Chemical irritation by contaminants in 'cut' cocaine further aggravates tissue necrosis. The use of pens or pencils to remove excessive cocaine from the nose increases the risk of nasal perforation [69]. Finally, snorting cocaine decreases the nasal defence against infection by damaging the 'nasal mucociliary transport system'. Therefore, reduction in nasal support results in a broad flat nose known as 'saddle nose deformity' [40]. Palatal perforations are follow-on from nasal perforation. These lesions are mostly seen on the hard palate. Sizes vary from a diameter of a pinhole to 15 mm. Perforation of the hard palate results in speech impairment and difficulties in eating or drinking due to nasal regurgitation.

75.2.5 Stimulants and Oral Health: Amphetamines and Related Compounds

Amphetamines are classified as CNS stimulants. They give a sense of well-being, combat sleepiness, suppress appetite and are relatively easy and

cheap to obtain and purchase [26, 57]. The drugs described in this section are (i) methamphetamine (MA) (known as 'Meth' or 'Speed') and (ii) 3,4-methylenedioxymethamphetamine (MDMA) (known as 'Ecstasy', 'XTC' or 'Adam'). MA and MDMA can be taken orally, by snorting, smoking or injecting, as they are readily water and alcohol soluble. MA hydrochloride is produced in clear chunky crystals called 'ice' that can be smoked and gives it names called 'Crystal Meth, Crystal Glass and Ice'. MDMA tablet is used orally but its powder can be snorted, inhaled or injected. Consumption of MDMA with alcohol, cannabis and cocaine has also been reported [76] and so the effects of amphetamines may be due to synergistic effects of alcohol, cannabis and cocaine upon the oral tissues.

75.2.5.1 Methamphetamine

Tooth-Related

Abuse of MA is associated with several negative effects on oral health. MA abusers generally present with rampant dental caries that clinically resembles early childhood caries. This form of presentation is known as 'Meth Mouth' [4]. Teeth are described by users as 'blackened, stained, rotting, crumbling or falling apart' [4]. The dental caries pattern in chronic Meth users involves 'buccal smooth surfaces of posterior teeth and interproximal surfaces of anterior teeth' [67]. Caries progression in MA users is described as slow and goes through periods of arrest instead of progressing rampantly [58]; however, eventually process progresses to involve the entire tooth [30]. This pattern of intermittent caries activity differentiates the carious lesions in MA users from the caries seen in cocaine and other narcotic drug users. Numerous studies have identified increased incidence of caries among MA users compared to non-MA users [45, 60, 61]. A combination of factors have been documented to cause 'Meth Mouth' suggesting it may be related to xerostomia (dry mouth), long periods of poor oral hygiene, frequent ingestion of sugar and fizzy drinks and acidic nature of MA [30, 32, 41].

Mucosa-Related

Strong evidence of oral health neglect has also been reported in MA users along with higher levels of gingival bleeding and periodontal disease among crystal meth users [60, 61].

Other

The role of MA in causing xerostomia is unclear; however, some explanations have been provided by Shaner et al. [67] associated with vasoconstriction and reduction in salivary flow and dehydration due to hyperactivity. Rommel et al. [60, 61] reported that 72% of MA users compared to non-MA users had dry mouth. With regard to clinical findings, their results suggested poorer saliva production and lower salivary pH values among MA users.

Tooth wear in MA users has also been associated as an outcome of increased bruxism [30]. Following the hyperactive phase after Meth use, users can begin 'tweaking' during the drug's wear off phase. This feeling is characterised by restless anxiety, irritability, fatigue and dysphoria, and it is during this phase they have a tendency to grinding and clenching of teeth and jaws resulting in temporomandibular joint pain [60, 61, 68].

75.2.5.2 MDMA (3,4-Methylenedioxy-Methamphetamine)

Tooth-Related

Ecstasy use has been reported to cause tooth erosion and dental caries as a result of its xerostomic effects. Dry mouth, for instance, was reported by 93–99% of Ecstasy abusers compared to non-Ecstasy users [41, 42, 55]. MDMA induces neuromuscular stimulation causing muscle rigidity and breakdown of muscle fibres leading to a raised body temperature. As this drug is popular among people who attend 'rave' parties, in combination with vigorous dancing in hot and crowded clubs, it could lead to an excess water intake [15]. Further complication of the drug is, therefore, that it stimulates the secretion of antidiuretic hormone, which is normally responsible for

regulating and balancing the amount of water in the body. Therefore, to prevent hyponatraemia, consumption of isotonic drinks is recommended; however, to relive dry mouth and dehydration, Ecstasy users consume fizzy sugary drinks, which ultimately leads to dental caries and tooth wear [42].

Mucosa-Related

In a questionnaire-based interview conducted by Verheyden et al. [79] on 466 regular MDMA users, symptoms of mouth ulcers were reported by 2.3% 24 hours later and 8.2% 24–48 hours later after use. Tropical application of the drug can also have profound effects on the oral mucosa. Brazier et al. [16] reported 'a swelling of the maxillary vestibule in relation to upper front teeth with some tooth mobility and pain on percussion' following use of MDMA. At the 2-day follow-up, once the swelling had resolved, mucosal fenestration with exposure of the underlying alveolar bone was observed. This clinical presentation was associated with placing Ecstasy tablet on the site of the lesion. In a second case report by Ahmed et al. [2], 'an 18-year-old patient presented with extensive perioral and intraoral swelling, consisting of substantial oedema of the upper and lower labial mucosa, bilateral buccal mucosa, dorsum of the tongue, and the bilateral tonsillar region. Grossly the appearance was of a greyish-white cast with a coarsely wrinkled surface after consumption of one Ecstasy tablet with unknown quantity of alcohol about two hours prior'.

Other

Jaw clenching (bruxism) and grinding of teeth have been frequently reported among Ecstasy users [41, 42, 55, 79]. There have been reports of painful jaw muscles [41], jaw clenching up to 24–8 hours after MDMA consumption [79], and tooth wear [42, 47].

MDMA interacts with medication prescribed to manage temporomandibular joint pain such as tricyclic antidepressants. Caution should be taken while administering local anaesthetic containing epinephrine.

75.2.6 Other Drugs and Oral Health: Tobacco (Nicotine)

Tobacco is smoked as cigarettes, cigars, bidis, kreteks, pipe or hookah. The use of e-cigarettes is one of the fastest-growing method of smoking. Socioeconomic, geographic and cultural factors strongly influence the type of smoking. Reverse smoking, mostly seen in India and South America, is a form in which the burning end of the cigarette or cigar is held inside the mouth. Smokeless tobacco is also used by many and is consumed either by sniffing (dry snuff) or chewing. Tobacco that is chewed comes in the form of loose leaf in pouches, plug or twist form which is placed in the mouth, cheek or lip and is either sucked or chewed. Tobacco pastes or powders are consumed in a similar way and applied to the gums or teeth. Twenty-eight carcinogens have currently been identified in smokeless tobacco [35]. Nicotine is an addictive chemical present in all tobacco products which is absorbed through the oral mucosa with a higher absorption occurring from products with a higher pH [10]. Nicotine has a wide range of negative effects on oral health. Therefore, the negative impact of tobacco consumption relates to both smoked and smokeless forms of consumption and will be discussed separately in this section.

75.2.6.1 Tobacco Smoking

Tooth-Related

There is limited evidence to support the role of tobacco smoking in caries causation. A systematic review published in 2013 [7] could identify just four studies to support an association between tobacco smoking and dental caries. It concluded by highlighting that the study quality was poor, hence questioning the substantiation for such an association. Saliva acts as a protective factor for dental caries and usually younger age groups have naturally higher salivary flow rate; therefore old age can be considered a confounder while identifying such as association. Further, lifestyle and socio-economic factors have been associated with caries experience. Therefore, the evidence supporting the actual role of tobacco smoking is

still lacking. Pipe smoking, on the other hand, can lead to tooth abrasion at the site of pipe placement.

Mucosal-Related

Tobacco smoking is the primary risk factor for oral and oropharyngeal cancer. Numerous studies describe tobacco-associated risk of oral cancer to be dose dependent, with the risk increasing significantly with increasing frequency and duration. A meta-analysis on 12 studies estimated cancer risk in the USA, Uruguay, Sweden, Italy, China, India, Taiwan and Korea reported the pooled cancer estimate to be 3.43 times higher in smokers compared to non-smokers [29]. Wyss et al. [88], in their work, used the pooled data from the International Head and Neck Cancer Epidemiology (INHANCE) Consortium (comprising 13,935 cases and 18,691 controls in 19 studies from 1981 to 2007). They [88] identified that cigarette smokers aged 45 years and above had higher risk of oral cancer compared to cigarette smokers under 45 years of age. They also found an independent increased risk of head and neck cancer with cigar (OR = 3.49) and pipe smoking (OR = 3.71). There is further evidence suggesting that there is a three times increased risk of oral cancer among bidi smokers compared with cigarette smokers [53]. Work by Montazeri et al. [43] has linked pipe smoking with oral cancer and precancerous lesions. The role of tobacco in causing cancer is due to the mutagenic actions causing chromosomal damage, impairing the cell's regulatory processes. The two primary carcinogens present in tobacco smoke are 'benzo (a)-pyrine' and 'nitrosamines' (TSNA). Despite tobacco smoke being a major risk factor for oral cancer, relatively lower proportions of those exposed develop malignancy. This is thought to be due to individual variation with regard to the ability of their enzyme systems to metabolise and deactivate the tobacco carcinogens.

Oral leukoplakia and erythroplakia are the two known precancerous lesions which are likely to transform into oropharyngeal cancer over time. Presence of oral epithelial dysplasia is the hallmark for cancer development [83] and appears mostly in exclusive tobacco consumptions and exclusive alcohol consumption. Other non-cancerous effects of tobacco smoking on mucosa include candidal infections, smokers' melanosis and smoker's palate [82].

Smoking has a major negative impact on periodontal health. A systematic review involving 70 cross-sectional, 14 case-control and 20 cohort studies indicated a strong association between smoking and periodontal disease [8]. Numerous mechanisms have been postulated to explain tobacco smoking-related periodontal pathogenesis: (i) smoking may cause a disruption in the composition of microflora due to a decrease in the oxygen levels in the periodontal pockets, (ii) disruption in cell-mediated and humoral-mediated immunity of the host, (iii) alteration of periodontal inflammatory responses and (iv) increased secretion of bone resorbing factors. Furthermore, tobacco smoking and its association with tooth loss have also been documented extensively in cross-sectional [48] as well as longitudinal studies [21].

Warnakulasuriya et al. [82] in their work summarise additional studies to explore this association corroborating the above findings. They [82] point to studies outside of the Europe and the USA where the evidence to support the association between smoking and periodontal disease is poor.

Other

Warnakulasuriya et al. [82] in their work report other causes of tobacco smoking such as black/brown discoloration of teeth and dental restorations and dentures, alteration of taste and smell, black hairy tongue (coated tongue), smoker's breath and impaired and delayed wound healing after tooth extractions or any other surgical procedure. Although there is limited evidence, current literature suggests dental implant failure is more common among smokers than non-smokers. In a recent systematic review and meta-analysis, maternal passive smoking exposure was found to be associated with a 1.5-fold increase in the risk of non-syndromic orofacial clefts which is similar to that reported for active smoking previously [64]. Therefore, evidence of an association between maternal passive and active cigarette smoking and risk of oral cleft exists.

75.2.6.2 Smokeless Tobacco

Tooth-Related

Smokeless tobacco has been identified to be associated with cervical abrasion and root caries [59] along with an increased prevalence of decayed tooth surfaces including root surfaces [75]. Increased susceptibility to root caries results from gingival recession caused by smokeless tobacco and its high sugar content.

Mucosa-Related

Similar to tobacco smoking, smokeless tobacco has also been attributed to oral carcinogenesis. At present, the oral use of smokeless tobacco is practised in Africa, North America, Southeast Asia, Europe and the Middle East [35]. A systematic review on South East Asian countries [9] identified 11 publications on chewing tobacco and oral cancer, where the pooled odds ratio was 4.3 (3.1–5.8) after adjusting for alcohol and smoking. In the same study, chewing paan/betel quid with tobacco significantly increased the odds of oral cancer (adjusted for alcohol and/or smoking OR = 6.3). The study also identified a dose-response relationship. Two meta-analyses on American and European populations have documented the effects of smokeless tobacco and oral cancer. Weitkunat et al. [84] in their meta-analysis identified 38 studies for all types of smokeless tobacco of which six studies provided information on oral cancer relative risks specifically among never smokers. The pooled data from these studies were suggestive of an association between oral cancer and smokeless tobacco. In a second meta-analysis on population in the USA and Nordic countries, Boffetta et al. [14] stated that the relative risk for oral cancer was 1.8 (95% CI = 1.1–2.9; $p < 0.01$). More recently, Wyss et al. [89] in their study using pooled US data showed that snuff was strongly associated with cancer of the oral cavity among never cigarette smokers (OR = 3.01, 95% CI 1.63–5.55) than tobacco chewing (OR = 1.81, 95% CI 1.04–3.17). Berthiller et al. [9] argue that there may be differences in the type of smokeless tobacco used in South East Asia compared to North America and Europe, further highlighting the differences in the effect sizes and the effect of geography on the relationship between oral cancer and smokeless tobacco.

Leukoplakia or snuff-induced lesions present as white plaques with a wrinkled surface are the premalignant lesions usually seen at the site of tobacco placement [73].

Some studies have shown an association between smokeless tobacco consumption and increased incidence of gingival recession [44] whereas others have not [34]. Studies conducted among Asian populations have shown that smokeless tobacco users tend to have higher scores and risk for periodontal disease [5]. Similar finding was reported by a study based on National Health and Nutrition Examination Survey III data conduced in the US [25]. The pattern of periodontal destruction which has been reported suggests that mandibular tooth loss and gingival recession is observed at sites adjacent to mucosal lesions [44]. The mechanism of periodontal destruction cause by smokeless tobacco is similar to that for tobacco smoking.

75.2.7 Other Drugs and Oral Health: Gabapentin

Gabapentin and pregabalin have been reclassified as a Class C controlled substance in the UK [31], and is it known to have potential effects on oral health. This is primarily as a consequence of its anticholinergic effects upon salivation resulting in dry mouth. Therefore, dental caries is an unwanted outcome of the use of both gabapentin and pregabalin [12] (Table 75.3).

75.3 Conclusion

This chapter has presented the effects of substance use, including tobacco, alcohol and drugs upon on oral health. These effects range from dental caries, periodontal disease to oral cancer. These tooth and mucosa-related dental diseases are caused directly from the consumption of substances or arise indirectly as a consequence. The apparently easy access to substances and their

use makes it crucial for health care providers to be aware of the oral manifestations and respond in the best interest of any patient with a history of alcohol and drug use. We call for the inclusion of oral health as part of the common risk factor approach as an integral part of the care for people with a history of drug and alcohol use.

75.4 Clinical Relevance

This chapter points to the need for multidisciplinary working between medical and dental practitioners involved in the care of people with a history of substance use. Dental practitioners who see patients on a regular basis are in a position to notice and identify early signs of substance use in the dentition and oral cavity. Complaints about xerostomia or specific white patches in the mouth should alert dentists to be concerned of their patients' health status. Addiction medicine specialists, treating people with a history of alcohol and drug use, need to be mindful of the effect of these substances upon the oral tissues and the role of dentist in this regard. Addiction medicine specialists should be encouraged to complete an oral health assessment of their patients as part of a multidisciplinary team (MDT) approach and to have referral pathways for dental management. This is of central importance, since improved oral health, being able to smile, speak to others, eat and kiss, has a significant effect upon quality of life – reducing stigma and increasing confidence and self-esteem for those with a history of substance use. Therefore it is imperative that health care providers work in unison to provide holistic care for those with and recovering from substance use, to quote a survivor of substance use, 'The effects are transformative'.

Key Points

- Substance use, including tobacco, alcohol and drugs, has a severe detrimental effect upon oral health.
- People with a history of alcohol and drug use have a greater experience of xerostomia, dental caries, periodontal disease and oral cancer.
- People with a history of alcohol and drug use have greater unmet treatment need due to avoidance of dental treatment, dental anxiety and increased pain threshold associated in particular with opiate use. Health care providers should be aware of the oral manifestations and respond in the best interest of any patient with a history of alcohol and drug use.
- Preventive dental treatment must be provided especially for those with xerostomia in the form of high fluoride concentration toothpaste of 2500 ppm or 5000 ppm.
- Clinicians should be aware of the potential of drug interactions before providing local anaesthesia with ephedrine for dental treatment.
- On initial examination, treatment should be provided to assist the patient to be pain free; further treatment should be tailored to patient need and their current substance use status.

Gastrointestinal Disorders Related to Alcohol and Other Drug Use

76

Guang Chen and Paul S. Haber

Contents

Abstract

Acute and chronic gastrointestinal (GI) problems are common in the setting of alcohol, tobacco, and prescription and recreational drug use. Excessive alcohol use is associated with injury to all parts of the gastrointestinal tract. Alcohol-related liver disease, alcohol-related pancreatitis, and gastrointestinal cancer are important causes of morbidity and mortality related to excessive alcohol use. Tobacco use is associated with gastroesophageal reflux, peptic ulceration, gastrointestinal cancer, and Crohn's disease but appears to protect against ulcerative colitis. Opioids have important effects on gastrointestinal secretion and motility. Narcotic bowel syndrome may develop in the setting of escalating doses of opioid analgesia. Cannabis use is associated with both relief of nausea and vomiting associated with chemotherapy and adverse gastrointestinal effects. Cannabinoid hyperemesis syndrome should be considered in the setting of heavy cannabis use and recurrent vomiting. The body packing syndrome is sporadically encountered at hospitals near international transport hubs and can be challenging when encountered.

76.1 Introduction

This chapter describes gastrointestinal (GI) effects of gastrointestinal disorders secondary to the effects of alcohol, tobacco, prescription, and recreational drugs. Excessive alcohol use is associated with injury to all parts of the gastrointestinal tract. Several detailed reviews have been published [22]. The gastric mucosa also contributes to the oxidation of alcohol. Within the gastrointestinal tract, liver disease and pancreatitis are important causes of morbidity and mortality related to excessive alcohol use. Symptoms of intestinal dysfunction are common among patients with alcohol dependence and include diarrhea and malabsorption. Tobacco use is associated with gastroesophageal reflux, peptic ulceration, gastrointestinal malignancy, and Crohn's disease but appears to protect against ulcerative colitis. Opiates have important effects on gastrointestinal secretion and motility. Other drugs such as cannabis and cocaine uncommonly affect the gastrointestinal tract. The body packing syndrome is sporadically encountered at hospitals near international transport hubs and can be challenging when encountered.

76.2 Alcohol

The relative risk of alcohol-related GI toxicity appears to differ between affected tissues and between benign and neoplastic disorders. Similarly the pattern and type of beverage have not been consistently shown to predispose to any specific GI effects of alcohol.

76.2.1 Parotid Glands and Oral Cavity

Painless symmetrical enlargement of the parotid glands (termed sialosis or sialadenosis) is common in patients with alcohol-related liver injury [120]. Abelson et al. [1] found 61% of patients with alcohol-related cirrhosis had enlarged parotid glands. Sialosis is characterized by the triad of acinar cell hypertrophy, myoepithelial degeneration, and neural degeneration. The effect of alcohol use on salivary function in humans is controversial with reports of increased, unaltered [134], and decreased salivary flow [120]. Moreover, patients with alcohol use disorder may suffer from inflammation of the tongue (glossitis) and the mouth (stomatitis). It is unclear, however, whether these changes result from poor nutrition or reflect a direct effect of alcohol on the mucosa.

76.2.2 Esophagus

Both acute and chronic alcohol consumption are associated with symptomatic gastroesophageal reflux disease (GERD). Reflux episodes were increased by 60 g of ethanol given with a meal to healthy subjects without alcohol dependence (Kaufman and Kaye 1979). These episodes were measured by measurement of esophageal pH for 3 h after a standard meal and most were asymptomatic. A number of mechanisms have been identified that may contribute to these effects of alcohol [44]. Direct application of 30% ethanol, but not lower concentrations, causes injury to the esophageal mucosa. An acute dose of alcohol reduces lower esophageal sphincter pressure (LESP) [74] and reduced maximal LESP stimulated by a meal [103]. Chronic excessive alcohol use is also associated with manometric abnormalities relevant to GERD that recover after a month of abstinence [83, 134].

Upper gastrointestinal bleeding (UGIB) is more frequent in patients with alcohol use disorder, especially those with cirrhosis. In a 2007 UK audit of 6,750 patients with acute UGIB, 9% had known cirrhosis and 26% a history of alcohol excess [69]. Mallory–Weiss syndrome is characterized by massive bleeding caused by tears in the mucosa at the cardio-esophageal junction after vomiting. The syndrome accounts for 5–15% of all cases of bleeding in the upper GI tract. Mallory–Weiss syndrome prevalence varies; it is uncommon in China [179]. In one series, almost

50% of these patients were associated with repeated retching and vomiting following excessive acute alcohol consumption [89].

76.2.3 Stomach

76.2.3.1 Alcoholic Gastritis

The clinical term "alcoholic gastritis" is nonspecific and is often used to refer to a broad range of upper gastrointestinal symptoms experienced by patients who drink alcohol excessively. It has been surprisingly controversial despite considerable study [44, 86]. The term gastritis is used to denote inflammation associated with mucosal injury. Epithelial cell damage and regeneration without associated inflammation are referred to as "gastropathy" [36]. It is often difficult to establish with certainty that a particular agent, such as alcohol, has caused gastropathy. Exposure of the gastric mucosa to 20% alcohol induces gastric mucosal injury. Lower concentrations are not toxic, whereas higher concentrations lead to extensive hemorrhagic injury [86].

76.2.3.2 Dyspepsia and Ulcer

In patients admitted for treatment of alcohol dependence, gastric hemorrhagic and erosive lesions and ulcers were commonly seen [129]. Interestingly, Brown et al. [20] found that gastritis was not more common in patients with cirrhosis than healthy controls. Gastritis in patients with alcohol use disorder is strongly associated with H. pylori infection, with histological and symptomatic relief after eradication of the organism, but no improvement with abstinence from alcohol [158]. The presence of alcohol dehydrogenase (ADH) activity in H. pylori organisms may tend to protect the alcohol drinking host from infection as exposure to alcohol leads to the generation of acetaldehyde that may be bactericidal. Alcohol use disorder is associated with reduced medication compliance and delayed healing [123], but the healing of established ulcers is not retarded by moderate alcohol consumption [11].

The available evidence does not convincingly support the conclusion that alcoholic beverages cause chronic chemical gastropathy [26]. Moreover, there does not appear to be a link between chronic atrophic gastritis and alcohol consumption [2]. Other causes may be account for gastritis-like symptoms. Fatty liver may cause upper abdominal discomfort and nausea. It has been proposed that alcohol may directly induce vomiting by central stimulation of the chemoreceptor trigger zone in the area postrema of the floor of the fourth ventricle in the absence of peripheral disease [131]. In addition, bacterial overgrowth has been reported to be more common in patients who drink alcohol excessively and may also contribute to upper abdominal symptoms and diarrhea [68].

76.2.3.3 Alcohol-Related Pancreatitis

Approximately 10% of patients with chronic alcohol use disorder develop attacks of clinically acute pancreatitis. Conversely, alcohol is responsible for approximately 30% of cases of acute pancreatitis in the USA [174]. In a large cohort study from the USA, alcohol was estimated to account half of the cases of chronic pancreatitis, and the incidence has increased in the past 20 years [172] similar to the UK [79].

Definitions

The term acute pancreatitis refers to an acute inflammatory process of the pancreas, with variable involvement of other regional tissues or remote organ systems. Chronic pancreatitis is characterized by chronic inflammation, glandular atrophy, and fibrosis. Clinically, it manifests pain with exocrine or endocrine insufficiency. The revised Atlanta classification of acute pancreatitis identified two phases of the disease: early and late. Severity is classified as mild, moderate, or severe. Mild acute pancreatitis, the most common form, has no organ failure and local or systemic complications and usually resolves in the first week. Moderately severe acute pancreatitis is defined by the presence of transient organ failure, local complications, or exacerbation of comorbid disease. Severe acute pancreatitis is defined by persistent organ failure, that is, organ failure >48 h. Local complications are peripancreatic fluid collections, pancreatic and peripancreatic necrosis (sterile or infected), pseudocyst, and

walled-off necrosis (sterile or infected). Morbidity and mortality is high in this group [8].

Etiology

The most common associations of acute pancreatitis in Western societies are gallstones and heavy alcohol use which together account for approximately 75% cases. Yadav et al. [172] found that while alcohol was the most common etiology in men (59%), it was a less common etiology in women (28%). Nonetheless, only a minority of heavy drinkers develop clinically evident pancreatic disease.

The association between alcohol and pancreatitis appears to be dose-related. Pancreatitis typically occurs in subjects who have consumed greater than 100 g alcohol per day for at least 5–10 years and rarely if ever follows an isolated large alcoholic binge. The risk of pancreatitis may be increased in developing countries raising the hypothesis that impurities within country-made alcoholic products may cause pancreatic injury [9]. Once the disease is established, episodic heavy drinking often precipitates relapses. Relapses have been described after only 1 day of recurrent drinking. Pancreatitis is common among patients with HIV particularly in association with heavy alcohol use [38, 165]. Many patients with acute alcoholic pancreatitis progress to chronic pancreatitis, with continued alcohol abuse being a key prognostic factor [5].

Other than gallstones, relatively common causes for pancreatitis that should be considered include hypercalcemia of any cause and severe hypertriglyceridemia. Hypertriglyceridemia (greater than 10 mmol/l (approximately 1,000 mg/dl) with lipemic serum) of any cause is associated with recurrent attacks of pancreatitis [56]. Although alcohol abuse is a known cause of hypertriglyceridemia, the majority of cases of alcoholic pancreatitis are not associated with marked hyperlipidemia [62]. Other causes include pancreatic trauma, duct pathology, and a number of drugs. In most series, about 10% of cases are idiopathic.

Predisposing Factors

Numerous investigators have attempted to account for this individual susceptibility by studying associations between alcoholic pancreatitis and potential risk factors. These studies have been previously reviewed [63] and have focused on the amount, type, and pattern of alcohol consumption, genetic markers, diet [166], hypertriglyceridemia [62], tobacco consumption [64], and pancreatic ischemia. Numerous genetic markers have been studied, but there is insufficient evidence to consider that any of the above factors are well established. Two important genetic mutations are linked to pancreatitis, but not the alcoholic form. Gain-of-function mutations in the serine protease 1 gene (PRSS1) on chromosome 7q35, which encodes cationic trypsinogen, result in an autosomal dominantly inherited form of hereditary pancreatitis. Mutations in the cystic fibrosis gene (CFTR) have been associated with an autosomal recessive form of pancreatitis [121]. In alcoholic pancreatitis, a mutation of the gene coding for pancreatic secretory trypsin inhibitor (SPINK1) has been described in 5.8% of patients compared with 1% of alcoholic controls [169]. Mutations in chymotrypsin C (CTRC) have also been identified in pancreatitis [127]. These two studies support the concept that genetic factors influence susceptibility to pancreatitis, but given that only 6% and 3% of the subjects carried these mutations, respectively, individual susceptibility to this disease remains largely unexplained.

Pathogenesis

Two important factors leading to tissue injury in pancreatitis are autodigestion and oxidant stress. Several lines of evidence indicate that activated digestive enzymes play an important role in pancreatitis [61]. Oxidant stress is characterized by the production of reactive oxygen species that are atoms or molecules containing oxygen with an unpaired electron in the outer shell (free radicals). Free radicals are highly reactive and bind to lipids, proteins, and nucleic acids leading to cellular injury [50].

Several mechanisms have been proposed to explain why alcohol-related pancreatitis occurs only after many years of alcohol abuse and not after a single binge in humans. These include the role of progressive pancreatic fibrosis related to activation of pancreatic stellate cells by acetaldehyde and oxidative stress [60] and the potential for endotoxin to precipitate pancreatitis in the

alcohol-exposed gland [162]. Plasma lipopolysaccharide levels have been shown to be significantly higher in drinkers (either after chronic alcohol intake or a single binge) compared to nondrinkers and in patients with alcoholic liver disease compared to those with liver disease of other etiologies [15].

Diagnosis

A confident diagnosis of pancreatitis can often be made on the basis of an attack of severe abdominal pain and tenderness with elevation of the serum amylase and or lipase more than three times the upper limit of normal and with imaging studies suggestive of inflammation in and around the pancreas.

Newer tests that may be more specific for acute pancreatitis include trypsinogen activation peptide and trypsinogen-2 but are not widely available [175]. Gallstones should be excluded by ultrasound examination. In cases with a negative ultrasound, serum alkaline phosphatase or transaminase levels raised at least twofold suggest associated gallstones which may be detected by repeat ultrasonography or endoscopic retrograde cholangiopancreatography (ERCP) [55, 160]. Magnetic resonance cholangiography [143] and endoscopic ultrasound are increasingly supplanting ERCP for diagnosis of gallstones in this setting. Dilated common bile duct has been recently described in patients on methadone and with opioid dependence in the absence of gallstones [130].

Assessment of Severity

Several clinical findings, including thirst, poor urine output, progressive tachycardia, tachypnea, hypoxemia, agitation, confusion, a rising hematocrit level, and a lack of improvement in symptoms within the first 48 h, are warning signs of impending severe disease. Admission to an intensive care unit should be considered. Enzyme levels do not correlate well with disease severity. A number of clinical and laboratory scoring systems have been developed to identify patients at risk of complications so that they may be treated more intensively at an earlier stage.

Contrast-enhanced CT scan is now widely performed to detect pancreatic necrosis and complications of severe pancreatitis such as fluid collections, pseudocysts, and abscesses [85]. Caution in the unrestricted use of contrast-enhanced CT scans appears warranted. CT scanning without contrast can detect most diagnostic features of pancreatitis and is often performed. MRI is an option that may spare radiation exposure.

Treatment

Overall, about 20% of patients with acute pancreatitis have a severe course, of these 10–30% will die, despite improvements in intensive care treatment [106]. Severe cases, particularly those associated with respiratory or renal failure, require treatment in an intensive care unit.

Initially, patients are treated with bed rest, analgesics, intravenous fluids, and fasting. Intravenous opiates may be required, usually in the form of a patient-controlled analgesia pump. Fentanyl is being increasingly used due to its better safety profile, especially in renal impairment. Meperidine (pethidine) has traditionally been favored over morphine has a short half-life and repeated doses can lead to accumulation of the metabolite normeperidine that causes neuromuscular irritation and, rarely, seizures. Ebbehøj et al. [40] showed the use of indomethacin suppositories (50 mg twice daily) reduced opioid requirements in 30 patients with acute pancreatitis without risk of gastrointestinal bleeding. There is currently no difference in the risk of pancreatitis complications or clinically serious adverse events between opioids and other analgesia options [10].

Fluid resuscitation should be goal directed including monitoring heart rate, mean arterial pressure, serum urea concentration, and urine output [32]. Aggressive fluid resuscitation is associated with respiratory complications and abdominal compartment syndrome. Ringers lactate may be superior than normal saline [33, 170].

Early feeding is beneficial in acute pancreatitis and may reduce the risk of developing infected pancreatic and peripancreatic necrosis [167]. Delayed feeding (generally defined as >24 h) is associated with higher rates of infected peripancreatic necrosis, multiple organ failure, and necrotizing pancreatitis [7, 41, 182]. Success of early feeding has been demonstrated with low fat, normal fat, and soft or solid consistency, and

thus it is not necessary to start patients with acute pancreatitis on a clear liquid diet before advancement to a solid diet [77, 107]. Patients who cannot tolerate an oral diet may require enteral tube placement for nutritional support, which is preferred over total parenteral nutrition (TPN) [58, 82].

In patients with mild acute pancreatitis, there appears to be no role for prophylactic antibiotics in the absence of cholangitis or other extrapancreatic infections [78].

A number of antioxidant therapies have been evaluated for both acute and chronic pancreatitis given the role of oxidative stress in the pathogenesis of these diseases and encouraging results from early small trials. However, a well-conducted recent trial in acute pancreatitis found no benefit [138]. Protease inhibitors may limit the damage done by activated digestive enzymes, but it is not possible to commence treatment early enough in the attack of pancreatitis to be effective. Peritoneal lavage might improve the outcome by removing toxic inflammatory products from the peritoneum, but the results of controlled studies have been conflicting [104, 144].

ERCP with endoscopic sphincterotomy has been shown to reduce the morbidity of patients with unremitting severe gallstone pancreatitis in two randomized controlled studies [43, 110]. In general, ERCP should be performed within 72 h in those with a high suspicion of persistent bile duct stones (i.e., visible common bile duct stone on noninvasive imaging, persistently dilated common bile duct, jaundice, or rising liver chemistries) but plays no role in alcohol-related pancreatitis.

Surgery is uncommonly required, the main indication being necrotizing pancreatitis [105]. Observational data support delaying surgical debridement of necrotic tissue for at least two weeks if possible while the patient's medical condition is optimized and viable pancreatic tissue becomes evident. This approach appears to improve survival and maximize organ preservation. Pancreatic abscess carries a very high mortality and is an absolute indication for drainage by open surgery or percutaneous techniques. Multiple procedures may be required. Small pseudocysts may resolve spontaneously, but large or symptomatic ones usually require drainage via endoscopic, percutaneous, or operative techniques [101].

Chronic Pancreatitis (CP)

Recurrent episodes of acute pancreatitis, clinical or subclinical, may lead to chronic pancreatitis. Chronic excessive consumption of alcohol is the most common cause and accounts for approximately 75% of cases in Western societies. Interestingly idiopathic pancreatitis is the most common type in India (tropical pancreatitis) and China, accounting for approximately 70% of all cases of CP [53].

Clinical Features

The main clinical problem is usually pain and this may be very challenging. Like that of acute pancreatitis, the pain of chronic pancreatitis is typically diffusely located in the upper abdomen and may radiate to the back when severe. Pain tends to increase with meals and decreases appetite and food consumption and often results in weight loss. A minority present without pain. The other manifestations are endocrine (diabetes mellitus) and exocrine failure (steatorrhea). Weight loss is common but typically is mild. Vitamin deficiency is generally subclinical. Investigations may reveal malabsorption of fat-soluble vitamins and osteopenia. Other complications include pseudocyst formation, bile duct or duodenal obstruction, pancreatic ascites or pleural effusion, splenic vein thrombosis, pseudoaneurysms, and pancreatic cancer.

Treatment

Complete abstinence from alcohol is essential to minimize progression of the disease. Reassurance that the disorder is benign with a tendency to slowly remit is helpful. Nonnarcotic analgesia may suffice, but opioids are often required and should not be unreasonably withheld. A Danish randomized double-blind clinical trial of 64 patients found that pregabalin compared with placebo was a more effective analgesic after 3 weeks of treatment (36% vs. 24%; mean difference) [112]. Celiac plexus neurolysis improves

pain in about 60% of chronic pancreatitis patients. Recent advances in endoscopic ultrasound (EUS) technology and technique have resulted in the development of celiac ganglia neurolysis (CGN). EUS CGN is more effective than traditional celiac plexus neurolysis [176]. Pancreatic enzyme supplements have been evaluated for the treatment of pain, but the evidence is mixed. A trial of 1 month is sufficient to determine whether this works in practice. An emerging treatment option for resistant cases of pain is total pancreatectomy with islet autotransplantation (IAT) which has shown favorable outcomes with regard to pain reduction. Concurrent IAT enabled 46% of patients to be independent of insulin supplementation at 5 years [19].

There is mixed evidence concerning antioxidant therapy in chronic pancreatitis. One study using a combination preparation that contained selenium, beta-carotene, vitamin C, vitamin E, and l-methionine found reduced pain and improve quality of life [84]. Antioxidants were considered useful in a subset of patients with idiopathic and obstructive but not alcohol-related chronic pancreatitis in a non-randomized study [23]. Recent randomized trials yielded conflicting results, but antioxidant therapy was disappointing in alcohol-related pancreatitis [13, 18, 139].

The relationship between pancreatic duct obstruction and pain is not clear, but relief of obstruction is frequently clinically associated with relief of pain. Endoscopic approaches to dilate pancreatic duct strictures and remove calculi have been developed, and surgery is typically reserved for refractory cases. Extracorporeal shock wave lithotripsy (ESWL) creates millimetric fragmentation of pancreatic stones, which has improved the results of endoscopic therapy and may have additional indications in the treatment of patients with chronic pancreatitis. Whipple procedures or modified Whipple procedures are the most commonly performed procedure. The Puestow procedure (lateral pancreaticojejunostomy) involves decompression of a dilated pancreatic duct and side-to-side anastomosis onto a Roux-en-Y loop of jejunum. Two small randomized trials comparing endoscopic and surgical drainage of dilated pancreatic duct in chronic pancreatitis showed that surgery was associated with better long-term analgesia and quality of life [24, 35].

Exocrine failure is treated by dietary modification, vitamin therapy, and pancreatic enzyme replacement. Reduction of dietary fat intake reduces steatorrhea. Pancreatic enzymes are required with each meal and snack. The newer enteric-coated microsphere preparations are more potent and are preferred as they release enzymes only in the duodenum, reducing inactivation of lipase by gastric acid. Lipase inactivation is also due to failure of pancreatic bicarbonate secretion, and proton pump inhibitors may increase effectiveness of treatment. Normalization of fecal fat levels does not typically occur. Diabetes associated with chronic pancreatitis is known as Type 3c (pancreatogenic) diabetes mellitus. It is treated with dietary modification, treatment of malabsorption, and specific therapy. Some patients respond to oral hypoglycemic agents, but most require insulin. The diabetes is "brittle" in that the patient is susceptible to hypoglycemia due to loss of both insulin and glucagon secretion. Long-term surviving patients with this form of diabetes are prone to diabetic complications and should be monitored accordingly [67]. Patients with substantial steatorrhea may require fat-soluble vitamins. The 25-hydroxylated form of vitamin D (calcifediol) is more polar than vitamin D2 or D3 and is therefore more easily absorbed in patients with fat malabsorption. The serum calcium should be monitored for the first few weeks of therapy with this naturally occurring analogue since it is more potent than vitamin D2 or D3 and can more easily produce hypercalcemia.

76.2.3.4 Small Intestine

Diarrhea is common among those who drink alcohol excessively, both acutely and chronically. Multiple factors contribute to this problem including altered motility, permeability, and nutritional disorders. Small intestinal mucosal injury can occur after acute or chronic administration of alcohol. Alcohol is directly toxic to the mucosa. Perfusion of the hamster jejunum with 4.8% ethanol caused separation of the tip of the

villus epithelium forming blebs [12]. Gut microbiome research has recently shown that alcohol may lead to quantitative and qualitative dysbiotic changes leading to inflammation and hyperpermeability [42].

Mucosal blood flow is acutely increased with increased endothelial permeability [12]. Acute administration of alcohol leads to increased gut permeability resulting both in abnormal absorption of luminal content (such as endotoxin, which contributes to the pathogenesis of alcohol-related liver disease; see previous chapter) and abnormal leakage of mucosal contents (such as albumin). Ethanol also inhibits absorption of actively transported sugars, dipeptides, and amino acids. Many defects in absorption have been reported in patients with alcohol use disorder, including water [90, 91], carbohydrate, lipid, vitamins (notably thiamine, folate), and minerals (calcium, iron, zinc, and selenium) [12]. Folate deficiency, common among patients with alcohol use disorder, causes intestinal injury leading to malabsorption and diarrhea and further loss of folate. Ethanol may exacerbate lactase deficiency [117].

76.2.3.5 Colon

Portal hypertension may manifest uncommonly with hemorrhoids and rarely with colonic varices. Colonic varices appear as filling defects on barium enema and may occur in any part of the colon, most commonly in the rectum [44]. Alcohol has also been reported to cause non-ulcerative inflammatory changes in human colonic epithelium [21]. Inappropriate alcohol enema has been reported to cause a chemical colitis [71], and this may result from a toxic effect similar to the direct toxicity of alcohol on the gastric mucosa.

76.2.3.6 Alcohol and Gastrointestinal Cancer

Alcohol use is a recognized risk factor for several gastrointestinal neoplasms, including tumors of the tongue, mouth, pharynx, larynx, esophagus, stomach, pancreas, colon, and liver [48, 97, 125]. The effect of alcohol on cancer risk appears to be dose related. A recent comprehensive Australian overview of the literature reports that relatively modest average daily consumption, 25 g per day, within the guidelines for men in many countries including the USA, is associated with increased risk of gastrointestinal cancer. For example, consumption of 25 g per day was associated with a relative risk of 1.76 for oropharyngeal cancer and 1.52 for esophageal cancer, approximately 1.05 for colon and rectum and 1.17 for liver [96]. Cancer risk rose from zero alcohol consumption with no safe level, suggesting that the less alcohol consumed, the lower the risk of cancer.

The pathophysiology of ethanol-associated gastrointestinal malignancy is varied. Current understanding suggests that alcohol and its metabolites (in particular acetaldehyde) affect the generation of reactive oxygen species (ROS), transforming growth factor-b signaling pathways, the immune system, and cell death and apoptosis and have direct toxic effects, among them the ability to produce aberrant methylation of DNA, with an impairment of its self-repair capacity [59]. Ethanol-induced induction of CYP2E1 increases carcinogen activation, potentiates oxidant stress, diminishes DNA repair, suppresses immune responses, and increases nutritional depletion such as folate deficiency [108]. For example, alcohol-fed rats given N-nitrosomethylbenzylamine developed more esophageal tumors than non-alcohol-fed rats [109]. In addition, nonalcoholic components of alcoholic beverages may in turn add to carcinogenesis. Interestingly, racial differences appear to affect the risk of carcinogenesis. In Asia, a large proportion of individuals carry a mutation of acetaldehyde dehydrogenase (ALDH) 2 which has very low activity leading to an accumulation of acetaldehyde after alcohol consumption. Homozygotes of the ALDH2 mutation develop severe side effects with small amounts of alcohol and hence reduce their drinking and are protected against alcohol-related disorders. In Japan, heterozygosity is prevalent in patients with alcohol use disorder and is significantly associated with oropharyngolaryngeal (OR 11.14), esophageal (OR 12.50), and esophageal cancer concomitant with oropharyngolaryngeal and/or stomach cancer (OR 54.20) [180].

Oropharynx and Esophagus

Alcohol use is associated with an increased incidence of esophageal (and oropharyngeal) cancer,

especially in those who also smoke. A Chinese population-based case–control study of esophageal cancer with 902 cases and 1,552 controls showed the combined effect of heavy smoking and drinking among men was pronounced: OR was 12.0 for those who smoked more than 1 pack per day and drank more than 750 g of ethanol per week [51]. Blot et al. [14] reported a 5.8-fold increased risk among those who drink alcohol, a 7.4-fold increased risk among smokers, and a 38-fold increased risk among those who both drank and smoked. The risk of oral, oropharyngeal, and esophageal cancer is further increased in South American countries where there is a high prevalence of concurrent alcohol, tobacco, and mate use [171]. A recent large meta-analysis of 20 case–control and four cohort studies including a total of 5,500 cases concluded that there was no association between alcohol drinking and esophageal adenocarcinoma risk, even at higher levels of consumption [151, 152]. Moderate and high alcohol intake was associated with risk of esophageal SCC (ESCC). Light alcohol intake appears to be associated to ESCC mainly in studies in Asia, which suggests a possible role of genetic susceptibility factors [75]. The type and quantity of alcoholic beverages consumed may affect the risk of esophageal SCC. Spirits may have a higher risk than wine or beer; however, the cumulative amount of alcohol rather than the type is probably more important [157].

Stomach

The association between gastric cancer and alcohol consumption appears to be modest. Tramacere et al.'s [151, 152] meta-analysis of 34,557 patients provided definitive evidence of a lack of association between moderate alcohol drinking and gastric cancer risk. There was, however, a positive association with heavy alcohol drinking (RR 1.14 (95% CI 1.08–1.21) above 50 g/day). Gastric noncardia adenocarcinomas were more common than gastric cardia cancers. This is supported by the European Prospective Investigation into Cancer and Nutrition (EPIC) cohort study which also showed beer but not wine or spirits to be positively associated with gastric cancer [37]. Genetic susceptibility also appears to be important, especially in Asian populations. A Korean study showed ALDH2 polymorphisms were found to modify the susceptibility to the development of gastric cancer associated with alcohol intake, especially ALDH2 *1/*2 genotype [132].

Colonic

A large pooled analysis found that those who consumed 30–45 g per day of alcohol had no increased risk (RR) of colorectal cancer whereas this risk was increased those who consumed more than 45 g per day (RR 1.41 (CI 1.16–1.72)). The relative risks in men and women appeared similar, and the association was seen for cancers of all portions of the colon and rectum [28]. This data is reflected in the Netherlands Cohort Study [46], where risk appeared to increase from proximal colon (RR 1.29) through distal colon (RR 2.07, 95% CI: 1.03–4.18) and rectosigmoid cancer (1.69, 95% CI: 1.08–2.64) [16].

Pancreatic

The role of alcohol in pancreatic cancer pathogenesis appears to be uncertain. Retrospective analysis of the Swedish Inpatient Register suggested that excess risk for pancreatic cancer among patients with alcohol use disorder is small and could conceivably be attributed to confounding by smoking [177]. High lifetime ethanol intake from spirits/liquor tends to be associated with a higher risk, but no associations were observed for wine and beer consumption [52, 126].

76.2.4 Prescription Medications

76.2.4.1 Opioids

It has long been recognized that opioids affect gastrointestinal motility. A US survey of 98 patients with chronic non-cancer pain treated with opioids revealed constipation prevalence was 46.9%, nausea 27%, vomiting 9%, and gastroesophageal reflux disease 33%. Chronic abdominal pain was reported by 58.2% and 6.4% fulfilled the criteria of narcotic bowel syndrome (NBS; Fig. 76.1). It is attributed to the effects of

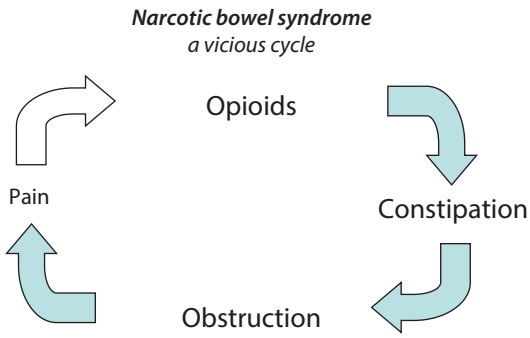

Fig. 76.1 Narcotic bowel syndrome

opioid drugs on bowel function and opioid-induced hyperalgesia [57]. Prevalence of constipation increased with duration of treatment. Health-related quality of life was low in patients with chronic abdominal pain [156]. Opioids act on gut function via all three receptor classes in the brain, spinal cord, and enteric nervous systems. Low doses act at enteric nervous system sites and higher doses also act within the CNS. These effects usually are manifest as constipation, but bloating, early satiety, and pain are possible. Occasionally, patients develop ileus or a syndrome characterized by a relatively high level of abdominal pain.

Opioids induce bowel dysfunction through several expected effects: blockade of propulsive peristalsis, inhibition of the secretion of intestinal fluids, and an increase in intestinal fluid absorption. Opioids decrease the activity of both excitatory and inhibitory neurons in the myenteric plexus. In addition, they increase smooth-muscle tone and inhibit the coordinated peristalsis required for propulsion, leading to disordered, nonpropulsive contractile activity, which contributes to nausea and vomiting as well as constipation. Longer gastrointestinal transit time causes excessive water and electrolyte reabsorption from feces, and decreased biliary and pancreatic secretion further dehydrates stool [34].

Concurrent use of other constipating drugs (e.g., tricyclic antidepressants), dehydration, advancing age, immobility, metabolic abnormalities (e.g., hypercalcemia), chemotherapy (particularly treatment with the vinca alkaloids), and tumor-related bowel obstruction may also contribute. Not all opioid formulations are equally constipating. A systematic review concluded that there is less constipation with transdermal fentanyl than with oral sustained-release morphine [146]. Combination formulation of oxycodone and naloxone may reduce opioid-related GI side effect [87].

Among methadone maintenance patients, constipation is common and tends to be worse early in treatment [93, 173] but persists long-term [65]. The high prevalence of persisting constipation suggests that tolerance to the gut effects of opioids occurs to only a limited extent. In one study, 58% of subjects in methadone maintenance experienced some degree of constipation and 10% had severe problems [181]. Fecal impaction, and even stercoral perforation, has been described [66] and usually responds to increased fluid intake and fiber supplementation to correct for poor dietary intake. Laxatives are not often required but osmotic agents such as lactulose are the laxatives of choice.

Two peripherally acting opioid-receptor antagonists are available for the management of severe opioid-induced constipation: methylnaltrexone and alvimopan. They do not cross the blood–brain barrier and have no antianalgesic effect. Methylnaltrexone was approved by the US FDA in 2008 as a subcutaneous injection for the treatment of opioid-induced constipation in patients with terminal illness requiring palliative care [149].

Randomized trials report some effectiveness for oral alvimopan in the treatment of opioid-induced constipation in patients with chronic pain [115].

76.2.4.2 Laxative Misuse

Surreptitious laxative misuse is among the more common causes for unexplained chronic diarrhea. It represents an intriguing form of substance misuse but is rare and is typically observed in patients without other substance misuse issues. These patients present to family physicians and gastroenterologists. Some are associated with bulimia. Others tend to be older women and the disorder can be viewed as a form of Munchausen's syndrome. The diagnosis rests on identification of laxatives by stool alkalinization, osmolality studies, or a bag search in the hospital [46].

76.2.4.3 Misuse of Anticholinergics

In high doses, anticholinergic drugs alter mood and are occasionally misused, particularly when prescribed to relieve extrapyramidal symptoms in the mentally ill [25] and among those with limited access to other drugs of abuse. Amitriptyline and other tricyclic antidepressant drugs are commonly misused by patients on opioid maintenance treatment [116]. Clonidine and/or buscopan prescribed for opioid withdrawal may also be misused. Patients develop marked constipation and abdominal pain as well as dry mouth and blurred vision.

76.2.5 Tobacco

Tobacco use is associated with a number or benign and malignant disorders of the gastrointestinal tract.

76.2.5.1 Gastroesophageal Reflux

Smoking has been linked to exacerbations of reflux symptoms, and cessation of smoking is one of the lifestyle changes traditionally recommended in the treatment of reflux [114]. Nicotine has been shown to reduce lower esophageal sphincter pressure and promote gastroesophageal reflux in response to straining during coughing and deep breathing [81]. At a practical level, smoking cessation is difficult to achieve and has not been shown to induce remission of reflux or healing of esophagitis. Snus is a form of smokeless tobacco commonly used in Scandinavia. A Swedish study found snus significantly alters the histology of the distal esophagus but does not impact on gastrointestinal symptoms or peptic ulcer disease [6].

Peptic Ulceration

Tobacco smoking increases the risk of both gastric and duodenal ulcers as compared with nonexposed people [113]. Smoking increases risk of ulcer according to the number of cigarettes smoked. Heavy smoking is associated with delayed ulcer healing and the risk of recurrence is increased [88, 140]. Smoking increases the risk of complications from peptic ulcer [119] and mortality [92, 128]. The mechanism by which smoking exacerbates peptic ulcer disease remains unclear.

Pancreatic Disease

Evidence from a number of countries provides a clear link between smoking and pancreatic cancer. Several studies have consistently found a moderately increased risk (about threefold) of pancreatic cancer among smokers [30, 145]. There have been inconsistent findings concerning the relationship between smoking and pancreatitis [30]. A case–control study compared tobacco use in a group with alcohol-related pancreatitis and a control group who drank at least as much alcohol yet did not develop pancreatitis and found no association with smoking [64]. A French study of 108 patients concluded that tobacco intake accelerates the course of alcohol-related chronic pancreatitis in a dose-dependent fashion with a threshold at 20 pack-years [122]. Overall, it would seem appropriate to recommend patients with alcohol-related pancreatitis to quit smoking, in addition to other risks of smoking.

76.2.5.2 Inflammatory Bowel Disease

A curious relationship exists between smoking and inflammatory bowel disease. A meta-analysis of 22 studies showed an association between current smoking and Crohn's disease (OR, 1.76; 95% confidence interval [CI], 1.40–2.22) and former smoking and ulcerative colitis (OR, 1.79; 95% CI, 1.37–2.34). Current smoking had a protective effect on the development of UC when compared with controls (OR, 0.58; 95% CI, 0.45–0.75) [99]. Smoking status is also strongly associated with microscopic collagenous and lymphocytic colitis. The risk is higher in current smokers and is not significantly affected by gender or alcohol consumption [178]. Smokers are more than twice as likely to develop Crohn's disease as nonsmokers [136]. Smoking may also increase the risk of recurrence of Crohn's disease. At least one study suggested that patients who stop smoking for more than 1 year can decrease the risk of flares [31]. Tobacco smoke appears to interfere with epithelial integrity and

immune responses to pathogenic bacteria, but research in this area is ongoing [161].

Patients with ulcerative colitis who begin smoking after the diagnosis of their disease present a significant reduction in the number of recurrences [47], and hospitalization and surgical procedure occur most frequently in heavy smokers who quit smoking before the onset of ulcerative colitis [17]. This suggests nicotine may have a therapeutic potential for this disease. Nicotine influences immune cellular function, increases mucin production, relaxes colonic smooth muscle, increases endogenous glucocorticoids, and influences rectal blood flow and intestinal permeability [148]. Less toxic approaches to this form of therapy have been sought and include topical colonic administration of nicotine. These approaches remain experimental at this time [98].

76.2.5.3 Gastrointestinal Malignancy

Smoking has been strongly linked to cancers of the upper gastrointestinal tract and pancreas as discussed above. The link between smoking and stomach cancer is weaker but is present in most studies [111, 155]. A Swedish population-based prospective cohort of 17,118 twins with up to 30 years of follow-up showed long-term heavy smoking was associated with a statistically significant threefold increased risk of colorectal cancer compared with never smoking (relative risk 3.1, 95% CI 1.4–7.1). Examining colorectal cancer subsites separately, a nonsignificant 60% increased risk of colon cancer was observed only for heavy smokers and a statistically significant fivefold increased risk was observed for rectal cancer [147]. The risk is related to total number of cigarettes smoked and the duration of smoking. Pipe and cigar smoking have a higher risk compared with cigarette smokers [49]. Interestingly, a recent meta-analysis of smokeless tobacco (snus or snuff) available in Scandinavia has shown to be not associated with cancers of the oropharynx, esophagus, stomach, and pancreas once the effects of smoking are removed [94]. Tobacco smoke contains multiple mutagenic and carcinogenic compounds including nicotine, nitrosamines, and polycyclic hydrocarbons. Mouse and cell models reveal a direct promoting action of nicotine on the growth of gastric tumor and neovascularization through sequential activation of the ERK/COX-2/VEGF signaling pathway [133]. The effects of tobacco and alcohol appear to be synergistic. Smoking increases the acetaldehyde burden following alcohol, and alcohol enhances the activation of various procarcinogens via cytochrome P450 induction.

E-Cigarettes

Electronic cigarettes or vaping has increased in popularity over the last few years, especially in the USA [95]. Adolescents tend to use more e-cigarettes compared to older adults [27]. Users of e-cigarettes tend to have more oral symptoms and broken teeth [29].

76.2.6 Body Packing

People smuggling illicit drugs may ingest large amounts of cocaine, heroin, or other drugs aiming to retrieve the packages after reaching their destination [153, 154]. This is referred to body packing, cocaine packing, or body stuffing syndrome [100]. Multiple packages made from latex condoms, wax, or plastic bags are either swallowed or placed retrogradely into rectum or vagina. The incidence of this practice is unknown. Most cases present in police custody raising ethical and potentially funding challenges of managing an involuntary patient. Some people may be coerced to smuggle drugs. Cases involving children and pregnant women have been described [153, 154]. Hospitals close to international airports may encounter these cases and should consider developing a management policy for this challenging problem. An early report describes 10 cases diagnosed only after death in which as many 147 packages were found [164]. Lethal drug absorption through rubber condoms may occur without rupture. The body packer may present with life-threatening symptoms of intoxication, including seizures and cardiorespiratory

collapse, as well as mechanical obstruction from the ingested drug packets. The distal ileum was the most common site of obstruction, whereas rupture tended to occur in the upper gastrointestinal tract [39]. The largest series comprises 61 cases from Milan, Italy, of which only two cases required laparotomy, one each for obstruction and nonfatal drug toxicity [3].

Plain X-ray is the method of choice to detect drug-filled packets within the gastrointestinal tract of body packers [70]. Dilute contrast has been reported to assist identification of the packages [54]. In some cases, CT is required, with potential concerns regarding radiation exposure if repeated examinations are needed. Extensive dose reduction makes low-dose CT a valuable alternative imaging modality for the examination of suspected body packers and might replace conventional abdominal radiographs as the first-line imaging modality [102].

Clinical monitoring comprises frequent clinical and neurological assessment and abdominal examination daily to the detected complications of acute drug intoxication or bowel obstruction or perforation. The patient should be kept in hospital until all drug packages have cleared due to the risk of life-threatening overdose if any rupture. Traub et al. [153, 154] presented a detailed review and clinical approach to management. A light solid diet with free liquids may be given. Oily or polyethylene glycol laxatives can be given repeatedly to accelerate passage of packages [73]. Symptomatic cases may require early surgery [135]. The risk of careful endoscopic removal from the esophagus is probably exaggerated, and in any case, the risk of endoscopic removal is almost certainly less than that of any other surgical approach to the esophagus. The rigid esophagoscope appears to have an advantage over the flexible instrument because of the wide lumen which will accommodate most average-sized pellets. Intact pellets in stomach and small bowel may be retrieved endoscopically or are evacuated through a single gastrotomy and/or enterotomy. Non-obstructing pellets in the colon pose an interesting dilemma. Removal through a colostomy will expose the patient to the risk of sepsis. The risk of rupture of pellets already in the colon must be very low as there are no noxious enzymes here and the pellets are subject to less turbulence within formed stool than they would be in the small intestine [39].

Methamphetamine body stuffers have similar demographics to those of body stuffers of other stimulants but tended to ingest fewer baggies with larger masses and had a higher percentage of severe outcomes (29%) than previously reported with other stimulants. Increases in presenting pulse rate and temperature (pulse rate 120 beats/min or 38.0 °C) are common in patients who will develop end-organ damage [163].

76.2.7 Psychostimulants

Gastrointestinal disorders are uncommon in patients with stimulant use. Juxtapyloric perforation has been described after the smoking of crack cocaine in 50 (95% male) consecutive patients [45]. Cocaine abuse can cause mesenteric ischemia and gangrene, which result in small and large bowel perforation as well as intraperitoneal hemorrhage [150]. This is thought to be related to cocaine-induced arterial vasospasm or vasoconstriction leading to intestinal ischemia with mucosal and transmural necrosis as well as mesenteric vascular thrombosis. The use of preoperative angiography is vital in detecting occlusive lesions that are amenable to revascularization [72]. The usual management of small or large bowel gangrene or perforation is by resection and primary anastomosis.

76.2.8 Cannabis

Cannabinoid receptors are widely expressed throughout both the upper and lower GI tract and are also expressed on hepatic stellate cells. Consequently, cannabinoids may influence a range of GI functions in health and disease [118]. Cannabinoids have been implicated in the patho-

physiology of satiety, nausea/emesis, gastrointestinal secretion, gastrointestinal motility, gastrointestinal sensation, as well as inflammation [76].

Nausea and vomiting are side effects of many chemotherapeutics and reduce the quality of life of patients with diabetes, cancer, and acquired immune deficiency syndrome. Cannabis and other cannabinoids appear to be effective antiemetics. The antiemetic effect has been demonstrated in an animal model and is related to the expression of CB1 receptors in the dorsal vagal nucleus [159]. Cannabinoids are also involved in inhibition of gastric emptying and gastric acid secretion.

The endocannabinoid system provides a potential therapeutic target for cannabis and cannabinoids and animal models have shown benefit in decreasing inflammation. A recent Cochrane review failed to show the benefit of cannabis for the treatment of Crohn's disease [80]

Cannabis use has been linked to recurrent intractable hyperemesis with associated dehydration and electrolyte abnormality [4, 137, 142]. Cannabinoid hyperemesis is often relieved by frequent hot showers [141]. The mechanism is not understood. Standard antiemetics are often ineffective. Benzodiazepines and antipsychotics have been shown to be effective in some cases [124, 168]. Capsaicin cream (typically 0.025–0.075% applied to the abdomen or back) is increasingly used in the emergency department setting, but there are no controlled trials. Side effects include heat and burning at the application site.

Key Points

- Excessive alcohol use is associated with injury to all parts of the gastrointestinal tract particularly the pancreas.
- Alcohol increases the risk of gastrointestinal cancer particularly in smokers.
- Tobacco use also leads to gastroesophageal reflux, peptic ulceration, gastrointestinal cancer, and Crohn's disease.
- Opioids have important effects on gastrointestinal secretion and motility.
- Narcotic bowel syndrome reflects a vicious cycle of pain and increasing doses.
- Cannabinoid hyperemesis syndrome is becoming more common and should be considered in cannabis users with recurrent vomiting.

Clinical Relevance

The gastrointestinal consequences of alcohol and drug use are very common but often neglected. For example, the link between even regular moderate alcohol use and colorectal cancer supports international guidelines to limit alcohol use even in the absence of an alcohol use disorder. Pancreatitis is becoming more common and is a serious, often life-threatening, disorder with the potential for debilitating chronic pain and other complications. Narcotic bowel syndrome is also growing in prevalence and is a significant clinical challenge to manage. Cannabis hyperemesis, once questioned or considered rare, is commonly seen in the emergency department, particularly in regions where cannabis use has risen as a result of regulatory changes. Diagnosis of the cause of these gastrointestinal disturbances allows for better management of their symptoms and, by linking these to the underlying substance use disorder, sets the foundation for comprehensive treatment and prevention of recurrences.

Contents

Abstract

The addiction specialist will encounter many patients with liver disease, most commonly either as a consequence of excess alcohol consumption or as a result of hepatitis C infection acquired through injection drug use. Less commonly this is due to hepatitis B infection and drug-induced liver injury due to idiosyncratic reactions to drugs of abuse. This chapter will outline the epidemiology and pathogenesis of

these individual conditions; it will then describe the investigation of liver disease and finally describe the management of chronic liver failure. The ideal pathway of care for patients with an addiction and chronic liver disease is a multidisciplinary team-based approach. The addiction specialist will help support adherence to therapy and provide prognosis for the addiction when decisions are being made about highly invasive therapies such as liver transplantation.

77.1 Introduction

77.1.1 Epidemiology of Substance-Related Liver Disease

Alcohol is the most prevalent misused substance worldwide with alcohol misuse disorders more common in men than women. Age-standardised prevalence is reducing, to a larger extent in women than in men, and there is geographical variation worldwide with alcohol misuse more common in high-income countries, compared to low-income countries. Religious beliefs, prohibiting alcohol consumption also accounts for geographical variation. Eastern Europe has the greatest age-standardised prevalence of alcohol misuse disorders with 4245.6/100,000 people, and Northern Africa and the Middle East have the lowest prevalence of 593/100,000 people [1]. Excessive alcohol use is a risk factor in over 200 diseases and injuries with the largest number of deaths related to cardiovascular diseases, traumatic injuries, gastrointestinal disease and cancer [2]. Globally, 3.3 million deaths and 139 million disability adjusted life years are attributable to excess alcohol annually [3].

The second most prevalent misused substance is opioid medication, including both prescribed medication and illicit substances such as heroin with an age-standardised prevalence 353·0 cases per 100 000 people and incidence of 26·8 million cases worldwide. Prevalence, like alcohol misuse, is higher in men than women with age-standardised prevalence reducing to a larger extent in women than in men. Geographical variation is also seen in drug misuse with the highest age-standardised prevalence in Australasia. Intravenous drug use leading to chronic hepatitis C infection (HCV), cirrhosis and hepatocellular carcinoma contributes substantially to the disease burden of drug misuse, and chronic hepatitis B (HBV) has a lesser but still significant impact [1]. Depending on the availability of needle exchange facilities and opiate substitution therapy, HCV prevalence among current and former PWID varies between 40% and 80%.

77.2 Pathophysiology of Substance Related Liver Disease

77.2.1 Alcohol-Related Liver Disease

The pathophysiology of alcohol-related liver disease is not completely understood but thought to be a combination of behavioural and environmental factors in a genetically susceptible host [4].

In low-level alcohol consumption, alcohol dehydrogenase acts within the cytosol of hepatocytes to convert ethanol to acetaldehyde, a hepatotoxic metabolite. In heavy alcohol consumption of more than 40 g of alcohol per day, cytochrome P450 2E1 (CYP2E1) in the mitochondria of hepatocytes is induced 10- to 20-fold to convert alcohol to acetaldehyde and other reactive oxidative species. This can occur after just 1 week of heavy alcohol consumption and leads to higher levels of toxic metabolite and hepatocyte damage [5].

The spectrum of alcoholic liver disease begins with steatosis, defined as fatty infiltration of the liver. Steatosis is seen in 90% of patients with heavy alcohol consumption, but only 30% develop more severe disease, in the form of alcoholic hepatitis, hepatic fibrosis, cirrhosis and hepatocellular carcinoma, indicating other factors are required to cause significant liver injury. Recognised factors include female gender, obesity, daily heavy drinking with young age of onset and some genetic differences [6] (Fig. 77.1).

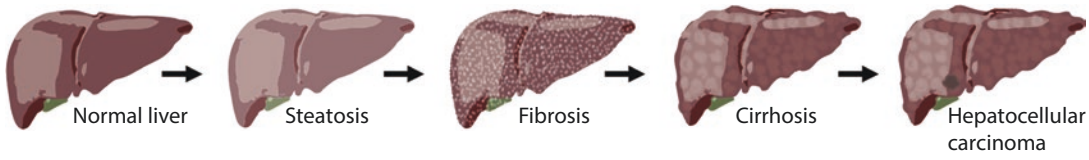

Fig. 77.1 Progression of liver disease

Accumulation of fat (triglycerides, phospholipids, and cholesterol esters) within hepatocytes occurs via three mechanisms. Hepatotoxic acetaldehyde causes reduced oxidation of fatty acids and increased lipogenesis within the hepatocyte. Outwith the hepatocyte, alcohol consumption reduces small bowel absorption of fatty acids, therefore stimulating compensatory mobilisation of fatty acids from adipose tissue and increased uptake by the liver [7]. Chronic alcohol consumption inhibits autophagy within hepatocytes, an important mechanism in the removal of fat from hepatocytes [6].

Sustained liver injury and steatosis associated with chronic heavy alcohol consumption results in fibrosis of the liver. In an attempt to heal damage, hepatic stellate cells are activated to myofibroblasts causing fibrogenesis and increased deposition of extra-cellular matrix (ECM) proteins, including collagen [8]. These cells also inhibit ECM breakdown by expressing tissue inhibitors of metalloproteinase (TIMPs). Removing the cause of liver injury (alcohol cessation) can lead to apoptosis of the hepatic stellate cells and loss of inhibition of ECM breakdown, reversing fibrosis in the liver [9].

Chronic liver injury and progressive fibrosis leads to cirrhosis. This is defined as an accumulation of ECM proteins to such an extent as to distort the liver architecture. Regenerative hepatic nodules and surrounding fibrous septa are seen, distorting hepatic vasculature, leading to portal hypertension and reduced functioning hepatocyte mass causing impaired liver function [10].

77.2.2 Drug-Related Liver Disease

Viral hepatitis C and B infections cause a similar spectrum of liver disease seen in alcohol misuse. Steatosis is less prominent except in HCV genotype 3. Acute infection with hepatitis C virus can be asymptomatic or lead to an acute hepatitis. Twenty to thirty percent of acute infections are cleared spontaneously, but the remaining 70–80% have viral persistence and progress to steatosis, fibrosis and cirrhosis. Once at the stage of advanced fibrosis or cirrhosis, 3–5% per annum develop hepatocellular carcinoma. Viral proteins are involved in the pathogenesis of all stages of liver disease. They interact with hepatic lipid metabolism causing accumulation of lipid within the liver, leading to steatosis. Viral proteins interfere with host DNA repair leading to accumulation of gene mutations, fibrosis, cirrhosis and oncogenic activation. When coexistent with the direct viral protein inhibition of tumour suppressors, hepatocellular carcinoma can develop [11].

Acute HBV infection in PWIDs is normally cleared in 90% of people, with most having a subclinical infection. Of those who develop chronic HBV infection, 40% progress to steatosis, fibrosis, cirrhosis and hepatocellular carcinoma with similar pathogenesis to HCV. There are higher rates of hepatocellular carcinoma associated with HBV than HCV, 19.2% compared to 7.2% respectively, of all cancers caused by infectious agents. Hepatitis B virus interferes with apoptosis signaling, promoting viral proliferation by increasing apoptosis and hepatocellular carcinoma progression by decreasing apoptosis [12].

77.2.3 Drug-Induced Liver Injury

Drug-induced liver injury (DILI) can be caused by prescribed medications and drugs of abuse; it is commonly mild but may on occasion be life threatening. A minority of drugs are dose-dependent liver toxins but most cause damage due to idiosyncratic reactions requiring host factors.

77.2.3.1 Cocaine

Cocaine-induced hepatotoxicity may sometimes be fatal, usually hours to a few days after an overdose, generally following or accompanying other major organ involvement (myocardial infarction, stroke, rhabdomyolysis and renal failure are the most frequent); the cause of death is generally not due only to an acute liver failure but to a multi-organ failure. Clinically, the pattern of hepatic injury is usually an acute necrosis with very high levels of serum aminotransferases and a rapid rise in prothrombin time. Most liver damage associated with cocaine is shock liver, secondary to hypotension, though DILI may occur due to conversion to a toxic metabolite as a result of P450 metabolism. The liver injury due to cocaine is self-limiting and resolves rapidly.

77.2.3.2 Ecstasy (MDMA)

Many cases of acute liver failure after ecstasy use have been reported. The clinical features may differ from acute liver failure with hyperthermia often prominent to the commonest presentation of a mild hepatitis. The mechanism of MDMA-induced hepatic damage is unclear as histological changes vary from a mild to moderate lobular hepatitis to massive hepatic parenchymal collapse with areas of nodular regeneration and cholestasis. The severity of liver failure does not seem to correlate with the amount or the frequency of ingested MDMA, suggesting an individual susceptibility for the related hepatic damage. Ecstasy users are also at increased risk of heatstroke because of the direct effect of MDMA on thermoregulation via central serotonergic nerve terminals; it is difficult to establish if ecstasy is directly hepatotoxic or if liver injury results from the hyperthermia. In acute liver failure without hyperthermia, liver damage can progress to need for liver transplantation.

77.2.3.3 Heroin, Marijuana and Amphetamines

Liver damage due to heroin, amphetamines and marijuana without co-factors is unproven, and reported cases may represent idiosyncratic liver injury.

77.2.3.4 Anabolic Steroids

Synthetic androgenic steroids are widely consumed for body building because of their anabolic effects; they can rarely cause cholestatic liver injury, and after a long-term use, they can be associated with liver tumours. The mechanism of hepatic injury is not well defined for the acute cholestatic disease, while an unregulated growth stimulus to hepatocytes is the cause of nodular regeneration and hepatic tumours.

77.3 Investigation and Staging of Liver Disease

In the patient with abnormal LFTs or physical signs of liver disease, the aim of investigation is to diagnose the aetiology and stage how advanced the disease is. Patients with hepatic steatosis or fibrosis are often asymptomatic, occassionally becoming symptomatic once steatohepatitis occurs or cirrhosis is established. Clinical signs are also sparse in steatosis or fibrosis and are mainly consistent with those related to the underlying aetiology. In alcohol-related liver disease (ARLD), these may include bilateral parotid gland hypertrophy, muscle wasting, malnutrition, Dupuytren's contracture, bilateral peripheral neuropathy and hepatomegaly [4]. In drug-related liver disease these may include evidence of drug use such as track marks or sinus formation at injection sites.

Diagnosis of the earlier stages of liver disease is commonly made incidentally on bloods or imaging requested for other reasons. A diagnosis of ARLD can be made clinically and biochemically in patients with heavy alcohol consumption after other causes of liver disease are ruled out [13]. This can be done with a careful history to assess patients' risk and an appropriate biochemical liver screen. Clinical history should include an in-depth discussion about alcohol intake behaviour; drug history, including prescribed, over-the-counter, herbal and illicit drugs, in particular any risky behaviours associated with increased risk of contracting blood-borne viruses such as HBV and HCV; travel history; occupational risk; social risk (tick bite, muscle injury, tattoos, piercings); sexual

history and any features of metabolic syndrome. A liver screen should include hepatitis B surface antigen, hepatitis C antibody, ferritin and transferrin saturation, and an autoimmune liver disease antibody screen (anti-mitochondrial antibody, anti-smooth muscle antibody, anti-nuclear antibody and serum immunoglobulin screen). α1-antitrypsin and caeruloplasmin should be tested for in young patients [14].

77.3.1 Biochemical Markers

Biochemical markers can point towards the aetiology or stage of liver disease:

- Macrocytosis is commonly seen in heavy alcohol consumption secondary to direct toxicity of alcohol on bone marrow, folate or vitamin B12 deficiency due to malnutrition or increased lipid deposition in erythrocyte membranes [15].
- Serum gamma-glutamyl transpeptidase (GGT) can be raised in heavy alcohol consumption with or without liver disease. Values 2–3 times the upper limit of normal with resolution on abstinence in 80% of cases are seen in those without liver disease. Values in those with liver disease are raised to a greater extent, 8–10 times the upper limit of normal and often remain elevated on abstinence. These values are raised disproportionately to any alkaline phosphatase (ALP) rise, with a proportionate rise in GGT and ALP more consistent with biliary disease [16]. An isolated ALP rise points to an extra-hepatic source, such as bone, intestine, kidney, placenta or white blood cells [14].
- Hepatitis of any aetiology causes raised aspartate aminotransferase (AST) and alanine aminotransferase (ALT) secondary to hepatocyte injury. These give an idea of the level of injury sustained rather than level of liver dysfunction which can be gauged by measuring albumin, prothrombin time ratio and bilirubin. ALT is more specific to liver injury as AST is also found in cardiac, skeletal and smooth muscle and can be raised secondary to damage of any of these tissues [14].
- Along with elevated aminotransferases (AST/ALT), hepatocyte inflammation reduces the livers ability to process bilirubin, causing hyperbilirubinaemia. A leucocytosis may also be seen in severe inflammation. Evidence of hepatic synthetic dysfunction can be seen at this point with hypoalbuminaeamia and coagulopathy in the form of a raised prothrombin time ratio (PTr). Coagulopathy can also be a result of dietary deficiency of vitamin K in malnourished patients, a common scenario in patients with alcohol and drug misuse [17].
- When hepatic fibrosis accumulates, leading to cirrhosis, the distorted liver architecture and abnormal pressures on vasculature cause portal hypertension. Biochemically this is seen as thrombocytopenia secondary to hypersplenism.
- Heavy alcohol consumption can also cause a pancytopenia secondary to a direct toxic effect on the bone marrow or reduced thrombopoietin production in synthetic liver dysfunction [18].

77.3.2 Imaging

Ultrasound (US), computed tomography (CT) and magnetic resonance imaging (MRI) can help determine the stage of liver disease but cannot confirm aetiology.

For initial assessment of liver disease, US is an adequate, non-invasive test that delivers no radiation. Steatosis is described as a hyperechoic echotexture with smooth outline, often with coexistent hepatomegaly. A fibrotic liver maintains the smooth outline but the echotexture becomes coarse. The smooth outline is lost in cirrhosis, replaced with a nodular outline and shrunken liver with a coarse echotexture. Associated features of cirrhosis, related to portal hypertension such as splenomegaly, varices and ascites, may also be seen. CT and MRI may be more sensitive and specific than US and are used to delineate any focal liver lesions but are not cost-effective for initial assessment [13]. The main role of imaging is to exclude other causes of LFT abnormality including biliary pathology, HCC and metastatic disease.

77.3.3 Staging of Liver Disease Using Non-invasive Fibrosis Scores

There are multiple non-invasive fibrosis scores that aim to quantify fibrosis stage, including FibroTest, NAFLD Fibrosis score, APRI and ELF. These scores were initially validated in viral hepatitis and NAFLD. Some studies have shown accuracy in distinguishing between mild and severe fibrosis in ALD, but they poorly differentiate intermediate fibrosis and are not yet validated for use in ALD [19].
