Transient elastography (TE) can be used to identify and quantify fibrosis and cirrhosis by measuring the stiffness of the liver using shear waves. Reduced shear wave velocity correlates to increased liver stiffness, and numerical cut-offs specific to aetiology relate to the level of fibrosis or cirrhosis present [20]. TE is better validated in chronic viral hepatitis and non-alcoholic fatty liver disease (NAFLD), and there are few studies relating to ALD, but they have shown accuracy when compared to liver biopsy of those with alcoholic liver disease [21]. Co-existent alcoholic hepatitis can falsely raise the liver stiffness, and therefore a period of abstinence improves diagnostic accuracy. The falsely elevated scores correlate with raised ALT or AST [22]. The EASL-ALEH guidelines recommend caution when interpreting TE in patients with ongoing heavy alcohol consumption and raised ALT or AST greater than five times the upper limit of normal, along with obesity, congestive liver, extra-hepatic cholestasis and an interquartile range larger than 30 during TE measurement [20].

77.3.4 Liver Biopsy

Although liver biopsy was previously thought to be the gold standard in diagnosis of liver disease, it is a costly and invasive procedure that does not come without risk. Inter-observer error is possible and there is a risk the small area of tissue sampled may not be representative of the organ as a whole. With the introduction of non-invasive fibrosis scores, liver biopsy should be reserved for those with complex disease, uncertain aetiology or where there is a discrepancy between the clinical picture and non-invasive scores to clarify disease staging [20].

77.4 Diagnosis of Alcohol and Drug-Related Liver Disease

A diagnosis of ALD should be suspected in patients who regularly consume excess alcohol (>20 g/day in females and > 30 g/day in men) and have clinical or biochemical evidence of liver damage. Similarly, drug related liver disease should be suspected in patients who abuse offending drugs. Other causes of liver disease should be ruled out with a careful clinical history, examination and an appropriate biochemical liver screen [19].

Diagnosis can often be difficult as many patients are asymptomatic so a high index of suspicion is imperative. In patients who are suspected to have liver disease, baseline biochemical investigation should including LFTs (ALT, AST, GGT, bilirubin, albumin), U&Es, FBC, coagulation screen and liver screen, structural imaging in the form of USS and fibrosis scoring via TE [19]. These investigations should provide enough information to diagnose aetiology and stage of liver disease along with any complications.

77.5 Clinical Management of Advanced Liver Disease

Regardless of aetiology, the patient with sufficient remaining functioning liver is termed as having compensated cirrhosis, and when they develop liver failure or a complication, they are described as having decompensated cirrhosis.

77.5.1 Compensated Cirrhosis

Although compensated liver cirrhosis may be asymptomatic, clinical signs may be evident at this stage. Along with signs visible in earlier stages of ARLD, there may be stigmata of chronic liver disease, including spider angiomata (supe-

rior vena caval distribution), gynaecomastia, testicular atrophy, palmar erythema, finger clubbing, hypertrophic osteoarthropathy and hypoalbuminaemic nail changes. The liver may be enlarged, normal or shrunken in cirrhosis with a firm, nodular edge. If portal hypertension is present, there may be signs of splenomegaly, caput medusa and hepatic fetor [13].

Along with biochemical changes seen in earlier stages, there may be evidence of hepatic synthetic dysfunction (hypoalbuminaemia and coagulopathy) and hypersplenism if portal hypertension is present (thrombocytopenia) [17].

Abstinence is the cornerstone of management at every stage of ARLD, whether the aim is to prevent fibrosis occurring in the early stages of steatosis, promote resolution of fibrosis already sustained, prevent decompensation of cirrhosis or prevent alcoholic hepatitis. The benefits of abstinence are clear, so identification of patients who drink alcohol to excess followed by a brief intervention is beneficial in reducing harm, regardless of stage of ARLD [23]. In chronic HCV at any stage of liver disease, cure of HCV with anti-viral medication should be achieved; with the locally preferred regimen, this will often be delivered in shared care models between addictions physicians and specialists in viral hepatitis [24]. Patients with chronic HBV are complex and should undergo assessment by an expert; a minority will need treatment or viral suppression therapy, and this should be supervised by an expert in the subject [25].

77.5.2 Decompensated Cirrhosis

Acute decompensated liver cirrhosis is a medical emergency and requires admission under a physician with expertise in liver disease. It occurs when a cirrhotic patient develops hepatic encephalopathy, ascites, peripheral oedema, variceal bleeding or jaundice. It can occur progressively as a chronic decompensation secondary to chronic liver insult, such as continued alcohol consumption in ARLD, or be precipitated acutely by infection (specifically spontaneous bacterial peritonitis), dehydration, constipation, medication changes, hepatocellular carcinoma or variceal bleeding.

Patients that present in a decompensated state should be investigated and treated for the above precipitating factors [26]. Abstinence from alcohol is the main factor correlating with long-term survival [27] and is important even in cirrhosis secondary to viral hepatitis. Medical management is supportive, focussing on correcting electrolyte derangement; malnutrition; alcohol or drug withdrawal; Wernicke's and hepatic encephalopathy; ascites and prevention of complications such as AKI and infection [19]. Protein malnutrition is common in severe decompensated cirrhosis and is associated with poor prognosis. The European Society for Clinical Nutrition and Metabolism recommends a daily energy and protein intake of 35–40 kcal/kg and 2–1.5 g/kg, respectively, with prompt use of nasogastric feeding when goals are not met orally [28–30]. Intravenous vitamin B complex should be administered to reduce the risk of Wernicke's encephalopathy secondary to Vitamin B1 (thiamine) deficiency [19]. The major complications of cirrhosis that define decompensation are ascites, hepatic encephalopathy, variceal bleeding as well as liver failure; a complication particular to alcohol-related aetiology is alcoholic hepatitis.

77.5.2.1 Hepatic Encephalopathy

Hepatic encephalopathy is defined as a spectrum of neurological or psychiatric abnormalities ranging from sub-clinical alterations to encephalopathic coma secondary to liver dysfunction and portosystemic shunting. Clinically it is subdivided into four grades [31].

Grade	Description
I	Trivial lack of awareness, euphoria, anxiety, shortened attention span, impairment of addition or subtraction, altered sleep rhythm
II	Lethargy, apathy, disorientation to time, obvious personality change, inappropriate behaviour, dyspraxia, asterixis
III	Somnolence to semi-stupor, responsive to stimuli, confused, gross disorientation, bizarre behaviour
IV	Coma

Ammonia is the main neurotoxin involved in the development of hepatic encephalopathy. Liver dysfunction and portosystemic shunting

reduce excretion of ammonia, which crosses the blood brain barrier and is converted into glutamine in the astrocytes, leading to astrocyte swelling and cerebral oedema [32]. The use of lactulose as first-line therapy for hepatic encephalopathy and secondary prophylaxis has been validated in many randomized controlled trials [33]. The non-absorbable disaccharide is metabolized to lactic acid by colonic bacteria with the resultant acidic intestinal environment leading to transfer of ammonia into the lumen for excretion and reducing ammonia producing colonic bacteria [34]. Clinically, increasing the dose to achieve 2–3 soft stools daily is adequate.

Rifaximin, a semi-synthetic, non-absorbable antibiotic with gut-selective, non-pathogenic antimicrobial activity can be used as an adjunct to lactulose in secondary prevention of hepatic encephalopathy by reducing the number of ammonia producing luminal bacteria [32].

77.5.2.2 Ascites

The development of ascites is the most common form of cirrhotic decompensation with a marked increase in mortality after its development (40% at 1 year, 50% at 2 years). Increased levels of vasodilators are present in cirrhotic patients with portal hypertension, causing splanchnic vasodilatation and reduced mean arterial pressure. This leads to activation of the renin-angiotensin-aldosterone system (RAAS), increased antidiuretic hormone (ADH) and increased activation of sympathetic nervous system. The RAAS retains sodium and water from the renal collecting tubules, ADH retains free water from the renal collecting tubules and sympathetic activity causes systemic/renal vasoconstriction, all in an attempt to raise circulating volume. The net effect is sodium retention and free water retention leading to accumulation of fluid in the peritoneal cavity and subcutaneous tissues (ascites and peripheral oedema, respectively) [35].

Dietary sodium restriction and diuretic therapy are the mainstays of ascites management. Potassium sparing diuretics such as spironolactone should be used initially and loop diuretics such as furosemide used adjunctively. Spironolactone can be initiated at 100 mg once daily, increasing by 100 mg daily each week to a maximum dose of 400 mg. Furosemide can be initiated at 40 mg once daily, increasing by 40 mg daily each week to a maximum dose of 160 mg. Renal function, sodium and potassium should be monitored weekly over this time [35, 36].

Patients who fail to respond to these measures, whether due to lack of drug effectiveness or development of complications (hyponatraemia, hyperkalaemia, renal dysfunction), are deemed to have refractory ascites and should be treated with large volume paracentesis and considered for liver transplantation [26]; if not suitable, TIPSS can also be considered. Refractory ascites confers a further increase in mortality to 75% at 1 year [36].

77.5.2.3 Variceal Bleeding

Variceal bleeding is the second most common presentation of cirrhotic decompensation and confers the most immediate mortality risk [26]; it presents with haematemesis and is a medical emergency requiring urgent admission. Splanchnic arteriolar vasodilatation increases portal venous inflow; distorted hepatic sinusoids and intrahepatic vasoconstriction increases resistance to portal venous outflow; the net effect being increased portal pressure. When the hepatic venous pressure gradient between the portal and hepatic veins is greater than 10 mmHg, portosystemic collaterals (varices) form in an attempt to decompress the portal venous system. The risk of bleeding depends on the portal pressure, variceal radius and wall thickness [37].

The aim of management is prevention of bleeding. Current guidelines recommend that all patients should be screened for varices at diagnosis of cirrhosis and at each decompensation. If no varices are detected, screening should be repeated every 2–3 years and annually if grade 1 varices are seen [26]. Non-selective beta-blockers (NSBB) such as propranolol and carvedilol are used as primary and secondary prophylaxis of variceal bleeding as they reduce cardiac output and splanchnic vasodilatation leading to reduced portal pressure [38–40]. Endoscopic band ligation to eradicate varices is recommended as secondary prophylaxis in combination with NSBB

after variceal bleeding has occurred due to the high mortality and 60–70% re-bleeding risk without intervention. Repeated endoscopy with variceal band ligation until no varices remain eliminates current varices but does not reduce the underlying problem of portal hypertension, leading to risk of recurrence [26].

77.5.3 Alcoholic Hepatitis

The term alcoholic hepatitis (AH) is used to describe both a histological appearance and a clinical syndrome that are not the same. Histological AH has features of fatty liver with additional necro-inflammation; it does not correlate directly with the clinical syndrome. Clinically AH is the sudden onset of jaundice in the context of sustained alcohol excess which features an inflammatory state without overt sepsis; it can occur with any degree of alcohol-related liver disease [41]. AH should be suspected in any patient developing acute onset jaundice with heavy alcohol use within the past 3–4 weeks; some patients stop or reduce drinking with the onset of the symptoms. There are often associated features of a systemic inflammatory response, decompensated cirrhosis, alcohol withdrawal and malnutrition with the differential diagnosis including sepsis and end-stage liver failure. Excluding sepsis is key, so a full sepsis workup (CXR, blood cultures, ascitic tap, urinalysis and abdominal imaging) should be carried out, as well as considering and excluding other causes of cirrhotic decompensation [42].

The severity of alcoholic hepatitis can be predicted using scoring systems such as Maddrey's discriminant function (mDF) or the Glasgow alcoholic hepatitis score (GAHS) [43]. An mDF score of more than 32 identifies severe disease and need for medical management. Untreated 1 month mortality in this group is 50%, with those scoring less than 32 (non-severe disease) having a 1 month mortality of less than 10% [19]. A GAHS score >/=9 identifies a high-mortality group.

Maddrey's Discriminant Function (mDF)

$$= [4.6\times (\text{Patient PT} - \text{Control PT})] + \text{Bilirubin}.$$

Glasgow Alcoholic Hepatitis Score (GAHS)

Score given	1	2	3
Age	<50	≥50	–
WCC (109/L)	<15	≥15	–
Urea (mmol/L)	<5	≥5	
PTr/INR	<1.5	1.5-2.0	>2.0
Bilirubin (μmol/L)	<125	125-250	>250

WCC white cell count, PTr prothrombin time ration, INR international normalised ratio

Treatment is supportive, as described for decompensated cirrhosis above. Corticosteroids are the mainstay of treatment for severe AH although conflicting evidence exists regarding their use. The STOPAH trail showed that patients with severe alcoholic hepatitis (Maddrey's discriminant function ≥32) treated with prednisolone 40 mg daily for 28 days had slightly reduced 28 day mortality, compared to those treated with placebo or pentoxifylline. Unfortunately this

reduced mortality was not seen long term with no mortality difference at 90 days and 1 year [44]. A recent Cochrane review of 16 trials looking at prednisolone versus no treatment or placebo in severe AH found no evidence of difference between these groups on all-cause mortality, health-related quality of life or serious adverse events during treatment, conceding that the level of evidence in all trials reviewed was low with high bias [45].

Both AH, cirrhosis and corticosteroid use can increase the risk of developing infection. Corticosteroids significantly increase the risk of serious infections during treatment and after treatment. If an infection is present at diagnosis of AH, a course of antibiotics prior to and during corticosteroid therapy confers a mortality advantage over an antibiotic course commencing after corticosteroids [46].

77.5.4 Hepatocellular Carcinoma

Eighty to ninety percent of hepatocellular carcinoma (HCC) occurs in cirrhotic patients, secondary to chronic inflammation and severe oxidative stress. One-third of cirrhotic patients, regardless of underlying aetiology, will develop hepatocellular carcinoma in their lifetime. The highest risk is associated with chronic viral hepatitis; chronic hepatitis B patients are at risk prior to the development of cirrhosis. Worldwide incidence of HCC is increasing with a male preponderance (M:F 2–2.5:1) [47]. There are many mechanisms through which heavy alcohol consumption can cause carcinogenesis, including acetaldehyde as a carcinogenic, upregulation of CYP2E1 increasing reactive oxygen species and immunosuppressive effects of both liver disease and excessive alcohol consumption [48].

Due to the high mortality associated with HCC, cirrhotic patients who are well enough to undergo HCC treatment should be surveyed with USS of abdomen every 6 months. If any suspicious lesions are seen, this should be followed with a CT or MRI of the liver. Depending on both degree of cirrhosis and stage of HCC, there are options for treatment and discussion of possible therapeutic options should be held at dedicated multidisciplinary meetings. Therapeutic options include liver transplant, liver resection, ablation, chemo-embolisation, systemic chemotherapy or supportive care [47].

77.5.5 Liver Transplant

Liver transplant is the only curative treatment for liver cirrhosis. With prevalence of liver cirrhosis increasing and the number of liver donors plateauing, it is important that all cirrhotic patients are effectively managed to slow the progression of cirrhosis, prevent complications that can lead to decompensation and therefore reduce the need for liver transplantation [38]. Withdrawing the insult to the liver, for example, abstinence in ARLD and anti-viral treatment in viral hepatitis, has a positive impact on both of these goals.

All patients who develop complications of their cirrhosis (ascites, variceal haemorrhage, hepato-renal syndrome and encephalopathy) should be considered for transplant assessment as the high mortality associated with liver failure outweighs the risk of liver transplantation. The model of end-stage liver disease (MELD) score predicts short-term mortality pre-transplant and is used to select patient for assessment and prioritise patients on the waiting list. It is a function of renal function, PTr, bilirubin and sodium, and all patient with a score greater or equal to 15 should be referred for liver transplant assessment [49].

Assessment for liver transplant is a complex medical, physical and psychological assessment. In alcohol-related disease, the psychological assessment is important to ascertain the risk of recurrence of alcohol misuse and is usually performed by an addictions psychiatrist. This risk is currently estimated at 15–40% and is related to length of follow-up post-liver transplant and length of abstinence pre-transplant. In the UK most transplant centres require a period of alcohol abstinence of 6 months prior to transplant assessment as this can often reduce the severity of liver disease, negating the need for transplant, and is an indication of compliance that could be expected post-transplant [49].

Key Points

1. Regardless of aetiology, the basic spectrum of liver disease is similar. This ranges from steatosis through hepatic fibrosis, cirrhosis and hepatocellular carcinoma.
2. Removing the liver insult (e.g. alcohol cessation or antiviral treatment) can allow hepatocyte regeneration and reversal of steatosis and fibrosis. Once progression to cirrhosis has occurred, reversal is not possible and removing the insult aims to maintain a compensated liver.
3. Many drugs of abuse can cause a wide range of liver disease, from mild cholestasis or hepatitis to fulminant liver failure.
4. Initial investigation should include baseline bloods (FBC, U&E, LFT, coagulation screen), US abdomen and a liver screen (hepatitis B surface antigen, hepatitis C antibody, ferritin and transferrin saturation and an autoimmune liver disease antibody screen, α1-antitrypsin and caeruloplasmin).
5. Referral to local gastroenterology services should be sought if any evidence of liver disease is found.
6. Acute decompensated liver cirrhosis (hepatic encephalopathy, ascites, peripheral oedema, variceal bleeding or jaundice) is a medical emergency and requires admission under a physician with expertise in liver disease.
7. Alcoholic hepatitis is a medical emergency, requiring admission under a physician with expertise in liver disease, and should be suspected in any patient developing acute onset jaundice with heavy alcohol use within the past 3–4 weeks.
8. Hepatocellular carcinoma incidence is high in cirrhotic patients, with high mortality. Six monthly screening aims to reduce this by allowing early detection and treatment.
9. Liver transplant is the only curative therapy for liver cirrhosis and should be considered in all patients who have decompensated cirrhosis. Six months abstinence from alcohol is required for assessment of patients with alcohol-related liver disease.

Clinical Relevance

High morbidity and mortality are attributed to both alcohol and drug misuse with a large proportion of this related to liver disease which can often be asymptomatic. This necessitates a high level of suspicion at every clinical consultation. If liver disease is diagnosed prior to the development of cirrhosis, cessation of alcohol and drug misuse can have a greater impact on the disease course and reduce morbidity and mortality. As many patients that are at risk of liver disease secondary to alcohol and drug misuse are users of addiction medicine services, it is important that the investigation, diagnosis, treatment and prognosis of these conditions are understood so that appropriate referral to gastroenterology services can be sought.

Abstract

The kidneys receive approximately 25% of cardiac output and are highly exposed to the influence of drugs of addiction. While many drugs have long been known to cause kidney injury or other metabolic derangements, such as electrolyte and acid-base disorders, the mechanism and the longer-term implications of many drug-induced kidney diseases often remain poorly understood. However, both drug-induced kidney injury and pre-existing kidney disease are frequently encountered in primary care, acute medicine and critical care and when treating people with a history of drug use or addiction. Here, we define the classification and presentation of renal disease before describing the wide spectrum of renal disease associated with drugs of addiction. Both direct nephrotoxicity and indirect injury stemming from injecting drug use, such as the renal complications of blood-borne viruses, are reviewed. In addition, the interaction between drug use and chronic kidney disease and renal replacement therapy is briefly considered. Finally, we describe the spectrum of electrolyte and acid-base derangements associated with drug use.

Keywords

Acute kidney injury · Chronic kidney disease
Nephrotoxicity · Rhabdomyolysis
Blood-borne virus · Electrolyte disorders

Abbreviations

AIN	Acute interstitial nephritis
AKI	Acute kidney injury
ANCA	Anti-neutrophil cytoplasmic antibody
ATN	Acute tubular necrosis
AVP	Argenine vasopressin
CHS	Cannabis hyperemesis syndrome
CK	Creatine kinase
CKD	Chronic kidney disease
DAA	Direct acting antivirals
eGFR	Estimated glomerular filtration rate
ESKD	End-stage kidney disease
FSGS	Focal sclerosing glomerulonephritis
GIT	Gastrointestinal tract
GN	Glomerulonephritis
HAART	Highly active anti-retroviral therapy
HAN	Heroin associated nephropathy
HBV	Hepatitis B virus
HCV	Hepatitis C virus
HIV	Human immunodeficiency virus
HIVAN	HIV associated nephropathy
HIVICK	HIV-immune complex kidney disease
IVDU	Intravenous drug use
KDIGO	Kidney disease: Improving Global Outcomes
MDMA	3,4-Methylenedioxymethamphetamine
MPGN	Mesangioproliferative glomerulonephritis
NSAIDs	Non-steroidal anti-inflammatories
ODS	Osmotic demyelination syndrome
PrEP	Pre-exposure prophylaxis
RTA	Renal tubular acidosis
SIADH	Syndrome of inappropriate secretion of ADH

78.1 Introduction

The relationship between drug use and renal disease is frequently indirect. Drug-associated behaviour or injuries may lead to nephrotoxicity (as in rhabdomyolysis following a prolonged lie after a drug overdose), blood-borne infections or their treatment may result in kidney disease (as in the glomerular diseases associated with hepatitis C or the renal tubular toxicity of some highly active antiretrovirals (HAART)) or other pathologies owing to drug use may cause secondary renal disease (as in hepatorenal syndrome following alcohol-related cirrhosis or hypertensive kidney disease in the context of excess alcohol intake). Finally, the continued development of novel drugs of abuse (‘designer drugs’) results in an ever evolving field as many of these agents can be associated with unpredictable nephrotoxicity.

78.2 Classification and Assessment of Renal Disease

The kidneys perform a wide variety of functions: clearance of toxins (including drugs and their metabolites) and waste products of metabolism; maintenance of acid-base and electrolyte homeostasis; and regulation of blood pressure, sodium and water balance and hormonal functions involving bone and mineral metabolism and haematopoiesis. Of these, it is the first that is most typically recognised via the measurement of serum urea and creatinine, but it is useful to recognise that derangement of all of the normal functions of the kidney frequently coexist and may have implications for clinical management.

Recognition of renal disease frequently begins with the finding of abnormalities in serum creatinine and its derived parameter – estimated glomerular filtration rate (eGFR). Creatinine originates in muscle and is excreted via both glomerular filtration and direct tubular secretion. Consequently, the amount in serum is dependent on muscle mass relative to overall body size. The equations utilised to calculate eGFR are based on population averages with the result that people at the extremes of body habitus may have renal function that deviates substantially from that provided by eGFR. Alternative equations such as the Cockroft-Gault may be useful in determining whether eGFR is over- or underestimating true glomerular filtration.

Acute kidney injury (AKI) is a rapid decline in renal function defined by a rise in serum creatinine and/or a reduction in urine output. Various classification schemes are in use, but from a practical standpoint, it suffices to understand that the risk of life-threatening complications and need for transfer to a facility with the ability to provide urgent dialysis increases along with the magnitude of rise in creatinine and the extent of the reduction in urine output. Chronic kidney disease (CKD) is the presence of a sustained, and typically permanent, reduction in renal function or the presence of persistent abnormalities of urine sediment (i.e., proteinuria or microscopic haematuria). Both acute and chronic kidney injury can be approached by considering the primary site of pathology within the renal parenchyma. Broadly, kidney diseases may be glomerular (e.g., glomerulonephritis), tubular (i.e., affecting the cells lining the tubules of the nephrons) or interstitial (e.g., acute or chronic interstitial nephritis). To this must be added renal pathology resulting from insufficient renal perfusion (i.e., pre-renal) or obstruction to urine outflow (i.e., post-renal).

In addition to a thorough history and examination (including blood pressure and fluid status), the assessment of an individual with an elevated creatinine involves testing for the presence of haematuria and proteinuria (with quantification most simply achieved with a spot urine albumin/creatinine or protein/creatinine ratio) and exclusion of important derangement of electrolytes and acid-base balance. Radiological imaging to exclude hydronephrosis or an unexpected anatomical abnormality is also often warranted. The results of these tests will help to refine the differential diagnosis and direct further testing and management.

78.3 Acute Kidney Injury

78.3.1 Overview

The causes of AKI are manifold but may be loosely categorised as pre-renal, intra-renal and post-renal. This schema aids in assessing patients with AKI by directing the history and clinical examination (Table 78.1).

78.3.2 Pre-renal AKI

Hypotension or hypovolaemia triggers neurohormonal reflex constriction of renal efferent glomerular arterioles. This acts to maintain glomerular filtration rate despite reduced renal blood flow. However, this autoregulatory mech-

Table 78.1 Drugs of abuse and renal pathology

Pattern of renal injury	Substance use association
Pre-renal AKI in the setting of cardiogenic shock, hypovolaemia, multi-organ failure or septic shock. May lead to acute tubular necrosis if prolonged or severe	Any severe overdose including acute alcohol poisoning
	Hepatorenal syndrome in the context of alcohol-induced cirrhosis
	Severe bacterial infection (e.g., associated with intravenous drug use, chronic alcohol abuse and malnutrition)
	Dehydration in the context of stimulant-induced exertion
Rhabdomyolysis resulting in acute tubular necrosis	Overdose resulting in long lie and pressure injury (alcohol, opioids)
	Stimulant-induced exertion (amphetamines, MDMA, cocaine, 'bath salts', PCP, 'herbal ecstasy')
	Hyperthermia, serotonin syndrome, seizures (amphetamines, MDMA, other stimulants)
Malignant hypertension	Cocaine, MDMA, amphetamines, chronic alcohol abuse
Renal vasoconstriction and renal infarction	Cocaine, methamphetamine
Acute interstitial nephritis	NSAIDs, cocaine, amphetamines, 'herbal' ecstasy, synthetic cannabinoids
Acute tubular necrosis (unrelated to rhabdomyolysis or pre-renal AKI)	NSAIDs, synthetic cannabinoids
Renal complications of intravascular infection (e.g., immune-complex-mediated glomerulonephritis secondary to bacterial endocarditis)	Any intravenous drug use
Blood-borne viruses with renal consequences	
HCV-related cryoglobulinemia	
HBV-related minimal change disease, membranous or mesangiocapillary glomerulonephritis	
HIV-related nephropathies	
Amyloid-A amyloidosis from chronic infection and inflammation	
Vasculitis (including anti-glomerular basement antibody disease) causing acute glomerulonephritis	Cocaine
Chronic glomerulonephritis	Heroin
Renal consequences of cirrhosis Hepatorenal syndrome IgA nephritis	Alcohol, viral hepatitis due to intravenous drug use
Obstructive uropathy	Chronic ketamine use, (rarely) MDMA, lithogenic antiretrovirals, NSAID-induced renal tubular acidosis causing nephrolithiasis

anism may be insufficient in the face of severe or prolonged hypotension or in the presence of nephrotoxins, inflammatory mediators or drugs that interfere with intrarenal signalling (e.g., non-steroidal anti-inflammatories [NSAIDs]). In these cases, pre-renal AKI may progress to acute tubular necrosis (a form of intra-renal AKI) resulting in a more prolonged and potentially incomplete recovery. Pre-renal AKI is a frequent contributor to drug-associated renal injury.

78.3.3 Intra-renal AKI

Any AKI that is not reversible by restoration of poor renal perfusion or urinary outflow is termed intra-renal. The causes of intra-renal AKI can be practically subdivided by common histo- and pathophysiologies into glomerulonephritis (typically autoimmune), acute tubular necrosis (typically due to toxins or a severe pre-renal insult) and tubulointerstitial nephritis (typically drug-induced). In some cases, for instance, bacterial

endocarditis, all of these causes may be possible diagnoses for a single patient.

78.3.4 Post-renal AKI

Obstruction of the ureters or bladder outflow tract should be considered in all cases of AKI and can be rapidly identified with renal ultrasonography or computed tomography. Although rarely related to drug abuse, a number of uncommon associations do exist. These include urinary retention due to MDMA; renal calculi due to protease inhibitors indinavir, atazanavir and darunavir [48]; and calcium calculi in the presence of renal tubular acidosis due to non-steroidal inflammatory (NSAID) use. In addition, around one-third of chronic ketamine users have urological disorders, ranging from haematuria and urinary frequency to ureteral strictures, hydronephrosis and papillary necrosis. Severe cases have resulted in the need for surgical ureteric diversion [65].

78.3.5 Management of AKI

While pre-renal or intra-renal acute tubular necrosis is most common, the clinician should be alert to signs or symptoms suggestive of systemic autoimmune disease, unexplained pulmonary and renal disease (e.g., as seen in ANCA vasculitis or anti-glomerular basement membrane disease), infection or urinary tract obstruction, which might point to other forms of renal injury. A thorough drug and medication history is essential. Analysis of urine sediment is also essential; although moderate amounts of blood and protein may be present in acute tubular necrosis, the presence of a significant degree of proteinuria and/or microscopic haematuria should prompt consideration of glomerulonephritis (see below). Pre-renal AKI is associated with a bland urine sediment and urinary sodium concentration <20 mmol/l. If acute tubular necrosis has developed then granular casts may be present, these may be pigmented if rhabdomyolysis is present. In most instances, the treatment of AKI is purely supportive and is focused on restoring intravascular volume and managing concurrent electrolyte or acid-base disorders. Treatment of severe hypertension or hyperthermia may also be required. Monitoring of urine output (with or without use of a urinary catheter) is also important as oliguric renal injury has a worse prognosis. The presence of oliguria (<30 ml/h) and/or severe acidosis, derangement of electrolytes or elevation of creatinine should prompt transfer to a unit capable of providing acute dialysis. In such cases, it is also imperative that intravenous fluid administration is carefully monitored given the risks of iatrogenic fluid overload.

78.3.6 Drug-Specific Associations with AKI

78.3.6.1 Alcohol

AKI in the context of acute alcohol intoxication is likely to be pre-renal. Alcohol causes the suppression of pituitary secretion of vasopressin, leading to diuresis and risk of hypovolaemia [29], which is often compounded by fluid loss from vomiting. In the presence of drugs that impair renal autoregulation (such as NSAID or cocaine) or nephrotoxins (as occurs in rhabdomyolysis), intra-renal injury may occur and the presence of such exacerbating factors should always be considered [74, 96]. There is also evidence of alcohol causing direct muscular toxicity [92] contributing to the development of rhabdomyolysis, either isolated or in combination with immobility, the mechanism of which is not fully understood, although oxidative stress, mitochondrial dysfunction and inflammation are thought to be contributing factors [46, 99].

78.3.6.2 Cocaine

The classic form of cocaine-associated renal injury is renal infarction resulting from intense renal vasoconstriction. In addition to vasoactive properties, cocaine also upregulates vascular endothelin-1 receptors, causing decreased renal perfusion and which in severe cases may manifest as intravascular thrombosis within small renal arterioles (known as thrombotic microangiopathy) [8, 49, 59, 109]. The presentation may be

marked by severe hypertension, although this is not universal [68]. The risks of co-ingestion of other drugs with renal vasoactive properties (including NSAIDs) cannot be underestimated in this setting. Other precipitating factors may include dehydration caused by poor oral intake combined with excessive physical activity and high heat environments [13], rhabdomyolysis (which may also be exacerbated by hyperthermia and impaired thermoregulation) [30, 109] and concurrent alcohol abuse [68]. Cocaine-associated acute interstitial nephritis has also been reported, although this appears to be rare, and it remains unclear if these instances were due to the drug or to contaminants (especially when used in the form of crack cocaine) [2, 6, 39].

78.3.6.3 Amphetamines and Other Stimulants

Like alcohol and cocaine, amphetamine derivatives are associated with pre-renal AKI owing to dehydration following exertion at dance parties and may be compounded by toxicity from non-traumatic rhabdomyolysis. Acute tubular necrosis and renal infarction have been described and are believed to be due to vasoconstriction and malignant hypertension. Post-renal AKI due to bladder outlet obstruction following MDMA has also been reported, although the precise mechanism of anti-cholinergic and/or alpha-adrenergic stimulation responsible for this is not clear [12, 15]. Rarely, like cocaine, MDMA has also been associated with thrombotic microangiopathy [53]. In addition to renal pathology, MDMA is also associated with severe and sometimes fatal hyponatraemia (discussed in detail at the end of this chapter). Serotonin syndrome is a potentially lethal complication of MDMA and especially of derivatives such as PMMA, characterised by malignant hyperthermia, rhabdomyolysis and acute kidney injury [76]. With the emergence of novel synthetic compounds – particularly stimulants such as synthetic cathinones (e.g., 'bath salts') and phenylpiperazine derivatives (e.g., 'herbal ecstasy') – a variety of types of AKI have been reported. Most instances represent pre-renal AKI and/or rhabdomyolysis, and the renal pathology is hypothesised to be similar to that associated with MDMA or cocaine, given the structural and pharmacological similarities [82, 83]. Finally, rare cases of acute interstitial nephritis (a type 4 hypersensitivity reaction) have been reported with amphetamines and with phenylpiperazine derivatives (e.g., 'herbal ecstasy') [35, 65].

78.3.6.4 Opioids

Heroin is most commonly associated with renal injury due to various forms of glomerulonephritis, which are discussed elsewhere in this text. However, heroin and other opioids have also been associated with rhabdomyolysis secondary to prolonged immobility in overdose or local necrosis caused by intravenous drug use (IVDU) [42, 77, 87]. More recently, a form of crystal nephropathy caused by precipitation of heroin or its metabolites in tubules in association with volume depletion and elevated urinary pH has also been reported [7].

78.3.6.5 Cannabis and Synthetic Cannabinoids

Although cannabis and the active substance (delta-9 tetrahydrocannabinol) do not appear to be nephrotoxic, cannabis hyperemesis syndrome caused by chronic cannabis may cause hypovolaemia leading to pre-renal AKI [43]. A related issue however is the relatively recent rise in cases of AKI associated with synthetic cannabinoids (e.g., 'Spice'). Synthetic cannabinoids consist of a variety of chemicals, both related and unrelated chemically to natural cannabinoids. These mixtures can stimulate both CB1 and CB2 receptors, which may play a part in the increased incidence of AKI [18]. Renal biopsies have most commonly demonstrated ATN as causative process, although AIN has also been seen [65, 107].

78.3.7 Rhabdomyolysis

Rhabdomyolysis is a common form of indirect renal injury, and this can arise from significant drug use, including acute alcohol poisoning, cocaine, MDMA and narcotic use and overdose

(prolonged immobilisation). Novel synthetic drugs have also been associated with rhabdomyolysis, including phenylpiperazine derivatives, synthetic cathinones and phencyclidine [65]. It is of particular concern in the setting of dehydration, hyperthermia and drug toxicity from MDMA used in dance settings. The specific pathophysiological abnormalities include direct tubular toxicity from myoglobin metabolites such as ferrihemate, vasoconstriction induced by these agents, and lipid peroxidation. Myoglobin casts can also form, leading to tubular obstruction. The diagnosis of rhabdomyolysis is confirmed by elevated levels of creatine kinase (CK) in the circulation. For AKI to occur, generally high CK levels (>15,000 U/l) are required except when the rhabdomyolysis is accompanied by acidosis, dehydration and/or sepsis.

Treatment involves fluid resuscitation and restoration of electrolyte disturbances. Recommended practice includes aggressive IV hydration to achieve a target urine output of at least 300 ml/h, with administration of alkali to establish urine pH > 6.5 [24]. A small randomised trial (n = 28) in doxylamine-induced rhabdomyolysis suggests that hydration with balanced crystalloid (e.g., Ringer's lactate) results in higher urine pH than 0.9% saline, although no differences in patient outcomes were identified [26]. A larger trial (n = 98), also in doxylamine-induced rhabdomyolysis, found lower CK levels at 6 h in participants treated with sodium bicarbonate containing fluid than in those treated with 0.9% saline [56]. No differences in renal outcomes were observed. The importance of these results is not clear. The principle underlying alkalinisation is not to reduce serum CK levels, but to prevent acute kidney injury. In practice, treatment intensity should be matched to the severity of rhabdomyolysis and of concomitant acute illness, with recognition that risk of AKI is greatest in the presence of dehydration and oliguria.

78.3.8 Hepatorenal Syndrome

Hepatorenal syndrome is a well-described and often terminal complication of cirrhosis of all causes. It is almost invariably associated with portal hypertension and the pathophysiology is linked to profound renal vasoconstriction in response to intense neurohormonal stimulation, including activation of the renin-angiotensin-aldosterone system. Additional pathological pathways may also contribute, including systemic inflammation and bile-salt-induced tubular damage [3]. Hepatorenal syndrome is classified as type 1, defined by rapidly progressing acute kidney and poor prognosis, and type 2, when renal deterioration is slower in onset and associated with ascites; the prognosis is still poor although survival is typically longer (months rather than weeks). Treatment of type 1 disease involves treatment of any precipitants, such as dehydration or over-diuresis, active upper GIT bleeding or bacterial peritonitis and albumin replacement and terlipressin, a vasopressin analogue. The addition of terlipressin significantly improves survival and transplant-free time, although mortality rates still average 45% [103].

78.4 Glomerulonephritis Associated with Drug Use

A variety of diseases associated with drug use specifically affect the glomeruli, causing glomerulonephritis. It is important to distinguish these cases from more common causes of renal injury as their prognosis and management can be distinct.

78.4.1 Diagnosis of Glomerulonephritis

The hallmark of glomerular disease is proteinuria – i.e., the excretion of greater than 300 mg/day of urinary protein (loosely approximated by a spot urinary protein-creatinine rate of 30 mg/mmol or 30 mg/g). Microscopic haematuria may also occur with some, but not all, causes of glomerulonephritis. In addition to quantitation of urinary protein excretion, analysis of urine sediment for casts (especially red cell casts – which are highly specific for glomerulonephritis) and

Table 78.2 Glomerulonephritis

	Nephritic	Nephrotic
Urine protein excretion	<3.5 g/day	>3.5 g/day
Microscopic haematuria	Present	Absent
Serum albumin	Normal	Low
Oedema	Mild or absent	Marked
Hypertension	Present	Absent
Reduced eGFR	Present	Absent

dysmorphic red cells will aid in the diagnosis. Note that common causes of chronic kidney disease which may coexist with drug use, notably diabetic nephropathy and, to a lesser degree, hypertensive or atherosclerotic nephropathy, may also exhibit proteinuria.

Glomerulonephritis is classically described as either nephritic or nephrotic (Table 78.2). Nephritic presentations are characterised by acute deteriorations in renal function, hypertension and microscopic haematuria with moderate proteinuria. Such presentations are classically associated with aggressive pathologies such as renal vasculitis, which if not treated can rapidly progress to end-stage kidney disease. Nephrotic presentations (classically, nephrotic syndrome) is defined by marked proteinuria and often dramatic reductions in serum albumin, with no or only mild reduction in renal function. While recognising these different presentations is useful to narrow the differential diagnosis, many patients will exhibit features of both syndromes, particularly in the presence of comorbidities such as chronic liver disease or malnutrition.

78.4.2 Rapidly Progressing Glomerulonephritis

Nephritic syndrome accompanied by a rapid decline in renal function requires urgent investigation and management. Typical causes include anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitis and systemic lupus erythematosus; however rare presentations are related to drug use. Anti-glomerular basement membrane disease (Goodpasture's disease), a nephritic syndrome presenting with a rapidly rising creatinine, acute pulmonary haemorrhage, haemoptysis and pulmonary oedema has been associated with intranasal and smoked 'crack' cocaine use [79]. The pathophysiology of this 'pulmonary-renal' syndrome is thought to result from exposure of alveolar basement membrane due to pulmonary injury and the formation of antibodies to type IV collagen, which is also found in the glomerular basement membrane. Renal biopsy is essential as serum anti-glomerular basement antibodies have been reported in 'crack' cocaine users with unrelated renal pathology [71]. Treatment with haemodialysis and immunosuppression or plasmapheresis is usually indicated for the specific treatment of uremia and for decreasing the circulating antibody. Cocaine adulterated with levamisole (which contaminates up to 70% of cocaine samples in the USA) has been associated with antineutrophic cytoplasmic antibody (ANCA)-positive vasculitis, which may present with skin purpura and deteriorating renal function [50]. It can result in severe renal failure requiring dialysis and require treatment with immunosuppression. Glomerular diseases associated with blood-borne viruses may be indirectly associated with drug use, and screening for HBV, HCV and HIV should be performed in all cases of rapidly progressing glomerulonephritis. These diseases are discussed specifically below under the heading of 'Blood-borne viruses in drug users and renal consequences'.

78.4.3 Glomerular Disease Associated with Bacterial Infection

Drug use is a common contributor to intravascular bacterial infection, either via bacterial seeding from intravenous injection or nasal disruption from nasal inhalation [58]. Renal dysfunction in this setting occurs in 35–45% of patients and can arise for a variety of reasons [85]. The primary differentials are acute tubular necrosis due to sepsis (or less commonly directly caused by high-dose penicillins, glycopeptide or aminoglycoside antibiotics [72], antibiotic-induced acute interstitial nephritis or immune-complex-mediated glomerulonephritis. Intravascular infections, e.g.,

endocarditis, can also cause renal impairment from infectious vasculitis with mycotic involvement (bacterial microabcesses) as well as necrotising segmental infarction from septic emboli. The time course of the deterioration in renal function and the presence or absence of proteinuria, microscopic haematuria and other features of nephritic syndrome aid in narrowing the diagnosis.

Less common complications of infection include AA amyloidosis which may affect the drug user with recurrent infection and presents with nephrotic range proteinuria, with or without the complete nephrotic syndrome [67]. Rare cases of ANCA-positive renal vasculitis have also been reported and present significant therapeutic challenge [23]. Increasingly, chronic staphylococcal infections (including endocarditis) associated with glomerulonephritis with IgA deposition are increasingly identified in older individuals with predisposing conditions such as cirrhosis, hepatitis C and, especially, diabetes [22, 66, 89]. The presentation of immune-complex-mediated glomerulonephritis is most usually nephritic syndrome (hypertension and haematuria), but in a minority of cases, it can be nephrotic with normal blood pressure.

Treatment of immune-complex-mediated glomerular disease in the setting of infection is directed at control of the infection, supportive care including dialysis if the renal impairment is severe and, if interstitial nephritis is suspected or confirmed, variation in antibiotic use. Renal biopsies are performed if diagnosis of acute interstitial nephritis is required to change the antibiotic choice or if the presentation is atypical or associated with nephrotic syndrome or rapidly progressive disease.

78.4.4 Nephrotic Syndromes

The most common lesion associated with nephrotic syndrome in those with a history of drug abuse is focal sclerosing glomerulosclerosis (FSGS). Historically linked to heroin use (termed heroin-associated nephropathy (HAN)), FSGS was thought to be due to contaminants (bacterial or viral) or poor-quality heroin or morphine as the incidence of these has declined in the era of proven blood-borne virus-related nephropathy. The striking association with FSGS, end-stage kidney disease (ESKD) and African-American ancestry was subsequently linked to the high prevalence (over 40%) of APOL1 variants in this population [60]. It is hypothesised that intravenous drug use provides a 'second hit' to those with underlying susceptibility to renal injury. Similarly, classic human immunodeficiency virus (HIV)-associated nephropathy (HIVAN), which is also disproportionately observed in African Americans and also presents with FSGS, is thought to similarly reflect this predisposing factor.

FSGS is only the most common of a variety of renal lesions found in drug users, which also includes minimal change disease, MPGN, mesangial proliferation, dysproteinemias and diabetic nephropathy, which presumably may, at times, be coincidental to the history of drug use. In a large post-mortem cohort of German drug users, hypertensive-ischemic nephropathy was identified as the most common renal histopathological abnormality, highlighting the importance of comorbid cardiovascular disease and hypertension in this group [16]. In this study, heavy IVDU was associated with interstitial inflammation and calcification, whereas cocaine abuse was strongly associated with hypertensive-ischemic changes. Anabolic steroid use is also associated with glomerular pathology, with case reports and one case series indicating that chronic use of these agents can result in variable degrees of proteinuria and impaired renal function. Biopsy reports indicate focal sclerosing glomerular sclerosis as the underlying pathology. The role of high protein intake–induced glomerular hyperfiltration is also likely to play an important role and the relative contribution of steroids alone is not clear [80].

78.4.5 Cirrhosis-Associated IgA Nephropathy

IgA disease (deposition of IgA in the mesangium of the glomerulus) can arise in the setting

of alcoholic cirrhosis, and IgA deposition is detected in up to 64% of autopsies from chronic alcoholics [90, 95]. Intriguingly, as in primary IgA nephropathy, circulating IgA molecules in cirrhotic patients display abnormal glycosylation, but the pattern of abnormal glycosylation appears distinct. While frequently of little clinical consequence, this secondary form of IgA nephropathy can result in proteinuria, haematuria and chronic kidney disease [93]. Case reports of nephrotic syndrome due to IgA deposition also exist [94]. Increased serum IgA levels in cirrhosis are thought to be due to increased production from intestinal lymphocytes as well as impaired hepatic clearance and porto-systemic shunting [31].

78.4.6 BBV in Drug Users and Renal Consequences

78.4.6.1 Hepatitis B

Hepatitis B is associated with membranous nephropathy and mesangiocapillary pattern (membranoproliferative) glomerulonephritis, the former presenting as nephrotic syndrome (more commonly in infected children) and the latter as nephritic syndrome with progressive renal failure if left untreated. Males are more likely to be affected. Other rarer manifestations are minimal change nephropathy (nephrotic syndrome) and polyarteritis nodosa (an aggressive form of glomerular disease associated with progressive renal damage). These are widely thought to represent a spectrum of immune disease ranging from in situ immune reactions to hepatitis antigens present in various components of the glomerulus (membrane and subepithelial locations) to the deposition of immune complexes arising from the chronic antigenemia in the circulation [101].

Treatment strategies in hepatitis B-related GN have been revolutionised by the use of effective antiviral therapies, which are associated with much higher rates of remission of renal disease than seen with supportive therapy alone [63, 102]. The role of adjunctive immunosuppressive therapy remains unclear. Meta-analysis (including 1 RCT and 11 non-randomised studies) suggests that the addition of immunosuppression (predominantly corticosteroids with an antiproliferative (mycophenolate or leflunomide)) to antiviral treatment results in more rapid remission of proteinuria without additional risk [108]. It is also important to note that antibodies to phospholipase-A2 receptor (PLA2R), often considered as synonymous with ‘idiopathic’ membranous GN, may also be common in patients with HBV-associated membranous GN [106]. It is not known if this identifies a subgroup more likely to benefit from immunosuppression, although successful use of rituximab has been reported [9].

78.4.6.2 Hepatitis C

Hepatitis C can be associated with cryoglobulinemic renal disease, which causes a membranoproliferative GN and can rapidly progress to irreversible renal injury. Presentation may include extra-renal manifestations such as purpura in the distal limbs, arthralgia and neurological symptoms [20]. Management of HCV-associated cryoglobulinemic glomerulonephritis is changing in the era of directly acting antivirals (DAA). Previous treatment frequently included immunosuppression with glucocorticoids and rituximab with consideration of plasmapheresis. However, provision of DAA now allows use of immunosuppression to be restricted to cases of severe vasculitis [86]. Less common associations of HCV are membranous nephropathy, fibrillary glomerulopathy, immunotactoid glomerulopathy and IgA nephropathy [63].

78.4.6.3 HIV

HIV is associated with a wide variety of renal pathology. Classic HIV-associated nephropathy (HIVAN) is a podocytopathy resulting in focal segmental glomerulosclerosis (FSGS), nephrotic syndrome and eventual progression to ESKD [63]. Some population subgroups, notably African-Americans, are at much greater risk for nephropathy in the presence of HIV infection. This appears to be mediated by a higher prevalence of APOL1 gene variants that increase the risk of FSGS. Fortunately, suppression of viremia with HAART is associated with slower pro-

gression of renal disease and a lower likelihood of reaching ESKD [70].

HIV immune complex kidney disease (HIVICK) is a separate entity to HIVAN and results in nephritic syndrome with proliferative GN and extensive immune activity ('full house' immunofluorescence staining for IgM, IgG, IgA, C3 and C1q) on biopsy [63]. Other renal pathologies associated with HIV include IgA nephropathy, membranous GN, immunotactoid GN, interstitial nephritis and amyloidosis, which highlights the importance of renal biopsy in patients with HIV and renal disease [64]. In general, treatment consists of HAART with additional therapies (including immunosuppression) guided by usual practice in the non-HIV population.

HIV-infected individuals have higher rate of chronic kidney disease, not only due to glomerulopathies described above but also likely due to chronic inflammation and exposure to the metabolic and nephrotoxic effects of HAART. In particular, tenofovir is associated with renal tubular toxicity manifesting as proteinuria, phosphaturia, glycosuria and variable degrees of reduction in renal function [44]. It should also be noted that a number of antiretrovirals (tenofovir, rilpirivine, dolutegravir and the boosting agent cobicistat) inhibit renal tubular creatinine secretion, which results in a persistent but reversible elevation of serum creatinine without underlying renal toxicity [44, 64]. The use of tenofovir in patients who have, or who develop, CKD is controversial, with studies conflicting as to the risk of further loss of renal function with tenofovir. It is suggested that tenofovir is best avoided in patients with an eGFR <60 ml/min/1.73 m^2, but that it may be used when other agents are not available, provided renal function is appropriately monitored [64]. The potential for renal toxicity from tenofovir should also be considered when using pre-exposure prophylaxis (PrEP). While the reductions in renal function identified are modest (and of uncertain clinical significance), they are greater in those with baseline impairment or renal function or older age [38].

78.5 Chronic Kidney Disease Associated with Drug Use

78.5.1 Classification

Chronic kidney disease (CKD) affects up to 1 in 10 individuals globally and a growing contributor to morbidity and mortality.It is defined as an estimated glomerular filtration rate (eGFR) < 60 ml/min/1.73 m^2 or by the presence of proteinuria (regardless of eGFR). The risk of progression is related to the degree of reduction in eGFR and degree of proteinuria, which can be used to define stages of CKD (see Fig. 78.1).

78.5.2 Approach to Chronic Kidney Disease in the Drug User

Use of illicit drugs is a risk factor for chronic kidney disease, which likely reflects the co-incidence of multiple renal risks, including infection with HIV or HCV and nephrotoxicity from drug abuse or from complications such as bacterial infection [17, 69]. More broadly, some authors hypothesise that drug addiction results in the premature appearance of diseases associated with ageing, such as cardiovascular disease and chronic kidney disease [5]. Whether this reflects a fundamental shift towards physiological stressors (e.g., oxidative stress, inflammation and mitochondrial dysfunction) or is more simply understood as the result of the presence of multiple risk factors such as cigarette smoking, alcohol-driven hypertension and metabolic disturbances and repeated infections or inflammatory insults is not clear. Alcohol may indirectly affect renal function by means of chronic hypertension and via its contribution to increased caloric intake, obesity and thus risk of diabetes mellitus. However, these relationships are complex. At a population level, moderate levels of alcohol use have been associated with both worse and better renal function [57, 78], and a recent meta-analysis suggested that higher alcohol consumption is associated with a lower risk of CKD [25]. Alcohol use has also been associated with albuminuria, although the degree to which this represents causation ver-

Prognosis of CKD by GFR and Albuminuria Categories: KDIGO 2012				Persistent albuminuria categories Description and range		
				A1	A2	A3
				Normal to mildly increased	Moderately increased	Severely increased
				<30 mg/g <3 mg/mmol	30–300 mg/g 30–30 mg/mmol	>300 mg/g >30 mg/mmol
GFR categories (ml/min/1.73 m²) Description and range	G1	Normal or high	≥90			
	G2	Mildly decreased	60–89			
	G3a	Mildly to moderately decreased	45–59			
	G3b	Moderately to severely decreased	30–44			
	G4	Severely decreased	15–29			
	G5	Kidney failure	<15			

Green: low risk (if no other markers of kidney disease, no CKD); Yellow: moderately increased risk; Orange: high risk, Red: very high risk.

Fig. 78.1 Prognosis of CKD by GFR and albuminuria category

sus unmeasured confounding by other behaviours or risk factors remains unclear [104]. Differences between populations (including between the form in which alcohol is consumed) and in study methodology may in part explain these differing results. Moreover, general population studies do not reflect the pathology of individuals with alcohol abuse disorders; a recent study focusing on individuals with a diagnosis of alcohol use disorders identified a twofold increase in the incidence of CKD [78]. As such, screening patients with alcohol abuse disorders for renal disease and for risk factors for CKD (e.g., hypertension and diabetes mellitus) appears prudent.

Core principles of the management of CKD can be found in guideline documents [54] or, more helpfully, in summary resources [55, 97, 100]. Essentially, it consists of optimisation of blood pressure, diabetes and cardiovascular risk factors as well as the use of angiotensin system blockade in patients with macroscopic proteinuria. Additional factors include drug dosing adjustments and avoidance or cautious use of potentially nephrotoxic agents.

Treatment of drug addiction may be affected by the presence of chronic kidney disease [4]. Disulfiram metabolites are renally excreted and its use should be carefully monitored in patients with impaired renal function. Acamprosate is contraindicated in severe renal impairment and dose reduction is recommended for those with moderately impaired renal function. Opioids and their derivatives (including methadone, naltrexone) are generally not nephrotoxic; however renal elimination of drug or active metabolites is common and reductions in dosage or frequency of administration should be considered along with cautious uptitration. Similar consid-

erations apply to baclofen, which is renally excreted and which has been the cause of life-threatening sedation when used in standard doses in patients with advanced renal disease [4]. Buprenorphine and methadone are primarily hepatically cleared; however in advanced (stage 4–5 including dialysis) CKD, small (50–75% normal) starting doses and cautious uptitration are still recommended [91].

78.6 Renal Replacement Therapy in the Setting of Drug Use

Although end-stage renal disease rarely arises de novo from drug use, this has been described with prolonged MDMA and cocaine use causing malignant hypertension. Providing long-term dialysis to individuals with drug and addiction issues can be complex. Issues of vascular access, repeated intravascular infection, difficulties with pain management and compliance with fluid restriction regimes are just a few of the complications. Use of illicit drugs at haemodialysis initiation is associated with shorter survival, particularly in younger patients whose adjusted risk of mortality is up to 9 times higher than similar patients without a history of drug use [41].

As in CKD, altered pharmacokinetics also needs to be considered. Drug clearance may be markedly reduced in the presence of advanced kidney disease, with clearance of drug on haemodialysis also needing consideration as dose may be best delayed until after dialysis. There is enormous variability within drug classes in the need to adjust dosages for renal impairment or renal replacement therapy. Opioids provide an illustrative example of this variation. Morphine undergoes hepatic metabolism to glucuronide conjugates, which are pharmacologically active and dependent on renal excretion such that toxicity is relatively more likely in those with marked reductions in renal function, primarily due to the unpredictable accumulation of active metabolites. Hydromorphone is preferred in advanced renal failure as its metabolites are better tolerated. In contrast, both methadone and buprenorphine are subject to hepatic metabolism with renal clearance of metabolites; however as these metabolites are inactive, no dose reduction is required in the presence of kidney disease (although 50–75% dose reduction is still recommended for those on dialysis or with eGFR <10 ml/min/1.73 m^2) [32]. Dialysability also differs widely. Hydromorphone and morphine to a lesser extent have relatively lower volumes of distribution and low protein binding, allowing them to be partially cleared on haemodialysis. The large volume of distribution and high protein binding of buprenorphine and methadone mean that they are not cleared to any significant degree on haemodialysis. In practice, even with potentially cleared drugs such as hydromorphone, additional opioid dosing after dialysis is rarely required. The core principle of opioid dosing in renal impairment is ‘start low and go slow’, and consult one of the many specialised resources available [91]. Kidney transplant recipients are most at risk of adverse events from drug interactions with their immunosuppressive agents (especially calcineurin inhibitors), and pre-emptive adjustments and close monitoring of drug levels may be required.

The optimal form of renal replacement therapy for most patient is kidney transplantation; however patients with a history of drug abuse or with blood-borne viral infections are less likely to be listed for transplantation and wait longer once listed [28, 88]. The reasons for this are complex as transplant in addicted individual poses particular challenges. Issues include peri-transplant pain management and vascular access and longer-term management chronic immunosuppression and its associated infection and cancer risk in individuals with ongoing high-risk behaviour, comorbid psychiatric diagnoses and/or minimal social support [61]. The role of clinician beliefs or biases in transplant listing should also be considered, in particular the perceived association between substance abuse and medication non-adherence – a strong risk factor for graft rejection, especially in young adults [88]. While evidence to support this association exists [19], interventions to improve compliance are available [36], and it is essential to individualise risk assessment and treatment decisions.

Transplantation may be preferable to the complexity of continuing dialysis in this setting.

Infection with hepatitis B, C or HIV is not a contraindication to renal transplantation. Despite the intensive immunosuppression required for successful transplantation, modern HAART and DAA now provide the ability to reliably eradicate (HCV) or suppress (HIV and HBV) blood-borne viruses [62]. While transplant recipients with chronic HCV infection have increased risk of graft loss and mortality, they still stand to gain substantial benefit as compared with remaining on dialysis [86]. Given that much of the existing data is from the pre-DAA era, it is likely that outcomes for HCV-positive recipients are improving. The success of HCV treatment with DAA, with sustained virological response in >95% of those treated [86], has encouraged the use of deceased donor kidneys from HCV-positive donors, typically for HCV-positive recipients who are therefore able to reduce their waiting time [62]. A viable argument is now being made for transplanting kidneys from HCV-positive donors for HCV-negative recipients based on successful case series [40] and observational data [62]. Since the introduction of lamivudine prophylaxis, HBV-positive renal transplant recipients have similar graft and overall survival, although their risk of liver failure remains higher than HBV-negative recipients [81].

78.7 Metabolic Derangements Associated with Drug Use

78.7.1 Dysnatraemias

Hyponatraemia is a potentially fatal consequence of amphetamine, primarily MDMA, use. Hyponatremic encephalopathy (caused by cerebral oedema secondary to the formation of an osmotic gradient between the hypo-osmolar serum and iso-osmolar cerebral interstitium) is the most feared complication. A majority of cases are females under the age of 30 who present with headache and vomiting followed by lowered level of consciousness which may lead to seizures, coma and death [51]. The primary factors appear to be the ingestion of water in the context of sweating and physical exertion along with the release of arginine vasopressin (AVP) under the influence of MDMA metabolites which causes the syndrome of inappropriate secretion of ADH (SIADH) [73, 105]. The risk of hyponatraemia and of hyponatremic encephalopathy appears to be higher in women, thought to be due to increased sensitivity to AVP and to oestrogen-induced differences in cerebral sodium handling. Indeed, one study found that one in four of female MDMA users sampled at a rave party had mild (subclinical) hyponatraemia as compared to only 3% of males, suggesting that particular caution should be exercised by female MDMA users [98]. In addition to MDMA, related compounds methylone and ethcathinone (marketed as 'legal ecstasy') have also been associated with severe hyponatraemia [14]. Hyponatraemia has rarely been reported in association with cocaine use; however three of the four cases involved cocaine adulterated with levamisole (the fourth case was not tested for levamisole), and it is possible that this (rather than the cocaine) may have been the cause of hyponatraemia [37, 52]. Management of severe, symptomatic hyponatraemia due to MDMA or related compounds involves administration of small boluses of hypertonic (3%) saline, with close monitoring and repeated boluses as needed to achieve a controlled rise in serum sodium [73].

Hyponatraemia is commonly associated with moderate to severe chronic alcohol abuse (so-called beer potomania). The pathophysiology relates to continued intake of fluid despite low solute intake. Low solute intake impairs the ability of even normally functioning kidneys to excrete water as urine solute concentration (osmolality) cannot fall below approximately 50 mOsm/l. This means that a minimum of 50 mOsm of solute must be consumed (or generated from catabolism) for each litre of free water consumed. Moreover, non-osmotic release of ADH in response to gastrointestinal losses from chronic diarrhoea, nausea or vomiting can result in the superposition of a state analogous to the syndrome of inappropriate ADH (SIADH), further predisposing to hyponatraemia. Importantly, patients with alcohol-associated chronic hyponatraemia appear to be at especially

high risk of osmotic demyelination syndrome (ODS) with overly rapid correction of hyponatraemia. Hence, cautious initiation of refeeding, close monitoring and a willingness to use hypotonic fluid to slow the rise in serum sodium may be required [47]. Early administration of thiamine is warranted in all cases. Finally, hyponatraemia is common in cirrhosis, regardless of cause of liver disease, and is associated with reduce survival. Management typically relies on fluid restriction and judicious use of diuretics.

78.7.2 Disorders of Acid-Base Balance and Other Electrolytes

Use of many illicit substances is not associated characteristic acid-base or electrolyte abnormalities beyond those that may emerge in with acute or chronic renal injury, but there are important exceptions. Chronic alcohol use is associated with a variety of electrolyte disorders (in addition to hyponatraemia described above), most often via indirect mechanisms such as excessive vomiting/gastritis, chronic diarrhoea and pancreatitis. Electrolyte disturbance from alcohol-induced diarrhoea is well reported**.** There are additional complications related to specific inhibition of magnesium absorption and phosphate malabsorption and poor nutrition, but the major pathology is from rapid GIT transit time, mucosal damage and a range of gastropathies (gastritis, ulceration and paresis) [1]. Chronic alcohol intake is commonly associated with hypomagnesemia [33]. Alcoholic ketoacidosis may be present in malnourished alcohol-dependent patients and results in an elevated anion gap metabolic acidosis [1]. An emerging cause of metabolic acidosis is that associated with abuse of non-steroidal anti-inflammatories (NSAIDs), often via combined codeine-NSAID preparations. Chronic NSAID abuse results in a type-1 renal tubular acidosis (RTA) and is defined by normal anion gap acidosis (low bicarbonate, high chloride) and hypokalaemia, which may be profound [11, 27, 75]. Type 1 RTA also causes hypercalciuria and NSAID-induced RTA has been associated with nephrocalcinosis [34]. This RTA improves with cessation of NSAID use but may not fully resolve.

There are no direct renal consequences of marijuana use; cyclical vomiting can result in renal and electrolyte disturbances. Cannabis hyperemesis syndrome (CHS) is increasingly commonly seen in regions of the USA following legalisation [10]. Case reports have associated CHS with hypophosphatemia, hypokalaemia and acute renal failure, although these complications appear rare [21, 84]. CHS may also complicate the presentation of other illnesses, as shown in a case report of a cannabis user with type 1 diabetes presenting with the unusual combination of ketoacidosis and an elevated serum bicarbonate [45].

78.8 Conclusions

Drug use is associated with a myriad of renal and electrolyte pathologies and drug use should be considered as a potential contributor in all patients presenting with acute renal failure or acute electrolyte disturbances. Conversely, patients with a history of drug abuse are at increased risk of kidney disease and should be screened for elevated serum creatinine and for albuminuria. Despite the increased risks for this patient population, it remains essential that patients with a history of drug abuse receive equitable access to care. The management of CKD continues to evolve and new therapies may offer greater relative benefits to previously disadvantaged groups.

Key Points

- Acute kidney injury or electrolyte derangement can be caused by a wide variety of drugs of abuse, and a thorough drug history is essential in evaluating such presentations.
- Renal pathology in people with a history of drug use is often only indirectly related to drug use. Examples include

acute kidney injury due to rhabdomyolysis following overdose or the glomerular diseases associated with blood-borne viruses and IVDU.
- Chronic kidney disease and especially renal replacement therapy (dialysis or kidney transplantation) complicate the management of people with drug addiction. Additional psychosocial support and careful attention to drug-drug interactions and drug dosage adjustments are required.
- Acute electrolyte derangements, especially hyponatraemia associated with stimulants or chronic alcohol abuse, can be life-threatening and require prompt, but judicious, treatment to avoid potentially fatal brain injury.

Trauma and Addiction Medicine

79

Michael Dinh and Matthew Oliver

Contents

Abstract

Trauma systems are designed to transport, triage and treat severely injured apatients to maximise chances of survival and functional recovery. Drug abuse and addictions are closely associated with many types of severe physical injuries. Many patients presenting with trauma also have intercurrent and underlying drug- and alcohol-related comorbidities. Recognition of these in the acute setting helps to improve hospital management of these patients and minimise the risks of deterioration and complications. Acute hospital treatment also represents opportunities for interventions to help patients identify and better manage drug addictions.

79.1 Introduction

Injuries remain the leading cause of death around the world in people under 45 years of age [1]. It is estimated that over 16,000 people die every day from injuries and many more are left with permanent disabilities. As a result of increased urbanisation and road transportation in developing countries over the past 20 years, road trauma has risen to the sixth leading cause of early death in 2017 from eighth in 1990 [2]. In recognition of this, the World Health Organisation set out to reverse this trend by supporting a global decade of action on improving road safety from 2011 to 2020. Disturbingly, intentional or self-inflicted injuries follow closely behind road trauma as a cause of death in these age groups, and, as the population ages, particularly in developed nations, falls have become an increasingly common cause of morbidity in the elderly [3].

Substance abuse, particularly alcohol, has long been recognised as a risk factor for all these injury mechanisms [4, 5]. Causal associations exist on a number of levels. Firstly there are dose-related effects of certain drugs ranging from disinhibition and impaired concentration through to aggression and impaired level of consciousness that increase the risk of road crashes, falls and assaults [6]. Secondly social factors related to the acquisition and distribution of illicit drug use increase exposure to violent crime and penetrating trauma. Thirdly substance abuse often coexists with psychiatric disorders, increasing the risk of self-inflicted harm and harm to others [7]. Finally, major trauma is a well-described risk factor for the development of posttraumatic stress disorder, which itself leads to substance abuse and a vicious cycle of further injury [8]. For these reasons and more, substance abuse exacts an enormous cost to society. In Australia in 2009, the costs of alcohol abuse alone were estimated to be over $15 billion dollars, which includes tangible costs such as costs of road trauma, hospital treatment and crime and intangible costs such as lost productivity and emotional distress [9].

Emergency departments (EDs) function within health systems to identify and stabilise acute undifferentiated health problems [10]. This paradigm is exemplified by the modern trauma system, where the trauma team assesses and manages patients with life-threatening injuries and prepares the patient for definitive surgical treatment. EDs are also an important point of episodic health care for many people through unplanned admissions and exacerbations of chronic conditions. In most societies EDs also provide access to basic level care and a safety net for socially disadvantaged and isolated populations. Therefore EDs commonly identify and treat patients with substance abuse disorders [11].

These patients present to ED with a wide spectrum of problems, some of which are listed in Table 79.1. The effect of alcohol and drugs of addiction on a patient's cognition and physical abilities means that these patients are at a higher likelihood of suffering trauma. A study in Louisiana found that up to 70% of patients admitted after severe injuries had positive drug or etha-

nol urine screens [12]. A similar study of over 1000 trauma patients at the R Adams Cowley Shock Trauma Center in Baltimore found that rates of positive drug screens around 64% (opiates, cocaine and marijuana) in trauma patients [13]. Patients with substance abuse disorders often present with multiple complaints, confounding even the simplest presentations like a sprained ankle, making such patients amongst the most complex patients to deal with safely and successfully in the ED environment. These management difficulties are often compounded by a patient's own impaired judgement and increased risk-taking behaviours [14]. As a consequence the severity of injury and likelihood of suffering trauma tends to be higher in acutely intoxicated individuals than the general population [13, 15, 16]. Despite these increased chances of trauma, the evidence that these patients have a worse outcome compared to non-intoxicated patients is sparse. Only a handful of studies demonstrate worse outcomes for drug- and alcohol-intoxicated patients compared to non-intoxicated patients with the same injuries [17–21] (Table 79.2).

As a consequence this population is at an increased risk of motor vehicle accidents (MVAs), pedestrian injuries, blunt assault, penetrating assault (stab wound or gunshot wound), self-harm and falls [22, 23]. One study reviewing the odds of patients suffering from severe injury following an MVA identified alcohol use as the greatest predictor over other factors such as age, seat-belt use and vehicle crash. The presence of alcohol intoxication more than doubled the risk for serious injury [15].

Table 79.2 Risk behaviours found of acute and chronic alcohol users

Behaviour	Percentage of patients (n = 145) (%)
Driving	
Don't always wear seat belt	37.9
Don't always obey speed limit	71.1
Ridden with driver under the influence	41.1
Driving under the influence	33.8
Additional driving	
Recent citation/arrest/ license suspension	44.1
Prior DWI/DUI arrest	17.2
Violence	
Carried a weapon	10.3
Recent physical altercation	35.2
Prior assault with weapon	30.3
Suicide	
Suicidal ideation in last year	26.9
Prior suicide attempt	13.8
Additional risk factors	
Lifetime drug use	57.9
Current drug use	32.5
Prior alcohol/drug treatment	20.0

79.1.1 Injury Profiles

A variety of injury profiles are found in drug and alcohol users ranging from minor to major injuries depending on the mechanism. Minor injuries may include orthopaedic injuries such as ankle sprains or rib fractures, minor burns or soft tissue injuries. Although not requiring operative intervention in the majority of cases, minor injuries still account for a large burden on emergency department resources [24, 25]. Major injuries also account for a large burden on emergency departments but also intensive care, operating rooms and inpatient care accounting for a large financial and resource strain on hospitals [26, 27].

79.2 Clinical Considerations

79.2.1 Initial Assessment and Management

When patients arrive at trauma centres, an initial assessment of patient's injuries is made followed by implementations of therapy. Most centres follow an Advanced Trauma and Life Support (ATLS) structure, whereby evaluations of a patient's Airway, Breathing, Circulation and

Neurological state (ABC's) forms part of the 'Primary Survey' [28]. If a life-threatening abnormality is detected during assessment of these areas, then necessary interventions such as endotracheal intubation and blood product resuscitation are commenced immediately. These are usually undertaken in the context of a severely injured patient with limited corroborative history or available information about medical background. Following on from this, a 'secondary survey' is commenced whereby a patient is examined from head to toe, front and back to detect any other significant injuries. Further investigations often include chest and pelvis radiographs, computed tomography (CT) and an extended focused assessment with sonography in trauma (eFAST). Many of these processes occur simultaneously by numerous clinicians working in a resuscitation or trauma team.

Case Scenario

A 24-year-old male presents to an inner city emergency department with head and chest injuries following an assault in which he was beaten about the head with a baseball bat and stabbed with small knife. He has a history of alcohol and cannabis use. He admits to injecting 'ice' prior to the incident. He does not have family and frequently presents to this emergency department where he is well known for being disruptive and aggressive behaviour towards staff. On presentation he is sweaty, agitated, with a GCS of 13, heart rate of 130 and a blood pressure of 90/50. He has multiple facial abrasions, a large occipital scalp haematoma and a small 2 cm penetrating wound to his left upper chest. The patient becomes violent and demands to leave the emergency department stating that there are people out to 'get him'.

A number of variables dictate a patient's disposition and treatment in the emergency setting. For example, if a patient is severely injured and has tachycardia and hypotension, then clinicians will often presumptively treat for haemorrhagic shock with blood product transfusion and consideration for urgent operative intervention. However, without clinical evidence of ongoing haemorrhage or severe injuries, patients may not require urgent operative intervention and many patients can be managed conservatively. Another example may be the patient with a head injury and a normal Glasgow Coma Scale (GCS) of 15 who may not require further urgent management. However, a head injured patient with reduced conscious level, i.e., reduced GCS or focal neurological findings, may require urgent cranial CT and craniotomy if there is evidence of intracranial haematoma.

79.2.2 Acute Physiological Changes Related to Drugs and Alcohol Use

As shown in Table 79.3, there are a number of effects from alcohol and drugs that make standard assessment and management of an intoxicated patient a clinical challenge. The main areas of concern specific to these individuals are (i) haemodynamic status and (ii) neurological status.

79.2.2.1 Haemodynamic Status

Nearly all drug and alcohol use can affect blood pressure or pulse as shown in Table 79.3. The most concerning presentation to any physician managing trauma patients in general is haemorrhage. Signs of haemorrhage in an average non-intoxicated young adult include increased respiratory rate, tachycardia, peripheral vasoconstriction, anxiety and, later on, hypotension. Patients therefore intoxicated with any of the common substances of abuse could fit any of these criteria at any one time. Animal models have demonstrated the increased likelihood of bleeding with alcohol intoxication [29–33], most likely due to the inability to cause peripheral vasoconstriction to shunt blood to vital areas such as the heart, lungs and brain. Stimulant-affected patients such as cocaine or methamphet-

Table 79.3 Physiological effects of common drugs and alcohol

	Cardiovascular effects	Respiratory effects	Neurological effects
Alcohol	Peripheral vasodilation Increased risk of arrhythmias Myocardial dysfunction	Respiratory depression Reduced pulmonary clearance Higher incidence of pneumonia Reduced pulmonary vascular resistance	Reduced conscious level and airway compromise, disinhibition
Stimulants, e.g., cocaine, methamphetamine, ecstasy	Tachycardia, hypertension, vasoconstriction, arrhythmias, myocardial ischaemia	Increased respiratory rate	Agitation, aggression, anxiety, delirium, seizures
Sedatives/depressants Benzodiazepines Opiates Marijuana	Increased systemic vascular resistance	Reduced respiratory drive with opiate used	Depressed conscious level, confusion, psychosis

amine users are typically tachycardic and agitated, giving the appearance of someone who is in hypovolaemic shock. As a consequence, not only is the patient's ability to cope with blood loss affected but also the assessment by treating physicians may be confounded. Drug-affected patients are therefore more likely to get over-investigated due to the concern for missing potentially life-threatening injuries not detected on routine assessment. However, the converse could be true in that physicians may be tempted to attribute exam findings and vital signs to drug intoxication and potentially miss life-threatening injuries, resulting in delays to definitive care and misdiagnosis. This has large implications for healthcare resources as blood transfusion requirements are increased, rates of CT scanning increased resulting in longer in-patient length of stays [19, 26, 27].

79.2.2.2 Neurological Status

All drug use has potential significant effects on cognitive function. The primary difficulty with any intoxicated patient therefore is the assessment of the cognitive state and whether this is due to the intoxication or traumatic brain injury (TBI). Any unconscious patient (GCS < 9) often requires urgent airway intervention and possible endotracheal intubation and mechanical ventilation to prevent the occurrence of gastric aspiration and prevent secondary brain injury. Previous evidence has demonstrated that alcohol-intoxicated patients are more than twice as likely to require airway intubation compared to non-intoxicated patients with head injury [34]. Due to the alteration in cognitive level including aggression, agitation and sedation, intoxicated patients with evidence of head injury or involved in serious mechanisms of injury are more likely to undergo CT scanning [26]. Also due to the inability to perform an adequate physical exam, patients are more likely to require imaging of multiple body areas for evaluation [35]. Part of this imaging will frequently require not only cranial CT but also CT scans of the cervical spine. Well-described criteria are used in trauma patients to evaluate for cervical spine injury; however, patients must be alert and non-intoxicated to meet criteria for cervical spine clearance [36, 37]. Patients failing the criteria such as those with evidence of head injury or concerning mechanism of injury typically require CT cervical spine imaging to adequately clear the cervical spine of clinically significant injury. However the need for CT imaging needs to be balanced with radiation exposure to the neck, especially in younger patients. Waiting for the clinical effects acute drug intoxication to dissipate before reassessing or the use of plain radiographs are alternative strategies, although plain X

rays have similar radiation dose compared to modern CT scanning techniques. Cumulative radiation dose has been associated with increased risk of malignancy although the dose-risk relationship has yet to be defined [38].

79.2.3 Chronic Physiological Effects of Drugs and Alcohol

Intravenous drug use has a number of implications for acute injury management particularly in relation to difficult intravenous access [27]. However, chronic alcohol use is associated with a much more serious problem of coagulopathy and bone marrow suppression making haemorrhage control more problematic. The liver is responsible for production of clotting factors II, VII, IX and X as well as other components, all of which form essential elements of the coagulation cascade. Chronic alcohol users have reduced hepatic synthetic function, and therefore production of these clotting factors is reduced. Patients suffering trauma are at an increased risk of bleeding from a variety of mechanisms [39], and those patients with a pre-morbid reduction in clotting activity therefore have an increased risk of haemorrhage and death. Chronic alcohol use also impairs the immune response and subsequently these patients are at increased risk of post-injury sepsis, acute respiratory distress syndrome (ARDS) and multiple organ failure (MOF) [26].

Managing acute pain in the context of opiate abuse is a significant challenge for many staff in ED. Patients chronically abusing opiates such as oxycodone, codeine, fentanyl or heroin may require higher doses of analgesia compared to opiate naïve patients. Physicians need to be aware of the risks of under- and over-treating patients in this situation, and a multidisciplinary approach should be taken with early intervention from drug and alcohol specialists. Similarly, it has been recognised that the ED is a frequent source of opiates for patients, and therefore other non-opioid pain medications should be considered for patients at risk of addiction where possible [40]. Patients with alcohol dependence are also at serious risks of withdrawal and, as a consequence, are at risk of a myriad of signs and symptoms such as seizures, nausea, vomiting, abdominal pain diaphoresis, tachycardia and hypotension. These symptoms of withdrawal make assessment and management of the trauma victim difficult. Treating physicians need to be vigilant to this condition and take appropriate steps to prevent withdrawal features whilst excluding other trauma-related complications such as sepsis, raised intracranial pressure and ongoing haemorrhagic shock.

79.3 Emergency Department Considerations

79.3.1 Behavioural Management

Patients experiencing the acute effects of illicit drugs particularly methamphetamines are at risk of violent or aggressive behaviour, requiring behavioural control in ED [19, 41–43]. Measures include various de-escalation strategies, physical restraints, chemical sedation and seclusion. The most appropriate strategy is usually one which allows safe and thorough clinical assessment with restraint and sedation strategies considered as a last resort that should be consistent with local and institutional policies. If there is any clinical suspicion of serious head injury in the context of aggressive behaviour, the patient should undergo rapid sequence induction and endotracheal intubation and proceed to CT scanning of the brain and other imaging studies as indicated. Sedating aggressive patients with potential head injury without airway protection increases the risk of lung aspiration and other serious adverse clinical events.

79.3.2 Mental Health Assessment

Patients with self-inflicted physical injuries and attempted suicide can range from superficial lacerations to gun trauma and attempted hangings. Concurrent drug ingestion is common in these presentations. Patients with acute substance use like cannabis or amphetamines may also express

ongoing thoughts of self-harm or hallucinations. A mental state assessment should be made in the acute setting to diagnose the presence of an acute mental health disorder and determine the need to detain a patient for ongoing psychiatric care. Assessment should be repeated as the clinical effects of any drug intoxication abate to determine whether suicidal ideation or thought disorder persists. This becomes a critical decision when a patient with a serious injury requests to leave the emergency department against medical advice. If the patient has a potentially life-threatening condition and the patient's capacity to make an informed choice is impaired through evidence of substance use, then a patient may be detained under the common law principal of duty of care [44]. In this context, a patient who is mentally disordered due to acute drug ingestion should not be released back to the community until drug effects have cleared and potentially life-threatening injuries have been assessed for and excluded.

79.3.3 Social Problems

Patients with substance abuse disorders often access EDs due to poor social supports or financial difficulties [11]. In addition family members, partners or children of individuals with substance abuse disorders may also present with injuries as a result of interpersonal violence. It is important for EDs to have screening tools for these conditions as many jurisdictions have mandatory reporting requirements for suspected domestic violence and child abuse.

79.3.4 Security

Security personnel are often available in EDs to assist in the management of violent behaviour. Additional staff are often required to ensure patient safety by preventing them from absconding or to monitor and prevent harmful behaviours such as further self-inflicted harm whilst in ED. Patients presenting with gun-related injuries, particularly gang-related crime, should be managed as a potential security threat, and patients and visitors should be searched for potential weapons. The police should be notified if the clinician has reason to believe that a patient is in possession of a lethal weapon and poses an ongoing risk to self or others.

79.3.5 Emergency Department Burden

One of the most important challenges currently facing emergency departments around the world is overcrowding [45]. Lack of staffing and beds required to meet the demands of the healthcare system means that many EDs are chronically overcrowded with patients. The main manifestations are longer waiting times, reduced efficiency and patient safety. In this often chaotic environment, patients with substance abuse disorders particularly those with behavioural or mental health problems are more likely to escalate to violent or aggressive behaviour [43]. Some emergency departments have implemented models of care that involve dedicated mental health and drug and alcohol clinicians in an attempt to meet the demands of these patients at an earlier stage of management in ED.

79.3.6 Screening and Brief Intervention

Although systematic reviews have confirmed the effectiveness of screening and brief alcohol intervention in the primary care setting, it is difficult to extrapolate these to the emergency setting for trauma patients [46]. Acute distress due to a combination of injuries, mental health disorders and toxicological effects, in addition to the environmental considerations outlined above, make brief intervention less likely to be effective in this context. Indeed a meta-analysis abuse disorders present to ED, and the ability to connect a patient with the direct consequences of their substance use, screening and brief intervention in ED would appear to be at least an initial opportunity to discuss these issues with the patient and lends itself

to other opportunities such as follow-up referrals to specialised drug and alcohol services.

Level one trauma centre hospitals (those accredited to manage the most severe trauma patients) in the United States are now required by the American College of Surgeons to have an alcohol screening and brief intervention program for patients admitted under trauma. Few studies have investigated the effect of brief interventions in this context, and ones that have are limited by low follow-up rates (50–70%). Screening and brief intervention within trauma in-patient units offers a number of advantages to the ED setting, namely, the more controlled environment where injuries have been definitively treated, concomitant effects of drug intoxication have cleared and the patient more likely to be cooperative.

Clinical Relevance and Key Messages

- Severe injuries and drug- and alcohol-related comorbidities are often interrelated.
- Self-harm is an increasingly prevalent form of severe injury that is often associated with addiction.
- Drug dependence and withdrawal can complicate the acute assessment and management of severely injured patients, particularly with respect to pain control and vital sign interpretation.
- Early intervention with in-hospital drug and alcohol services can help identify and manage severe injuries with drug and alcohol addiction.

Abstract

Alcohol and substance misuse can cause a range of neurobiological disturbances. These may result from acute intoxication, following chronic misuse or drug withdrawal. This chapter will address these disturbances on a drug-by-drug basis. Relevant neurobiological mechanisms of drug action will also be described.

Keywords

Neurology · Alcohol · Sedatives · Stimulants · Opiates · Hallucinogens

80.1 Introduction

Neurological complications which result from substance misuse can lead to mortality and morbidity. Neurobiological mechanisms of drug action and their associated clinical neurological consequences occur during three 'phases' of substance misuse: (1) acute intoxication, (2) dependency and (3) withdrawal (Table 80.1). These will be discussed for various drug classes within this chapter.

80.2 Sedatives

80.2.1 Alcohol

Alcohol-use disorders are medical conditions which are diagnosed when a patient's drinking causes distress or harm. The recommended limit for alcohol intake varies across the world, and in the United Kingdom, it stands as 14 units of alcohol per week for both men and women.

Alcohol consumption can have a serious impact on the function of the whole nervous system but particularly the brain, leading to sedative, amnestic and ataxic effects. This occurs via the direct toxic effects of alcohol or indirectly as a consequence of damage to other organs (such as the liver), falls (leading to head injury) or nutritional deficits (in particular thiamine).

Table 80.1 Phases of substance misuse (all definitions adapted from ICD-10)

Acute intoxication
A condition that follows the administration of a psychoactive substance resulting in disturbances in level of consciousness, cognition, perception, affect or behaviour or other psycho-physiological functions and responses. The disturbances are directly related to the acute pharmacological effects of the substance and resolve with time, with complete recovery, except where tissue damage or other complications have arisen.
Dependence syndrome
A cluster of behavioural, cognitive and physiological phenomena that develop after repeated substance use. These typically include a strong desire to take the drug and difficulties in controlling its use, persisting in its use despite harmful consequences, a higher priority given to drug use than to other activities and obligations, increased tolerance and a physical withdrawal state.
Withdrawal state
A withdrawal state is a group of symptoms of variable clustering and severity occurring on absolute or relative withdrawal of a psychoactive subspace after persistent use of that substance. The onset and course of the withdrawal state is time-limited and related to the type of substance and dose being used immediately before cessation of reduction of use.

80.2.1.1 Neurobiological Mechanisms of Action

Alcohol is a psychotropic depressant of the central nervous system (CNS). It enhances gamma-aminobutyric (GABA), the main inhibitory neurotransmitter of the CNS, and inhibits glutamate, which is the main excitatory neurotransmitter of the CNS.

The inhibitory effects of GABA are mediated primarily by potentiation of the $GABA_A$ receptor function, leading to sedation and loss of social inhibitions. Chronic alcohol use eventually leads to GABA receptor downregulation, which is thought to explain the genesis of alcohol tolerance. This deficiency of GABA receptors also leads to withdrawal symptoms upon cessation of alcohol intake, with overactivity within the CNS producing delirium tremens and seizure activity.

Various glutamate receptor types are inhibited by alcohol, including the N-methyl-D-aspartate (NMDA) receptor, which has high sensitivity to low alcohol doses and is strongly involved in the

neuropharmacological effects of acute alcohol intake as well as the neurotoxicity observed in alcohol dependence [24]. In addition, long-term alcohol use leads to an increase in glutamatergic receptors in certain areas of the brain. During alcohol withdrawal the glutamate receptors that were previously inhibited by the continuous presence of alcohol are no longer inhibited. This means that they become hyperactive and trigger seizure activity or even stroke [6]. The glutamate receptor is also the main receptor involved in neuronal death due to increased permeability of the calcium channel associated with the receptor [21]. Inhibition of NMDA receptor activity is believed to be one of the mechanisms contributing to foetal alcohol syndrome, alcohol-related learning disabilities, neuronal loss and cognitive deficits.

Other potential alcohol targets include serotonin, glycine and nicotinic acetylcholine receptors, although the pharmacological mechanisms remain unclear. There are also indirect effects, altering presynaptic neurotransmitter release of dopamine, serotonin and endogenous opioids, which are believed to reinforce alcohol dependence.

The mesocorticolimbic dopamine system is believed to be particularly important in regulating motivated behaviours. The cell bodies of this pathway reside within the ventral tegmental area (VTA) and project along the median forebrain bundle to various targets including the nucleus accumbens, a key structure of the brain reward system. Alteration of dopamine release is therefore likely to be relevant to the propagation of alcohol misuse.

Brain serotonin is also important, being involved in regulation of attention, motivation and emotion. The cell bodies of serotoninergic neurons are primarily located in the medial and dorsal raphe nuclei, from where fibres project diffusely to many brain regions including the limbic system. An association between alcohol dependence and a deficiency of serotonin within the CNS has been reported [27]. This has led to the hypothesis that alcohol is consumed by certain individuals in order to normalise brain serotonin levels. Serotonin may also contribute to alcohol dependence via its interaction the mesolimbic dopamine neurotransmission [11].

Finally, acute alcohol intake increases the release of the endogenous opioids, endorphins and enkephalins in several brain regions, including the VTA and the nucleus accumbens, which is thought to reinforce alcohol dependence as opioid receptors modulate release of dopamine in the nucleus accumbens [17].

80.2.1.2 Acute Intoxication

The effects of acute alcohol intoxication will vary depending on the individual person, as well as the blood alcohol level reached. There may initially be impairment in tasks which require skill, followed by loss of inhibitions and increased social interaction. At a blood alcohol level of 150–200 mg/100 ml, loss of self-control occurs, with poor coordination (ataxia) and slurred speech (dysarthria). This is followed by memory loss, hypothermia, nausea and vomiting. By 400 mg/100 ml the individual is at risk of coma and respiratory depression. Acute ingestion of alcohol also leads to poor temperature regulation and a propensity towards hypothermia. The main mechanism for this appears to be impairment of shivering thermogenesis resulting from alcohol-induced hypoglycaemia, rather than by increasing heat dissipation via vasodilation [15].

80.2.1.3 Complications of Dependence

Wernicke's Encephalopathy and Korsakoff's Syndrome

Wernicke's encephalopathy is traditionally recognised as a clinical triad of acute confusion, ophthalmoplegia and ataxia, although other symptoms may be present. These include nystagmus, memory disturbances, unexplained hypotension with hypothermia and decreased conscious level. It occurs after exhaustion of B vitamin reserves and in particular thiamine. Treatment comprises intravenous administration followed by oral supplementation of this vitamin. Risk factors include intercurrent illness, peripheral neuropathy, delirium tremens, drinking greater than 20 units of alcohol per day, alcohol-related seizures and recent diarrhoea and vomiting. Typical MRI changes are shown in Fig. 80.1a and b.

Korsakoff's syndrome is characterised by a predominant anterograde amnestic syndrome with impaired recent memory (leading to confabulation) and relatively intact intellectual function [44]. It is associated with a lack of thiamine and subsequent disruption of the diencephalic-hippocampal circuitry, particularly between the thalamic nuclei and mammillary bodies.

Central Pontine and Extrapontine Myelinolysis

Hyponatraemia is particularly common in chronic alcohol misuse due to the large volumes of fluid imbibed. Furthermore, patients with alcohol dependence may not be able to maintain protective cerebral mechanisms against osmotic stress [35]. Cerebral oedema can be exacerbated by iatrogenic rapid correction of such electrolyte disturbances, leading to rapid osmotic shifts in the brain and secondary demyelination caused by complement-mediated oligodendrite toxicity [31].

Central pontine myelolysis (CPM) is characterised clinically as a brainstem syndrome with variable degrees of coma, confusion, quadriplegia and a 'locked-in-like syndrome' [28]. Extension of secondary demyelination into extrapontine regions occurs in around two-thirds of cases, although isolated extrapontine myelolysis (EPM) can exist in

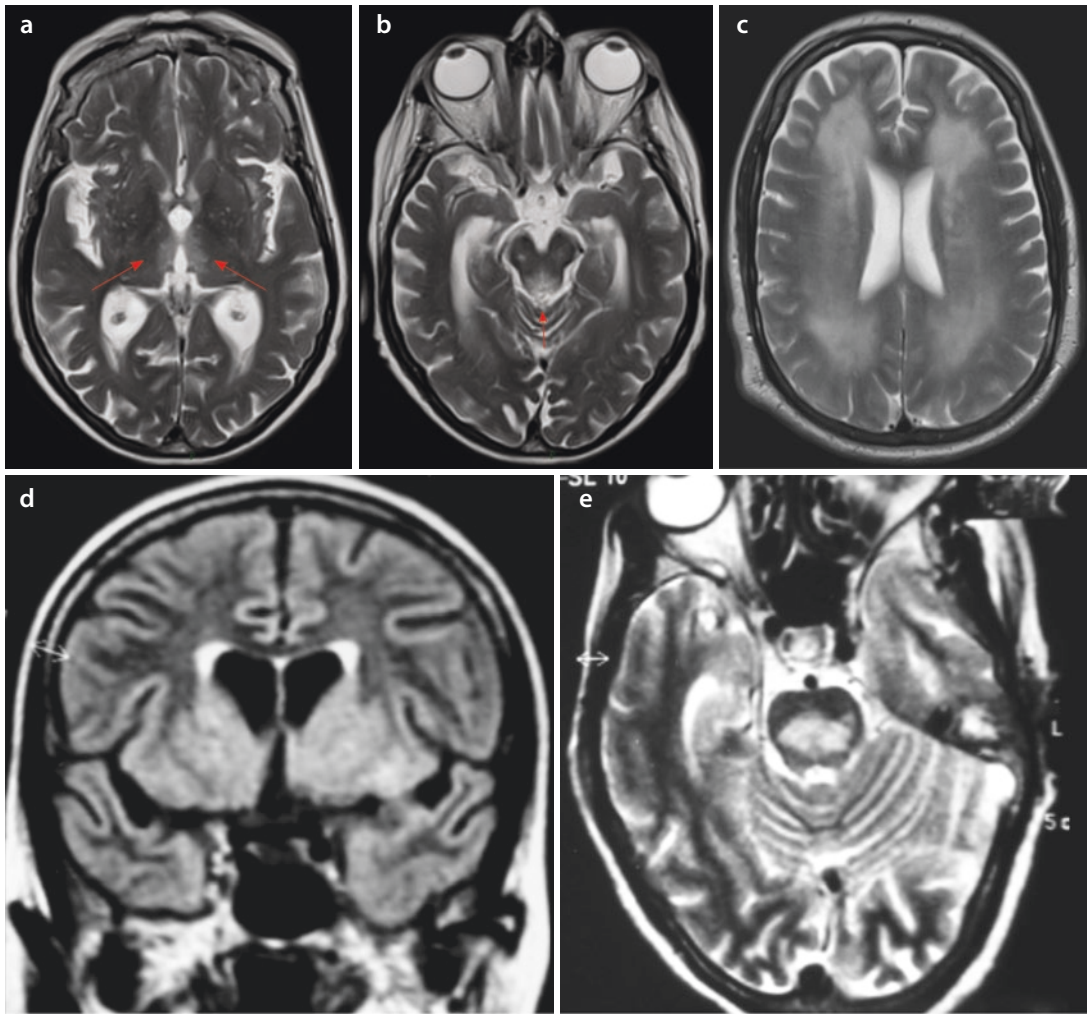

Fig. 80.1 Neuroimaging of neurological complications of drug addiction. T2 MRI sequences demonstrating (**a**) medial thalamic and (**b**) dorsal midbrain signal change in Wernicke's encephalopathy. (**c**) Diffuse white matter change in a patient with toxic leukoencephalopathy secondary to heroin inhalation. (**d**) T2 FLAIR and (**e**) T2 sequences indicative of extrapontine and central pontine myelinolysis

20% of cases [19]. Clinically, the symptoms suggestive of EPM reflect the predilection for basal ganglia structures: Parkinsonism, dystonia and/or choreiform movement disorders are most common. Radiologically, both EPM and CPM produce a striking appearance on MRI with T2 hyperintensity in the lentiform nuclei and brainstem, respectively (Fig. 80.1d and e). Despite the severity of the neurological insult, around two-thirds of patients recover independence. The main prognostic factor is the provision of medical treatment to avoid complications such as infection or thromboembolic events.

Hepatic Encephalopathy

This condition affects 60% of patients with liver cirrhosis. As the liver fails, ammonia levels rise. This has a direct neurotoxic effect on the brain. Symptoms include psychomotor slowing, asterixis, extrapyramidal rigidity, choreoathetosis and even dementia in its more chronic form [44]. Cognitively, hepatic encephalopathy (HE) is characterised by impairments in executive functioning, particularly selective attention and psychomotor speed. Recent studies have supported the idea that the cognitive impairment is irreversible with treatment of the hyperammonemic state and accumulative with each episode of HE [8]. Although the precise relationship to other forms of dementia remains unclear, patients with cirrhotic liver disease have accelerated levels of generalised cortical atrophy which correlate with their neuropsychometric impairment [2].

Cerebellar Ataxia

For reasons that are unclear, chronic alcohol misuse is particularly toxic to the cerebellar Purkinje neurons. Chronic alcohol abuse leads to neuronal degeneration within, and relatively selective atrophy of, the anterior and superior part of the cerebellar vermis. This condition affects over 30% of chronic alcoholics [41] and leads to a broad-based, ataxic gait with relative sparing of the arms.

Neuropathy

Alcohol also affects the peripheral nervous system. This may present acutely (e.g., nerve damage by direct compression while intoxicated) or in response to chronic alcohol misuse. The latter causes a symmetrical axonal sensorimotor peripheral neuropathy with early sensory involvement. Prevalence rates vary hugely between studies but may be as high as 67% when subclinical neuropathy is taken into account [1]. When symptomatic, alcohol-related neuropathy causes paraesthesia, burning pain, hyperaesthesia or numbness in the distal extremities, especially the legs. Varying degrees of balance and gait disturbance, as well as weakness, may be present. Clinical examination demonstrates generalised hyporeflexia and length-dependent sensory loss.

Although dietary deficiency of B vitamins (including thiamine) has long been thought to be contributing factor to neuropathy in alcoholics, there is limited direct evidence for this. In their study of 76 chronic alcoholics, Ammedola et al. demonstrated that neuropathy severity was independent of nutritional status. It did, however, correlate with the total lifetime dose of alcohol and disease duration. A dose-related toxic effect was also demonstrated in the absence of a nutritional effect in a cross-sectional study, supporting a direct neurotoxic mechanism [32].

80.2.1.4 Withdrawal

Delirium tremens is defined as the onset of confusion precipitated by abrupt alcohol withdrawal. It occurs in approximately 5% of people hospitalised for alcohol withdrawal [29]. A person requires at least two of the following eight symptoms for a diagnosis of delirium tremens to be made: autonomic hyperactivity, hand tremor, insomnia, nausea and vomiting, transient hallucinations or illusions, psychomotor agitation, anxiety and generalised tonic-clonic seizures (DSM-5 [12]). It is managed using CNS depressants such as benzodiazepines.

Alcohol withdrawal occurs in individuals who are physiologically dependent on alcohol. The latter is primarily secondary to upregulation of NMDA receptors and downregulation of GABA receptions within the brain. When alcohol intake stops suddenly, the inhibitory effects of alcohol cease, whereas these adaptive changes continue, leading to overactivity within the CNS. The clinical presentation of alcohol withdrawal can be defined as minor, intermediate or serious (Table 80.2).

Table 80.2 Clinical features of alcohol withdrawal

Minor 0–72 h	Intermediate 24–72 h	Serious 24–72 h
Anxiety, irritability Restlessness Insomnia Tachycardia Diaphoresis Weakness Anorexia	Minor features + Hypertension Confusion, illusions, disorientation Fear	Intermediate features + Delusions Hallucinations Seizures Arrhythmias Circulatory collapse

80.2.2 Benzodiazepines and Barbiturates

80.2.2.1 Neurobiological Mechanisms of Action

Benzodiazepines bind to the gamma subunit of the postsynaptic $GABA_A$ receptor complex as full agonists to increase the frequency of inhibitory channel opening and to decrease neuronal function. Barbiturates similarly act on the $GABA_A$ receptor but bind to the beta subunit and enhance neuronal inhibition by increasing the mean open time of these ion channels. Barbiturates also inhibit glutamate (AMPA) receptors.

80.2.2.2 Acute Intoxication

Benzodiazepines and barbiturates are anxiolytics and also aid sleep. They are used to treat seizure disorders, and certain barbiturates are additionally utilised in the management of raised intracranial pressure. Both these substances may lead to a reduced conscious level and similar complications to those described in heroin comas, including cardiorespiratory depression (especially barbiturates), aspiration, anoxic encephalopathy and peripheral nerve compression syndromes [13].

80.2.2.3 Complications of Dependence

Benzodiazepines and barbiturates are generally non-toxic to the peripheral and central nervous system, which explains the absence of clearly defined neurological complications of dependence. Most of the consequences of dependence are reflected in the behavioural changes associated with the continued cycle of withdrawal symptoms and drug-seeking behaviour.

80.2.2.4 Withdrawal

Withdrawal from prolonged benzodiazepine or barbiturate use can have life-threatening neurobiological complications. The symptoms of withdrawal consist of cognitive and memory impairment, impaired coordination, multisensory perceptual impairment and hypersomnia. The single most important presentation as part of this spectrum is withdrawal seizures, as these can lead to fatal status epilepticus [34]. Withdrawal seizures typically occur between 5–7 days following benzodiazepine withdrawal and 2–4 days following discontinuation of barbiturates. Benzodiazepine withdrawal seizures are more likely to occur following abrupt cessation from a higher dose and should be promptly treated in order to reduce the risk of mortality and morbidity associated with status epilepticus.

80.3 Stimulants

Common stimulants include nicotine, cocaine, methylenedioxy-methylamphetamine (MDMA), amphetamine, methamphetamine and synthetic cathinones (or 'bath salts'). As nicotine is not associated with any clinically relevant or common neurological complications, we have omitted it from further discussion.

80.3.1 Cocaine

80.3.1.1 Neurobiological Mechanisms of Action

Cocaine binds tightly to the dopamine transporter to block its function. Dopamine subsequently accumulates within the synaptic cleft. This results in prolonged and enhanced dopaminergic signalling in brain circuits which are related to the control of movement and reward, such as the limbic system. The latter reinforces drug-taking behaviours as it adapts to the excess of dopamine and becomes less sensitive to it.

Cocaine also reversibly blocks sodium channels. By doing this, it interferes with the propagation of action potentials and acts as a local anaesthetic. It also acts as a vasoconstrictor via its inhibition of norepinephrine reuptake in the autonomic nervous system [18].

80.3.1.2 Acute Intoxication

Cocaine produces elation and increased alertness, with increased motor activity (tremor, myoclonus) and endurance in the short and longer term. The intense euphoria from snorting cocaine typically lasts 5–10 min. Even though cocaine intoxication generally lasts less than 30 min, it is important to note that its major metabolites (e.g., benzoylecgonine) are broken down and eliminated from the body over a period of several days. Therefore, in conjunction with other complicating events, these active metabolites may continue to build up and contribute to the manifestation of adverse neurobiological complications several days post use.

Several neurobiological complications may occur as a result of cocaine intoxication. Mydriasis; hypersensitivity to sight, sound and touch; increased heart rate; arrhythmia; hypertension/hypertensive crisis and vasoconstriction may all occur. Hyperthermia may also result due to the direct effects of cocaine on the hypothalamus and the agitation and hyperactivity that stimulant drugs produce. This contributes, along with muscle vasoconstriction and central rigidity, to the rhabdomyolysis seen in more unwell patients. Cocaine may have a direct toxic effect on the cardiac and skeletal muscle [13]. 'Crack dancing' may also occur, comprising a variable combination of Parkinsonism, tics, choreiform movements and dystonia. This is well recognised by addicts as a transient complication which typically lasts for a week following initial exposure.

Seizures may be induced as a result of any combination of cocaine-induced hyperexcitability, cardiovascular dysfunction (arrhythmia), intracranial haemorrhage (hypertension) and/or cerebral ischaemia (vasoconstriction – seen within minutes of cocaine consumption on MRI angiogram). Sudden death may also occur, following initial misuse or after repeated abuse, as result of seizures followed by respiratory arrest.

Table 80.3 Mechanisms for infarction after stimulant misuse

Vasoconstriction as direct drug effect or secondary to subarachnoid haemorrhage
Cardiac arrhythmias/cardiomyopathy causing infarction by embolism or hypoperfusion
Embolism from infective endocarditis (venous thrombus or particulate contaminant) in those injecting stimulants
Cerebral vasculitis

Stroke is the most common lasting adverse neurological event associated with the use of these stimulant drugs. Cocaine is the leading cause of strokes in people under 45 years of age [10]. About 70% of strokes arising with intranasal and intravenous use are caused by haemorrhage rather than ischaemia [13]. Haemorrhages can be intracerebral (basal ganglia, thalamic, lobar or brainstem), intraventricular or subarachnoid. Fifty percent of intracranial haemorrhage occurs in individuals with pre-existing vascular malformations such as aneurysms and arteriovenous malformations [13]. Most haemorrhages occur within an hour of use, especially for crack and intravenous cocaine. A rapid increase in blood pressure is therefore believed to be the trigger for acute rupture.

Ischaemic infarcts also occur. The various mechanisms for ischaemic infarction after cocaine and other stimulant misuse are listed in Table 80.3.

80.3.1.3 Complications of Dependence

Chronic cocaine use is associated with cognitive dysfunction and cerebral atrophy [37]. This correlates with the duration of drug abuse, supporting the idea of a direct neurotoxic effect of cocaine. Cognitive impairment is marked in domains of executive functioning such as decision-making, judgement, attention, planning and mental flexibility. It remains unclear whether these are related to cortical atrophy induced by cocaine or are mechanistically related to neurovascular changes, as indexed by reduced prefrontal perfusion in abstinent patients [20].

80.3.1.4 Withdrawal

Acute neurological complications of cocaine withdrawal are rare. Strikingly, there are no reported cases of seizure, stroke or any other neurological syndrome associated with the withdrawal of cocaine. However, unpleasant dreams, insomnia, low mood and anxiety, slowed cognition, increased appetite and a craving for the drug are common.

80.3.2 Amphetamines, MDMA and Bath Salts

80.3.2.1 Neurobiological Mechanisms of Action

Amphetamines inhibit monoamine transporters and stimulate the release of norepinephrine via inhibition of vesicular monoamine transport, which is responsible for monoamine reuptake into vesicles for storage from the cytosol. Amphetamines also cause the release of dopamine from the mesocorticolimbic system and the nigrostriatal dopamine neurons, inhibit metabolic enzymes such as CYP2A6 and monoamine oxidase and act as a direct agonist on serotonin receptors.

MDMA induces monoamine neurotransmitters to be released from their storage sites in neurons via an inhibition of the vesicular monoamine transporter. This results in increased concentrations of serotonin, norepinephrine and dopamine in the cytoplasm. Compared to methamphetamine, MDMA causes a greater release of serotonin and a smaller release of dopamine. This relative excess of serotonin release may account for the mood elevating effects seen in MDMA use, as well as many of its neurobiological actions and complications.

Little is currently known about the pharmacokinetics and pharmacodynamics of bath salts, largely because these substances are frequently abused in combination with other substances and their true contents remain obscure. It has been shown that mephedrone and methylone act as substrates at transporters for norepinephrine, dopamine and serotonin, thereby stimulating release of these neurotransmitters [26].

80.3.2.2 Acute Intoxication

Neurobiological complications of amphetamines are similar to those seen in cocaine use and include seizure activity and movement disorders. Acute chorea is more common in amphetamine use than with other stimulants. Amphetamines also induce stroke disease, with similar characteristics and mechanisms as seen in cocaine use. After cocaine, amphetamines are the second leading cause of strokes in people under 45 years of age [10]. In a chronic user, stroke usually occurs in the first few hours after ingestion. Infarction is particularly common in crystal methamphetamine use. Angiography may be normal, but beading of large arteries may be seen, with vasospasm being the likely cause. This may persist for weeks [13]. Amphetamines are less likely to present as a 'typical' stoke – with more diffuse neurological deficits seen, often with a subacute progressive course. There may be headache, encephalopathy and diffuse radiological abnormalities comprising both haemorrhagic and ischaemic change [13]. Amphetamine and methamphetamine are also the drugs most commonly associated with vasculitis, especially when used chronically and intravenously. This, along with a sudden elevation in blood pressure when taking these drugs, may result in subarachnoid or intracerebral haemorrhage.

Acute intoxication with MDMA may lead to a state of confusion, depression, sleep problems and anxiety. The drug's effects last approximately 3–6 h. These neurobiological complications may occur within a few hours post use or present more gradually over a period of days. Toxicity can present with hyperpyrexia, seizures, hypertonia and coma leading to rhabdomyolysis and/or death [13]. On rare occasions, MDMA has also been associated with both intracranial haemorrhage and cerebral infarction.

Hyponatraemia is also a commonly reported complication of MDMA use. This is thought to result from several factors including overhydration in the setting of drug-induced secretion of vasopressin [39]. MDMA induces a large surge in the release of serotonin. In turn, serotonin triggers the release of the hormones oxytocin and vasopressin, which play important roles in love, trust, sexual arousal and other social

experiences and are likely associated with the characteristic feelings of heightened emotional closeness and increased empathy associated with MDMA abuse.

Mild versions of serotonin syndrome often develop. This comprises the triad of autonomic dysfunction (hyperthermia), altered mental status and neuromuscular excitation (hyperkinesia). The latter often presents with trismus (jaw clenching). Rest in a cooler environment generally settles these symptoms, although severe serotonin syndrome requires immediate and aggressive medical intervention with cooling, paralysis and the use of serotonin antagonists such as cyproheptadine or chlorpromazine. Serotonin syndrome has been proposed to have a direct relationship to neurotoxicity [36] and in severe cases can lead to death.

Neurobiological complications commonly associated with mephedrone intoxication include agitation, aggression, fatigue, impaired attention, increased empathy, talkativeness and/or an increased urge to move. Bruxism and teeth grinding can trigger jaw pain and headache. Tremor and seizures have also been associated with mephedrone intoxication [39]. Adverse events are likely to last 1–2 h post use. Patients with extreme agitation and seizures should be treated with benzodiazepines to mitigate hyperexcitability and help control seizures [39].

80.3.2.3 Complications of Dependence

Amphetamines may directly induce neurotoxicity and have direct neurotoxic effects. Some studies indicate that neuronal cell loss may be a consequence of excitotoxicity, mitochondrial dysfunction and/or the subsequent generation of free radicals and nitric oxide [10]. Indirect neurotoxicity may also result as a consequence of drug-induced damage to astrocytes, axons and/or the cerebral vasculature. Imaging studies show cerebral atrophy, with neuronal damage and glial proliferation following chronic amphetamine abuse [42]. Ischaemic infarction is also seen, especially in smaller calibre vessels. This could result from the vasoconstrictive effects associated with stimulant use and/or may be an acute hypersensitivity reaction. In the case of injectors, this could also be attributable to contaminants within the injection solution [13]. These complications may all result in the decreased brain volume seen in amphetamine abuse.

There is evidence that MDMA reduces the concentration of serotonin reuptake transporters in the brain upon repeated administration. There are some preclinical and clinical data to indicate that MDMA is associated with dopaminergic and especially serotonergic neurotoxicity, neurodegeneration and axonal loss, perhaps as a result of increased oxidative stress, excitotoxicity, apoptosis and/or mitochondrial dysfunction [10]. Heavy users of MDMA may experience long-term confusion, depression, sleep abnormalities and/or problems with attention and memory, although it is possible that some of these effects may be due to the use of other drugs in combination with MDMA (especially marijuana) [33].

There are no investigations that directly assess the chronic neurobiological complications of mephedrone abuse to date. Preclinical data indicate that repeated administration of mephedrone did not lower striatal dopamine levels or modify the expression of the dopamine transporter. In addition, it was also reported that mephedrone did not cause microglial activation nor did it increase glial fibrillary acidic protein levels in the striatum [4].

80.3.2.4 Withdrawal

Neurological manifestations amphetamine and bath salt withdrawal have not been extensively reported in the literature. However, approximately 60% of individuals who repeatedly abuse MDMA report withdrawal symptoms. These symptoms include fatigue, depression and trouble maintaining concentration [33].

80.4 Opioids

80.4.1 Neurobiological Mechanism of Drug Action

Opioids act by attaching to three types of opioid receptor: mu, delta and kappa. These receptors are found both pre- and postsynaptically on neu-

rones within the nucleus accumbens, amygdala and cerebral cortex of the brain, as well as the spinal cord, peripheral neurones and gastrointestinal tract. They regulate response to pain but also exert an effect on satiety, thirst and respiratory drive. The euphoric effects of opioids are thought to arise chiefly via activation of mu receptors, whereas the analgesic effects are thought to arise via activation of mu, kappa and delta receptors. In general, mu receptors are thought to mediate the analgesic effects of opioids by presynaptically enhancing the release of GABA via acute disinhibition.

80.4.2 Acute Intoxication

Acute opioid intoxication creates a sense of euphoria. Pupils constrict, and respiratory rate is decreased, with slowing of gut motility and subsequent constipation. There is associated cognitive slowing, sedation or even loss of consciousness. Most of these effects diminish as tolerance develops.

Opioid intoxication can be reversed with naloxone, a competitive mu opioid–receptor antagonist that reverses all signs of opioid intoxication. As opioids are metabolised at varying rates, care should be taken to monitor the patient closely. Reversal of opioid analgesic toxicity after the administration of single doses of naloxone is often transient. Recurrent respiratory depression is an indication for a continuous infusion.

Heart rate or respiratory drive can diminish to such an extent following opioid use that hypoxia results, with subsequent coma, anoxic brain injury and even death. The risk of this is even higher if vomiting and aspiration are involved, as this may further exacerbate hypoxia. Indeed, post-anoxic encephalopathy is one of the more frequent neurobiological complications of heroin abuse.

The seizure provoking property of opiates when administered acutely is supported by the finding that injectable heroin is the third most common cause of a provoked generalised seizure, and around 1% of all patients prescribed Tramadol will have a provoke seizure [16].

Acute heroin myelitis has been reported following inhalation of heroin [30], but is a rare complication.

80.4.3 Complications of Dependence

Opioids do not elevate blood pressure in the way that amphetamines do and thus do not increase the occurrence of ischaemic or haemorrhagic stroke via this mechanism. However, using non-sterile syringes/equipment when taking illicit and injectable opioids such as heroin facilitates the entry and dissemination of organisms into the blood stream. Illicit opiates themselves also often contain contaminants and bacteria. These factors, combined with the finding that intravenous addicts have altered immune systems (humoural, cell mediated and phagocytic defects), increase the incidence of septicaemia and endocarditis in this population. Infective emboli may then occlude cerebral and other vessels, which leads to irreversible necrosis and stroke. Contaminants such as talc or corn starch may also embolise and have been seen in retinal arteries or cause infarction in the brain or spinal cord. Other neurological consequences of infection include meningitis, cerebral abscess, septic arteritis and mycotic aneurysm causing intracranial haemorrhage and osteomyelitis and discitis causing extradural abscesses or spinal cord involvement.

80.4.3.1 Toxic Leukoencephalopathy

Toxic leukoencephalopathy alludes to progressive bilateral and symmetric destruction of the brain white matter, particularly myelin. Activated microglia have been found within affected brain areas, although the exact mechanism remains unknown [10]. Multiple illicit substances may cause this (including alcohol, MDMA and cocaine) but especially smoked heroin (‘chasing the dragon’). Individuals may present with inattention, changes in personality, dysarthria, ataxia, dementia, coma and even death. Pronounced, confluent, subcortical white matter changes are characteristic MRI appearances (Fig. 80.1c), which correlate with vacuolar degeneration of the deep white matter and axonal damage on post-

mortem examination [40]. No systematic case series has been published to date. Case reports nevertheless report the potential for a delayed but significant recovery, sometimes after several months following the initial ingestion [25].

80.4.3.2 Neurodegeneration and Brain Atrophy

An increase in the number and distribution of hyperphosphorylated tau-positive neurofibrillary pretangles has been noted in populations of young, chronic heroin abusers. Interestingly, despite the deposition tau in regions associated with Alzheimer's dementia, this was in the absence of amyloid beta peptides, the main component of amyloid plaques seen in this condition. In conjunction with reports of occasional ubiquitin-positive inclusions in neurones of drug abusers, this indicates that chronic opioid abuse also leads to drug-related neurodegeneration [23]. Consistent with these pathological findings, excessive brain atrophy has been recognised in heroin abusers. The relationship between this and the development of cognitive impairment or dementia is unknown. Lesions in the globus pallidus are also a recognised consequence of heroin abuse and are thought to be related to hypoxic injury [3]. Their clinical significance is also uncertain.

80.4.3.3 Peripheral Neuropathy and Neuromuscular

Subcutaneous injections ('skin popping') have been associated with cases of tetanus and botulism. Injection of heroin also increases the risk of abscess formation, rhabdomyolysis and neuropathies either via direct nerve trauma or secondary to localised oedema and compression. Peripheral neuropathy is common, affecting 25% of patients who inject heroin [9]. Compartment syndrome can also be seen after periods of prolonged coma and immobility.

80.4.4 Withdrawal

Opioid withdrawal symptoms typically occur between 6 and 48 h after cessation of opioid use, although this may be extended in longer-acting opioids such as methadone. Symptoms include dysphoria, restlessness, malaise, chills, yawning, nausea, vomiting, diarrhoea, muscle cramps and insomnia. Clinical signs of withdrawal include dilated pupils, rhinorrhoea, lacrimation and piloerection. While intoxication and iatrogenic reversal can be life-threatening, natural withdrawal is not and requires supportive care only with limited specific neurological syndromes arising.

80.5 Hallucinogens

80.5.1 Cannabinoids

80.5.1.1 Neurobiological Mechanisms of Action

THC is a partial agonist for CB1 and CB2 cannabinoid receptors. CB1 receptors are dispersed widely throughout the CNS including the basal ganglia, substantia nigra, hippocampus and cerebellum. When activated, CB1 receptors inhibit presynaptically both glutaminergic and GABAergic interneuronal neurotransmission, whereas CB2 receptors are expressed mainly in the immune cells of the periphery. Because THC activates CB1 receptors in the CNS, it is considered to be responsible for mediating the addictive effects of marijuana.

80.5.1.2 Acute Intoxication

Marijuana abuse can result in increased appetite, heightened sensory perception, inattentiveness, cognitive slowing and dysfunction, motor incoordination, an altered perception of time and talkativeness. It can also impair short-term memory. Effects can vary dramatically for individuals and, when smoked, typically persist for 1–3 h. With heavier marijuana smoking, toxic psychosis, hallucinations, paranoia and a loss of the sense of personal identity can occur. Stroke is a recognised but uncommon complication of acute cannabis intoxication**.** As with other substances of abuse, the proposed mechanisms for marijuana-induced ischaemic events include vasospasm, vasculitis and/or orthostatic hypotension [42].

A variety of neurobiological complications have also been described for Spice or K2 abusers

who have been taken to Poison Control Centres. Some complications that have been reported include tachycardia, nausea, agitation, confusion and hallucinations. There have also been a series of case reports describing stroke after synthetic cannabinoid use [14]. Synthetic cannabinoids are also a recognised cause of provoked seizure and status epilepticus [5]. In the clinical experience of the authors, this occurs more frequently than the current available literature would suggest.

80.5.1.3 Complications of Dependence

Chronic cannabis use is not thought to be associated with the development of epilepsy, neuropathy or cerebral cortical atrophy. An association with cognitive impairment has been suggested but remains controversial, and direct evidence for neurotoxicity is lacking. More recent data suggest that cannabis-related cognitive impairment resolves after 4–6 weeks of withdrawal [43].

80.5.1.4 Withdrawal

Regular smokers of marijuana or synthetic cannabinoids can experience withdrawal and addiction symptoms. With repeated abuse, CB1 receptors can homeostatically downregulate, which may contribute to cannabis-induced withdrawal symptoms when drug use is abruptly discontinued. Some of the neurobiological complications that regular marijuana smokers may experience during withdrawal consist of irritability, restlessness, anxiety, anorexia and insomnia. Specific neurological sequelae of the cannabis withdrawal syndrome are uncommon and infrequently reported.

80.5.2 Non-cannabinoid Hallucinogens

80.5.2.1 Neurobiological Mechanisms of Action

Many hallucinogens have chemical structures similar to those of natural catecholamine neurotransmitters such as acetylcholine, serotonin, dopamine or norepinephrine. Whereas the exact mechanisms remain unclear, psychedelic hallucinogens such as LSD, psilocin and mescaline appear to exert their effects via agonism of 5-HT2A serotonin receptors, perhaps in conjunction with mGluR2 receptors [22] acting within the prefrontal cortex. By comparison, dissociative hallucinogens such as PCP or ketamine appear to exert their effects by temporarily antagonising glutamatergic NMDA receptors, and deliriants are considered to be anticholinergics. PCP may also exert effects on dopamine, opioid and nicotinic receptors.

80.5.2.2 Acute Intoxication

Following acute intoxication, individuals who abuse low-to-moderate doses of LSD may experience hyperthermia and diaphoresis, sleeplessness and dry mouth. A generalised numbness of the extremities and loss of muscular coordination may occur. At higher doses, nystagmus, drooling and/or ataxia develop. LSD can typically take effect within 30 min of ingestion and can continue to produce symptoms for up to 12 h. The major neurobiological complications following LSD intoxication are psychological. Synaesthesia, where sensations seem to cross over, is well recognised. For example, an individual may ‘hear’ colours, while ‘seeing’ sounds. There have been a few reports of cerebral infarcts with large vessel occlusion, but concomitant substance misuse makes this difficult to interpret.

PCP intoxication results in particularly disturbing psychological symptoms, with suicidal and/or violent behaviour and often a misguided sense that one is invincible. This may be due to the diminution of the perception of pain, which can lead to a propensity to self-mutilate. Autonomic disturbances also occur. Higher doses of PCP cause ataxia, dysarthria and prominent nystagmus, as well as seizures activity, dystonic posturing, coma and death. Cases of fatal status epilepticus have occasionally been reported [33]. It is important to note that PCP-induced death is most likely to result from indirect consequences stemming from accidental injury or suicide than it is from a drug-induced physiological consequence.

Neurobiological complications arising from ketamine abuse are similar to those of PCP. Psychologically, acute intoxication with ketamine produces sensations of detachment

from an individual's perceived reality and one's self. There may be wild paranoid delusions, confusion, difficulty concentrating, agitation, alterations in mood, sleep disruptions/nightmares, catatonia, ataxia and/or deficits in working memory.

GHB can trigger muscle twitching and seizure activity.

80.5.2.3 Complications of Dependence

Most complications secondary to non-cannabinoid hallucinogen misuse are psychological rather than neurological, and will therefore not be discussed in detail here. Repeated abuse of LSD may produce tolerance over time. Towards this, an individual must ingest progressively higher doses of LSD to reach a similar level of acute intoxication that she/he experienced previously. Although LSD does not typically induce addictive-like, compulsive drug-seeking behaviours, this can occur with chronic abuse of PCP.

80.5.2.4 Withdrawal

There is no evidence that LSD produces physical or neurological withdrawal symptoms when chronic misuse of the drug is stopped. However, former LSD users have reported flashbacks, which have periodically been mistakenly diagnosed as brain tumours or other neurological disorders such as focal seizure activity [33]. Unlike LSD, the abrupt discontinuation of chronic PCP ingestion can be associated with withdrawal. Symptoms such as memory loss and depression may persist for up to a year after a chronic user stops taking this hallucinogen.

80.6 Organic Solvents/Inhalants

80.6.1 Neurobiological Mechanisms of Action

Volatile organic solvents are highly lipophilic and therefore neurotoxic. Mechanisms of action for inhalants appear to be similar to those produced by CNS depressants such as alcohol or barbiturates, although their effects are more immediate (within seconds) and shorter lived (commonly disappearing within fewer than 30 min). Some inhalants such as toluene have been shown to decrease neuronal excitability by acting as an NMDA receptor antagonist and a $GABA_A$ receptor positive allosteric modulator.

80.6.2 Acute Intoxication

Acute intoxication with organic solvents such as toluene can produce a variety of feelings including euphoria, exhilaration or giddiness. Because intoxication lasts only a few minutes, abusers frequently seek to prolong the high by inhaling repeatedly over the course of several hours. This is when the neurobiological complications from inhalant abuse become increasingly apparent. They may experience drowsiness and a lasting headache. Nystagmus, diplopia, dysarthria, ataxia and progressive cognitive dysfunction can become increasingly evident over time. In some instances, a protracted confusional state may last for several days [13]. With repeated exposure, inhalant-induced neurobiological complications become increasingly apparent and CNS recovery post abuse may be incomplete. Chronic toluene abuse has led to permanent cognitive changes, ocular motor abnormalities and pyramidal features that do not resolve when drug use has been discontinued. This is believed to be secondary to myelin sheath destruction [7]. Deterioration may continue for 1–4 months post cessation [13]. Demyelination and gliosis in the cerebral and cerebellar white matter have been observed up to 7 years after chronic abuse and appear to be irreversible [42]. Solvent-induced encephalopathy may also result in cognitive dysfunction and cortical and cerebellar brain atrophy [34]. It is also important to note that, in addition to the substance of abuse, other chemical ingredients found within the various types of inhalants may produce a variety of other neurobiological complications.

80.6.3 Complications of Dependence

Addictive-like behaviour is not unlikely to develop upon repeated use/abuse of inhalants.

80.6.4 Withdrawal

Although rare, compulsive use and a mild withdrawal syndrome have been reported in long-term inhalant abuse. Withdrawal symptoms include irritability, restlessness, inattentiveness, anxiety, hallucinations and depressed mood [38]. It has been argued in case reports that these mirror the presentation and severity of alcohol withdrawal symptoms. Despite this, no evidence-based treatment for inhalant use disorders currently exist, and this is still very much an area of ongoing research.

Abstract

Chronic use of different substances is associated with neural dysfunctions and related cognitive deficits. Neurocognitive disorders encompass reward, negative affect and control deficits underlying core addiction symptoms, and broader cognitive sequela affecting everyday functioning. In the first part of this chapter, we summarise the theoretical models posited to understand the nature and course of addiction-related cognitive deficits, with special emphasis on dual and tripartite models and recent international consensus. Then, we review the specific neurocognitive disorders associated with chronic use of different drugs, including alcohol, cannabis, opioids and stimulants, while acknowledging the role of premorbid cognitive alterations and polysubstance use. In the last part of the chapter, we analyse the neural dynamics underlying these deficits, including development-related changes underpinning the transition between recreational and chronic use and neuroplasticity-related changes that can be achieved via pharmacological enhancement, cognitive remediation and neuro-stimulation. We conclude by providing a critical view of the strengths and weaknesses of current frameworks and assessment and intervention approaches and a perspective of future horizons for neurocognitive research and clinical applications in addiction medicine.

81.1 Introduction

Chronic use of substances (i.e. alcohol, opioids, stimulants, cannabinoids, etc.) changes how our brain works. In a simplified mechanistic approach, both neuroadaptive and neurotoxic pathways contribute in the effect of substances in our brain [26, 68]. These brain changes happen in multiple layers including our neurons (e.g. changes in dopamine secretion patterns), circuits (e.g. changes in connectivity between brain networks) and cognition (e.g. attentional bias towards substance-related stimuli) and can be reflected in our subjective experiences (e.g. feeling craving) and behaviour (e.g. doing risky behaviours to obtain substances). There is also a growing body of evidence that some of our brains are neurodevelopmentally more vulnerable to move from recreational substance use to chronic use and then substance use disorders (SUDs) [70]. In this chapter, we put all these brain changes/vulnerabilities associated with SUDs into a single term of neurocognitive deficits (NCDs) and explore how NCDs can contribute to addiction medicine. Recent advances in neuroscience methods provide us with great opportunities to measure these NCDs and target them in interventions. In this book chapter, we will narrow our methodological approach to the measurement and intervention for NCDs into what human cognitive neuroscience provides. To facilitate dissemination among addiction medicine experts who may not be experts in human neuroscience, we will provide our readers with a straightforward approach to these NCDs using heuristic models. We hope this will make a shared language/terminology between different disciplines active in the field of addiction medicine and provide opportunities to bring more from the field of addiction neuroscience into addiction medicine. Other than shared language/terminology, heuristic models for NCDs associated with SUDs can also organise (1) our mechanistic understanding, (2) specific deficits/assessment targets, (3) temporal dynamics before starting to use towards SUD and then recovery and (4) intervention targets/methods. In the following five sections of the book, we (1) introduce the main domains of NCDs in the cognition level, (2) explore the cognitive mechanisms involved in NCDs, (3) describe NCD dynamics across time, (4) review promising interventions for NCDs and (5) discuss current gaps in our understanding about NCDs and how we can bring neurosci-

ence to addiction medicine in the international level. We encourage interested audience to follow more details on these topics in our books 'Neuroscience for Addiction Medicine' [28] and 'Cognition and Addiction: A Researcher's Guide from Mechanisms towards Interventions' [97].

81.2 Main Domains of NCDs

Novel dimensional approaches to SUDs, inspired by the Research Domain Criteria (RDoC) framework [48] (https://www.nimh.nih.gov/research/research-funded-by-nimh/rdoc/definitions-of-the-rdoc-domains-and-constructs.shtml), posit three neurocognitive domains implicated in SUDs vulnerability and disease progression: positive valence, negative valence and cognitive control [56, 82, 112]. This tripartite structure is similar to that proposed on 'dual models' of SUDs, which emphasise the imbalance between sensitisation of motivational and emotional systems (unpacked into positive and negative affective elements in tripartite models) and deterioration of cognitive control mechanisms [114]. These dimensional approaches provide a neuroscience-informed framework to characterise SUD-related NCDs and facilitate biomarker discovery [55]. Figure 81.1 provides a visual summary of the cross-talk between different neurocognitive dimensions according to recent tripartite models, including the National Institute of Drug Abuse (NIDA) Cognitive Phenotyping model [82] and the Addiction Neuroclinical Assessment (ANA) model [56]. In the following subsections, we describe the three key dimensions common to these models and explain their role in SUDs development and SUDs-related NCDs.

81.2.1 Positive Valence Domain

According to RDoC, the *Positive Valence System* is concerned with responses to positive motivational situations consisting of *reward responsiveness* (i.e. neural reactivity to hedonic responses), *reward learning* (i.e. learning what predicts positive outcomes) and *reward valuation* (i.e. processing ambiguity/risk, delay and efforts needed to gain the reward) constructs. The *reward responsiveness* construct has been widely examined in addiction studies showing disrupted brain activations, increased craving and increased urge to use which predispose users to relapse [54, 110, 114]. *Reward learning* is another major factor taking part in the development of SUDs. It refers to aberrant learning of positive reinforcement of drug and

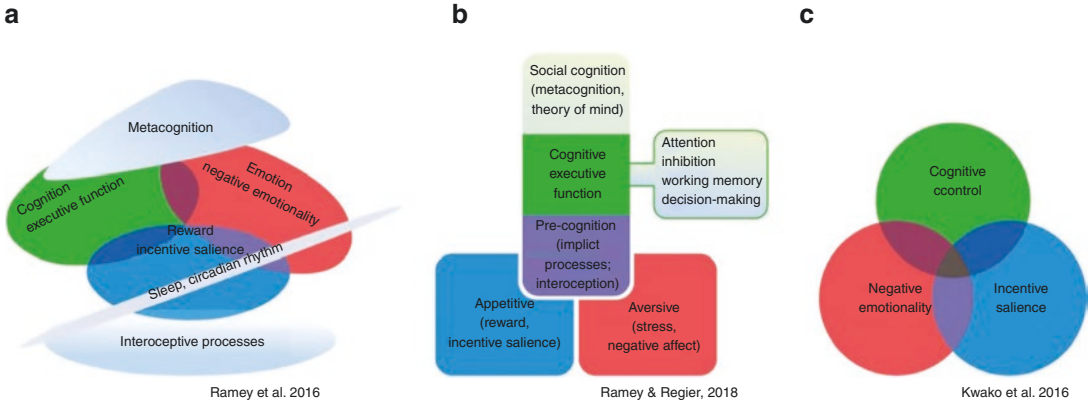

Fig. 81.1 Tripartite models of neurocognitive deficits in drug addiction. All models include (1) positive valence (blue), (2) negative valence (red) and (3) cognitive control systems (green). These three models have a dualistic notion of top-down and bottom-up interactions between positive and negative valence systems (down) and higher cognitive functions (top). (**a**) NIDA phenotyping battery. (**b**) Updated NIDA phenotyping battery. (**c**) Addiction neuroclinical assessments

drug-related stimuli and impairment in learning the association between the stimulus and the reward (or loss) outcomes [26, 51, 67]. For instance, people with SUDs show less successful results in comparison with healthy controls in Iowa and Cambridge gambling tasks (IGT/CGT), two tasks that measure the ability to predict reward outcomes in the context of uncertain and risky choices. *Reward valuation* refers to the attribution of high saliency to drugs' reward value [12, 16, 38, 56, 98]. These aberrant processes may arise from great activation of the brain's ventromedial network (VMN) and dampened activation of salience network (SN) and executive control network (ECN) [24, 27, 114].

81.2.2 Negative Valence Domain

The *Negative Valence System* has to do with responses to aversive stimuli, like fear, loss and anxiety. Drug consumption motivation can be either appetitive, as described in the positive valence system, or driven by negative reinforcement [44], meaning that the person wants to escape from negative feelings that he/she is feeling right now. These feelings can be *sustained threat* (prolonged emotional state of being exposed to aversive stimuli), *loss* (deprivation of something that had been motivationally significant) and *frustrative nonreward* (anhedonia). These constructs are manifested in different addiction models (Fig. 81.1), proposing that insufficient salience is attributed to non-drug-related rewards (frustrative nonreward) and deprivation of the hedonic state of consuming the drug (loss). Withdrawal states are proposed to be substantial to SUDs [6], and this hypohedonia may also explain the higher saliency attributed to drug rewards which leads to craving and drug consumption [27, 43]. *Negative emotionality* is counted as one of the main domains for both the ANA and the NIDA cognitive phenotyping models, as it is seen among people with active substance use and those who are in recovery, as a prognostic factor for relapse [56].

81.2.3 Cognitive Control System Domain

Poor cognitive function is known to be a significant feature of SUDs [39, 41]. Among RDoC constructs, *attention* seems to be biased towards drugs and drug-related stimuli, either as a result of positive or negative motivation; *response inhibition* is disrupted, as users struggle to suppress drug-related impulsive and compulsive responses either emotionally or behaviourally; *limited capacity working memory*, together with *goal setting* impairment, results in susceptibility of the person to relapse, as users may fail to hold goal-related information online (e.g. abstinence strategies) when they are overloaded with craving or stress [82, 89]. It is well known that one of the main mechanisms of addiction is impaired response inhibition, which seems to originate from top-down regulation dysfunctions, mainly in the ECN [21, 38, 56, 114] (Fig. 81.1b). The centrality of this mechanism is consistent with the findings of the neurocognitive literature on SUD (reviewed in Sect. 81.3), which stresses the presence of executive function deficits (i.e. working memory, response inhibition, flexibility and planning) among users of different substances.

81.3 Mechanisms for Neurocognitive Disorders in Substance Use Disorder

81.3.1 Neural Adaptations and Dysfunctions

Substance use–related changes in brain function can be classified in two broad categories: (1) neural adaptations associated with active use of the drug and related craving and preoccupation and (2) neural dysfunctions/toxicity (i.e. loss of integrity or functionality) associated with the long-term sequelae of chronic use (e.g. executive function and general cognitive impairments) [26]. Most drugs have overlapping effects on the dopaminergic mesolimbic system underpinning reward sensitisation and rebound negative affect, i.e. midbrain, striatum, amygdala and medial pre-

frontal cortex regions [53]. These neural adaptations underpin core symptoms of addiction, such as withdrawal, craving and inability to stop use. In addition, chronic use of different drugs generates varied neural dysfunctions, depending on their neuropharmacological effects and neuroadaptive/neurotoxic potential among other factors (e.g. genetic, trait and background characteristics, pharmacokinetics). Specifically, alcohol yields broad-spectrum and potent neurotoxic effects (i.e. loss of integrity and function) across the brain, stimulants such as cocaine and methamphetamine yield potent neuroadaptive and neurotoxic effects on frontal-striatal-limbic-cerebellar systems (i.e. loss of function and to a lesser extent integrity) and opioids and cannabinoids yield more subtle functional effects on dysregulation of frontal-striatal and fronto-limbic dynamics [65, 102, 104]. Neural adaptations associated with active use and craving play a key role in the transition between recreational drug use and addiction. However, neural dysfunctions underlie a range of cognitive deficits (e.g. executive functions, decision-making) associated with reduced treatment motivation and adherence, poorer quality of life and risk for relapse. Thus, in the following sections, we focus on reviewing neural dysfunction–related cognitive deficits.

81.3.2 Substance-Specific Neurocognitive Disorders

The following sections summarise cognitive deficits specifically associated with different drugs of abuse while acknowledging the role of premorbid factors and polysubstance use. We use the terms 'mild', 'moderate' and 'severe', equivalent to small, medium and large effect sizes for differences between substance users and healthy controls [113], to refer to the magnitude of the cognitive deficits described.

81.3.2.1 Premorbid Alterations

Impulsivity – rapid, unplanned reactions in pursuit of short-term gratification – is a premorbid vulnerability factor for SUDs [100]. In the context of cognitive systems, impulsivity traits may translate into difficulties in inhibitory control (or response inhibition) and reward-driven impulsive choice (e.g. steeper delay discounting or preference for smaller immediate rewards versus larger but delayed rewards and high risk/reward decisions). Thus, inhibitory control and impulsive choice deficits can be common across users of different substances. These deficits are more likely to occur among users with history of ADHD, conduct disorder or personality disorders from Cluster B (i.e. borderline, antisocial, narcissistic and histrionic) [1–3, 106]. Given strong genetic overlap and measurement covariance between inhibitory control and other executive functions such as working memory, reasoning and planning, it is plausible that broader executive dysfunctions predate substance use initiation. For example, it has been recently found that among stimulant (methamphetamine) users, school achievement indices were better predictors of current executive dysfunction than history of drug use [22]. Thus, cognitive findings speak to the need to examine executive functions in all cognitive assessments of people with SUDs, regardless of primary drug of choice or severity.

81.3.2.2 Cannabis

Cannabis and cannabinoid synthetic products interact with CB1 cannabinoid receptors. CB1 receptors are densely expressed in brain regions of the default mode network (DMN, i.e. ventromedial prefrontal cortex, posterior cingulate and medial temporal regions involved in introspection and inner experience), striatum, hippocampus and cerebellum [17, 18]. The most common cognitive deficits among heavy cannabis users are mild/moderate learning and memory problems [36, 42]. Specifically, heavy cannabis users have problems to organise new information to facilitate learning and to retrieve that information when needed. Episodic memory is often referred as the ability to engage in 'mental time travel' to retrieve specific details of past events. Heavy cannabis users have problems to make the most of that mental time travel, which might also affect their ability to make detailed plans for the future (i.e. episodic future thinking) [62]. A recent longitudinal twin study has also associated cannabis

use with working memory deficits, affecting their ability to hold and manipulate incoming information on line [66]. Clinicians often refer to motivational problems in cannabis users, and those problems can be related to cognitive difficulties to envisage future goals, to an imbalance between inner-oriented and task-oriented experience (as cannabis interacts with the introspection-related functions of the DMN and damages episodic memory) or to alterations in effort-related reward pursuit (i.e. reward valuation) [32, 57]. Cannabis users carrying genetic polymorphisms associated with poorer catecholamines and serotonin function are also more likely to experience mild working memory, selective attention and decision-making deficits [99].

81.3.2.3 Stimulants

Stimulant drugs including cocaine, amphetamine and methamphetamine damage dopamine signalling in frontal-striatal circuits involved in reward valuation/learning, executive functions and decision-making [11, 13, 20]. Thus, stimulant users frequently exhibit aberrant reward learning (i.e. the ability to learn which actions or stimuli are associated with obtaining a reinforcer) and moderate to severe deficits in working memory, inhibitory control, flexibility and decision-making [33–35]. An innovative strand of research has recently revealed broad social cognition deficits in cocaine users, including problems with social communication, affective empathy and interpersonal decision-making [47, 81, 105]. Interestingly, some of these social cognition deficits stem from core abnormalities in reward learning, as the same brain regions (e.g. medial orbitofrontal cortex (mOFC)) code the value of drug-related and social rewards [80, 94]. Core reward learning problems have been examined using reversal learning tasks and more recently model-based/model-free tasks amenable to computational modelling. These probes suggest that stimulant users have severe problems to generate 'models' of the association between their decisions and subsequent outcomes [107]. These reward learning problems result in erratic patterns of decision-making. Cocaine and methamphetamine users have also shown moderate to severe deficits across a range of higher-order executive function measures (i.e. planning, multitasking) and risk- and reward-based decision-making measures [31, 96]. Methamphetamine users also exhibit prospective memory deficits and thus may have difficulties to comply with planned/scheduled tasks [49, 83]. They also show episodic memory deficits, but at this stage, it is unclear if memory problems arise from executive dysfunction (i.e. difficulties to organise and retrieve stored information) or pure learning and memory encoding problems.

81.3.2.4 Opioids

Opioids, including heroin, morphine and opioid substitution and pain medications such as methadone, buprenorphine or oxycodone, interact with different opioid receptors, as well as dopamine systems. Meta-analytical research has shown that chronic heroin use is associated with moderate deficits in verbal fluency (ability to generate words within specific categories), verbal working memory, inhibitory control, planning and risk- and reward-based decision-making [8, 9]. More recent studies have additionally revealed visual memory and working memory deficits among chronic heroin users, including those enrolled in methadone treatment [10]. Methadone treatment has generally been associated with additional cognitive deficits, although the specific domains affected are unclear and methadone effects may be better explained by generalised cognitive slowing affecting speed of information processing across different tasks, but not core cognitive deficits [7]. Interestingly, buprenorphine seems to be a much cleaner drug in regard to cognitive consequences, with most studies showing cognitive improvement associated with buprenorphine treatment and 'normalising effects' on risk- and reward-based decision-making [76], which may have a preventive effect on relapse risk [72, 73]. There is a need for more research on novel pain prescription drugs, but research available to date has not observed significant cognitive deficits associated with their use [8].

81.3.2.5 Alcohol

Alcohol interacts with widely distributed GABA receptors as well as glutamate (especially during withdrawal) and dopamine, serotonin and cannabinoid systems [104]. Not surprisingly, heavy, chronic alcohol use is associated with broad-ranging, moderate to severe cognitive deficits. Research highlights moderate to severe cognitive deficits in visual-spatial and motor skills, attention, episodic and autobiographical memory, executive functions, decision-making and social cognition [15, 77–79, 88]. Recent reviews have stressed the impact of alcohol use in higher-order executive functions such as planning and cost-benefit decision-making and social communication and interaction, which likely have a significant impact on daily life (e.g. management of workloads and finances personal and social relationships) [88]. In addition to deficits directly associated with alcohol use disorder, chronic alcohol users may exhibit cognitive deficits secondary to well-defined, alcohol-related neurological syndromes, including Korsakoff's syndrome, Marchiafava-Bignami disease, hepatic encephalopathy and central pontine myelinolysis [63]. These syndromes have distinctive cognitive profiles, characterised by more severe memory and motor deficits and more florid neurological symptoms (e.g. confabulation) (see Maillard et al. for a detailed review). Cognitive and neuroimaging studies have also revealed additive or synergistic effects of alcohol + tobacco use, with co-users exhibiting substantially greater neuroadaptations and cognitive deficits and slower abstinence-related recovery [25, 71, 91, 108].

81.3.2.6 Polysubstance Use

Studies examining cohorts with concurrent use of multiple substances (e.g. alcohol + stimulants + heroin) invariably show cognitive deficits of greater magnitude than studies assessing cognition in users who are less exposed to multiple drugs. Recent meta- and mega-analyses of cognitive and neuroimaging data have also highlighted the role of alcohol and cannabis use in explaining the cognitive deficits of users who identified stimulants or opioids as their primary drug of concern [59, 61]. However, there is a dearth of well-controlled studies directly comparing poly- and mono-substance users. In addition, some of these studies have yielded paradoxical effects, e.g. less cognitive impairment in cocaine + alcohol versus cocaine or alcohol mono-users or less cognitive impairment in cannabis + methamphetamine users than in cannabis mono-users [40, 75, 90]. Thus, there is a clear need to conduct more research in this area, especially since polysubstance use is by far the most common and almost ubiquitous clinical presentation of treatment-seeking substance users. For now, we can conclude that chronic use of multiple substances results in more severe cognitive deficits than those described in users with more limited co-use, but that concurrent use of different substances and their specific effects needs to be assessed idiosyncratically; for example, alcohol + tobacco are consistently associated with more cognitive deficits, but alcohol + cocaine seems to be associated with less cognitive deficits.

81.4 Neurocognitive Deficits Across Time

Neurocognitive deficits associated with SUDs are dynamic across the time. These dynamic changes in NCDs can be seen at different levels of time resolution, from minutes to hours, days to weeks and months to years. Having good knowledge about these dynamic changes has critical effects on understanding the pathogenesis of SUDs, disease progression and potential targets for interventions.

81.4.1 Minutes to Hours

A brain that is shaped with the NCDs associated with SUDs responds to any conditioned cue associated with previous substance use with an intensive desire, which is called craving. Drug craving and resulting substance use are the results of the enhanced negative emotionality, the accentuated saliency processing of the drug related stimuli and lack of cognitive

control. These three main groups of NCDs interact dynamically in few minutes in a process to build up an intensive craving. First, environmental stimuli (E) trigger the process and provide the input to the brain, attention (A) provides resources to process information related to the triggers, and saliency (S) with the help of memory is attributed to the cue, leading to an interoceptive (I) state of craving which causes executive control system (Co) to either prepare for drug taking (Re) or inhibit the craving and stay abstinent (Fig. 81.2). Neurocognitive processes by which a trigger results in craving and drug use can also be tracked in the neural circuit level. It starts by attentive processing of the incentive salience of the drug in the VMN (nucleus accumbens (NAcc), ventromedial prefrontal cortex (vmPFC)); it passes then through the DMN, which forms the self-oriented goal; vmPFC-Precuneus generate the drug use scenario, and fronto-parietal networks strategically plan for its execution. Before the brain executes these plans, the SN selects whether to let it happen or inhibit it; if it passes the SN, then somatomotor region executes it [24]. Again, as it is deduced from these processes, the orchestrated NCDs through high salience attributed to drug-related stimuli, negative emotionality felt during exposure to environmental stimuli and interoceptive aversive state and low ability to cognitive control lead to drug taking.

81.4.2 Days to Weeks

SUD cannot be seen as a simple act of drug taking. Instead, the active user falls into a cycle separated into three stages. (1) *Binge and Intoxication:* at this stage, the person is taking the drug which changes the reward circuit and condition learning, leading to high saliency of drug-taking behaviours. (2) *Withdrawal and negative affect:* this stage is when the subject is abstinent, either for an hour to weeks. During this stage, the person loses his/her motivation in non-drug-related rewards and also is more sensitive to negative emotionality feelings. (3) *Preoccupation and anticipation:* when the negative emotionality is felt and the person remembers how valuable the rewards of drug stimuli were, the person feels craving that if not having enough ability to control, it eventually leads to relapse and this vicious cycle of substance use starts again [103] (Fig. 81.3).

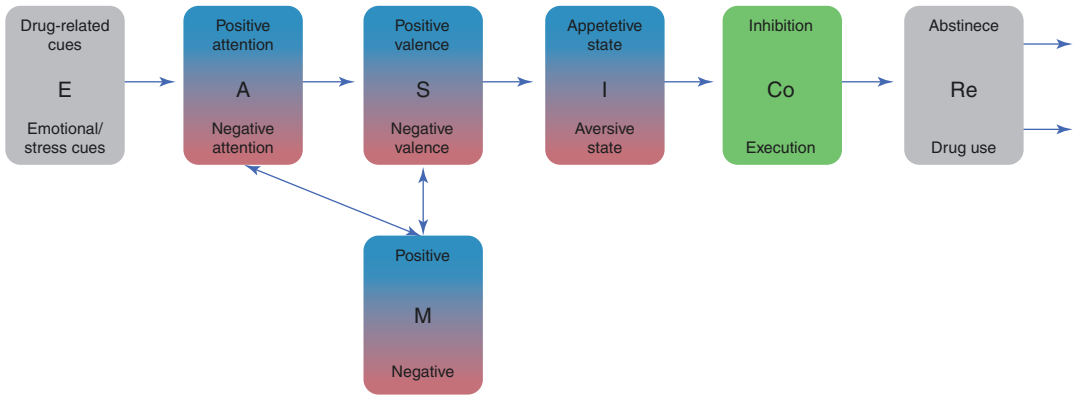

Fig. 81.2 Dynamic contribution of the neurocognitive processes to shape drug craving. This figure shows how environmental stimuli (*E*) trigger attention (A), saliency processing (S) and drug-related memories (M) and end up to an interoceptive (I) state perceived as craving. Perceived drug craving will eventually lead to either successful control (Co) and stay abstinent or failure to control the drug use response (Re) and relapse. Please see Fig. 81.1 for the colour codes (blue, red and green). E Environment, A attention, S saliency processing (significance), M memory, I internal state (interoception), Co control, Re response

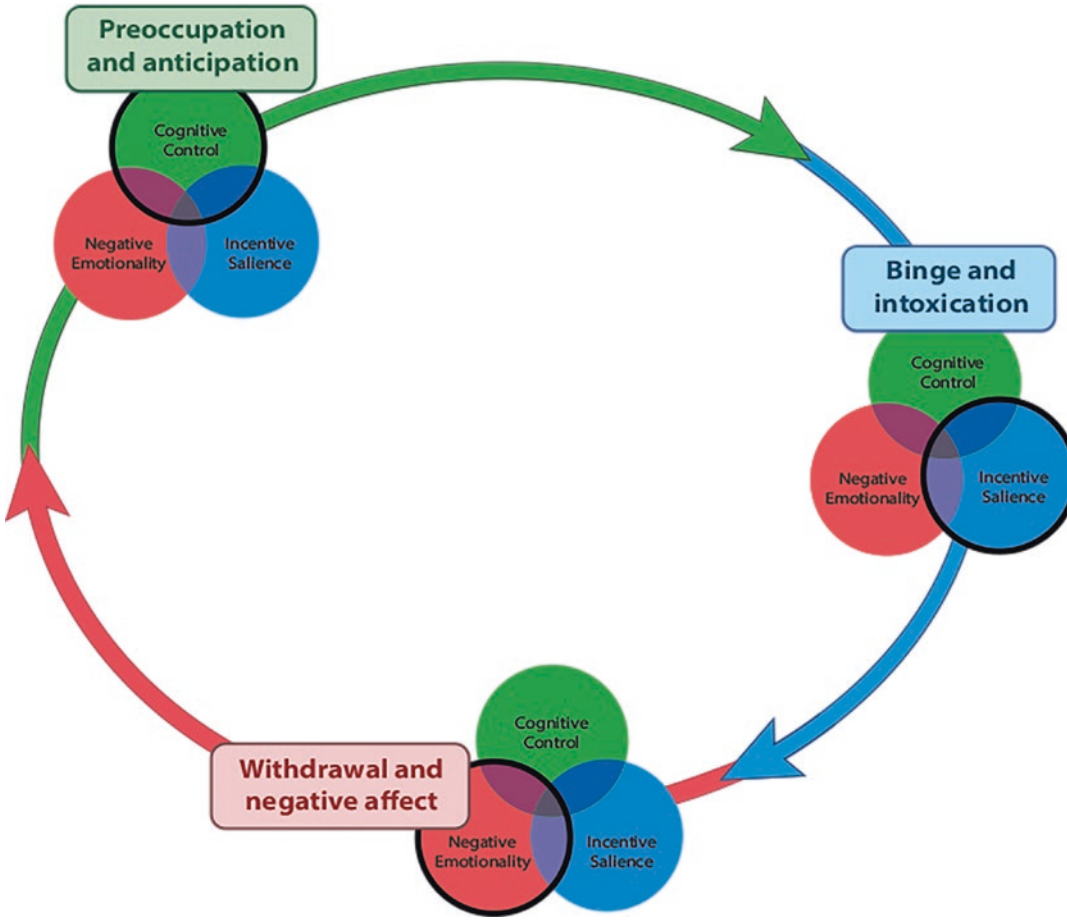

Fig. 81.3 Contribution of the neurocognitive deficits in the drug use cycle. When the person takes the drug during binge and intoxication, it induces an accentuated reward learning. During withdrawal and negative affect phase, negative feelings and stress are increasingly felt . During the preoccupation and anticipation phase, inability to resist and control the temptation of drug use will result in drug taking

81.4.3 Months to Years

As the result of the dynamic change in the NCDs, people's behaviours, experienced feelings and goal of drug consumption change over time with chronic substance use. At their early periods of taking the drug, substance users have voluntary actions to either take the drug or stay abstinent; it then changes to sometimes having trouble stopping taking drug and ends up with impulsive and compulsive actions and dozens of relapses in spite of trying to resist the temptations and stay abstinent. The feelings and goals of drug taking also are affected as the result of chronicity of use. Over time, the *binge and intoxication* phase changes, as in the first experiences the person feels euphoric of drug use, over months and years he/she feels just good, and then he/she takes the drug just to escape from the bad feelings. *Withdrawal and negative affect* phase will also change over time. It starts with the feeling of reduced energy, continues with reduced excitement/interest and eventually ends up with feeling depressed, anxious and restless. Over time, during *preoccupation and anticipation* phase, ability to resist the urges decreases from looking forward to taking the drug to desiring drug and then obsessing and planning to get the drug non-stop [103] (Fig. 81.4).

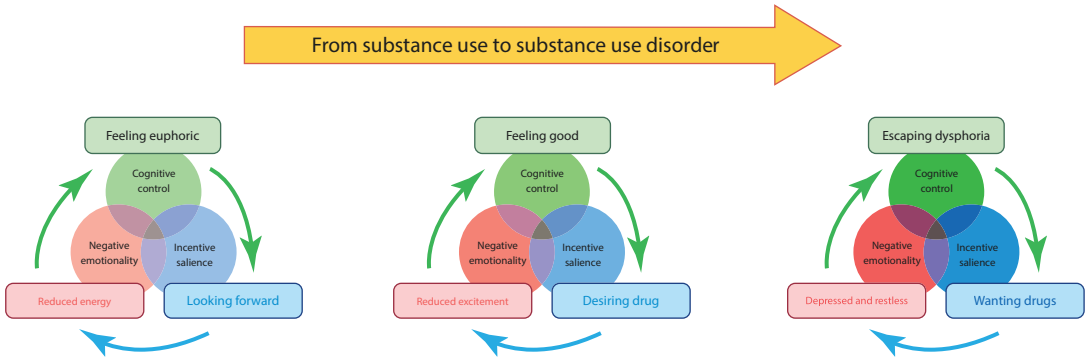

Fig. 81.4 Development of neurocognitive deficits associated with the substance use disorder in years of chronic use. This figure shows how the personal experiences during addiction cycle change over time as the person continues to use in months and years

Approaching NCDs associated with SUD as a series of dynamic processes that can be engaged or disengaged in minutes or reshaped over months and years and drive the behaviour unexpectedly will uncover some aspects of the complexities associated with SUD and its treatment failure.

81.5 Interventions in Neurocognitive Deficits

All three main groups of the neurocognitive deficits introduced in the tripartite models can be targeted by interventions to promote abstinence and recovery from SUD. Interventions may target the *positive valence* systems by reducing the saliency attributed to drug-related rewards and increasing the saliency to non-drug-related (natural/healthy) rewards. The goal of targeting *negative valence* systems is to attenuate negative emotions/body signals, like stress, dysphoria and pain, felt by the person especially during the withdrawal/abstinence state and meanwhile augmenting the negative valence for consequences of drug-seeking/drug-taking behaviour. *Cognitive control* can also be an important target to improve the ability to inhibit pre-potent drug-seeking/drug-taking behaviour and promote goal-directed behaviours (Fig. 81.5). Here we will briefly point out to the three main groups of interventions which aim at normalising and improving these NCDs in addiction medicine.

81.5.1 Pharmacotherapy

Medication, in an ideal scenario, should promote abstinence and aid in regaining the normal functions of the brain by relapse prevention and facilitating goal-directed decision-making [103]. However, we have not reached this aim for many substances yet [45, 52, 69, 92]. From a neurocognitive perspective, the main effects of the medications for treatment of SUDs can be classified as (1) controlling the symptoms of withdrawal and craving by decreasing negative emotionality during detoxification/abstinence states (like clonidine during opioid withdrawal or benzodiazepines for alcohol withdrawal), (2) preventing intoxication effects and decreasing the incentive saliency learned by previous drug-taking behaviours using substitution medications without inducing euphoria (like methadone for opioid use disorder) or using antagonistic medications to block the euphoria (like naltrexone for opioid and alcohol use disorders) and (3) reducing drug-oriented anticipatory and preparatory behaviours by improving cognitive control (for review, see [23]). Most of the currently available approved medications in the field of addiction medicine target the first two effects/goals (negative and positive saliency). However, there are hopes for medications that can promote cognitive control and executive functions to play a clinically meaningful role in addiction medicine [92]. For instance, in a randomised cross-over trial, during

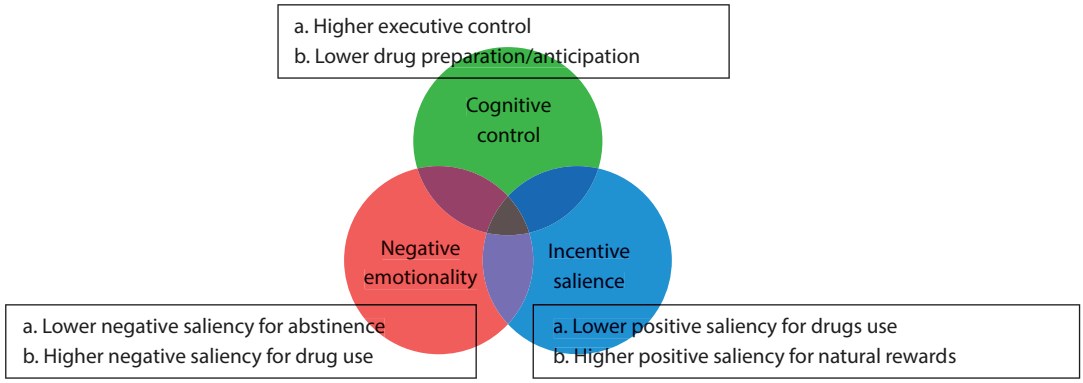

Fig. 81.5 Neurocognitive targets in addiction treatment. According to the tripartite model, aberrant dysfunction of each of the following domains could be a target for intervention. (**a**) Incentive salience can be altered in favour of increasing the non-drug-related rewards and decreasing the drug-related rewards. (**b**) Negative emotionality can be targeted by reducing negative emotional/bodily feelings associated with abstinence and increasing the negative emotional responses associated with drug-related stimuli/behaviours and their negative saliency. (**c**) Cognitive control can be improved by higher executive control ability and lower attention attracted towards drug-related stimuli. Better cognitive control will reduce anticipatory and preparatory drug use behaviours

varenicline administration phase compared to the placebo, people with nicotine use disorder showed improved sustained attention and working memory which were accompanied by reduced withdrawal symptoms and smoking urges [74]. In another study, people with cocaine use disorder who received intravenous methylphenidate showed improved response inhibition in stop-signal task [58].

81.5.2 Cognitive Interventions

Cognitive interventions are able to target all three main groups/domains of NCDs associated with SUDs. Here, we will bring six examples of cognitive interventions frequently used for SUDs treatment. (1) Contingency management (CM), as a behaviour-reinforcement cognitive intervention, gives simple natural rewards (vouchers to buy a simple gift from the clinic's shop) to the patient in the recovery as much as he/she stays abstinent (one voucher for each negative urine test). This intervention gradually increases the incentive salience of staying abstinent [60]. (2) Cognitive bias modification (CBM) is a family of interventions that aims at training attentional biases away from drug-related stimuli and modifying the automatic approach responses to appetitive drug-related stimuli. CBM may affect the top-down regulation by enhancing the activation of lateral PFC and dorsal anterior cingulate cortex (dACC) in craving management. Bottom-top regulation is also targeted by attenuating the activation of the NAcc and amygdala in reducing the effect of previously learned rewards [109]. (3) Mindfulness-based interventions train focused attention and open monitoring, which are reported to improve the activation of prefrontal regions aiding the cognitive control system and decrease the activations of limbic regions in charge of negative saliency [14, 37]. (4) Working memory training (WMT) practices 'online' maintenance and manipulation of increasing streams of information to build working memory capacity, which yields better cognitive control and reduced substance use [46, 82]. (5) Inhibitory control training (ICT) specifically targets cognitive control by applying repeated training of tasks requiring inhibition of pre-potent motor responses like go/no-go and stop-signal paradigms [5]. (6) Cognitive remediation/rehabilitation interventions are mainly designed to target cognitive control and executive functions (cold cognitive functions) using both psychoeducation, metacognitive training and cognitive games/exercises [85, 86]. Hot executive functions are those related to positive and negative feelings like craving, anhe-

donia, dysphoria, etc. They can also be targets for treatments like emotion regulation, reshaping addiction memories and mindfulness-based therapies to increase awareness. Recently, training both cold, i.e. executive functions, and hot, i.e. positive and negative saliency mechanisms, is bringing interesting potentials to the field (for comprehensive information, see [84]). (7) Goal Management Training (GMT) is a manualised group intervention for executive dysfunction that has been shown to improve cognitive control and reduce stress in SUDs [4, 95]. GMT uses instruction, discussion and mindfulness and cognitive exercises (e.g. stop and multitasking tasks) to improve hot and cold executive functions and trains an overarching strategy, i.e. 'Breath – Stop – State Goal – Check' that targets automatic positive and negative biases towards impulsive behaviour ('Breath, Stop') and reorients attention towards goals ('State Goal, Check'). Participants are trained to apply the GMT strategy to everyday scenarios and projects, thus fostering generalisability. (8) Psychoeducation is considered as an effective intervention in different domains of mental health disorders [87]. By informing people with SUDs about their cognitive deficits, we can increase meta-cognitive awareness and treatment motivation [29].

81.5.3 Neuromodulation

There are many ways to use different technologies to externally modulate the brain activities from invasive deep brain stimulation (DBS) to non-invasive technologies like transcranial electrical stimulation (tES) or transcranial magnetic stimulation (TMS). Although they are different in some respects like their feasibility of application and their effects, they have a goal in common and that is to directionally modulate dysfunctional brain activity. There are systematic reviews and meta-analyses which report effectiveness of neuromodulation, especially repetitive TMS (rTMS), tES and DBS [19, 50, 64, 93, 111]. Repetitive TMS creates a magnetic field that induces trains of electrical changes, and tES directly causes electrical induction to the brain, which can either increase or decrease the activation of the targeted region according to what protocol is used. Both tES and TMS techniques exert their effect on cortico-striatal-thalamic pathway by dampening the activations of the reward circuit which shows aberrantly high value to drug-related cues and low to non-drug-related cues; the treatment of the first one causes normalised incentive salience and the latter leads to reduced negative emotionality. It also increase the activation of dACC, anterior insula, DLPFC which lead to higher cognitive control over drug craving and also less saliency to drug which will lead to better self-control (for review, see [24]). DBS aims more at the subcortical areas specifically NAcc and tries to regulate the activations of the reward system to alleviate incentive salience to drug [19]. For more details, you may read [30].

81.6 Clinical Implications and Future Horizons for NCDs in Addiction Medicine

In the previous sections, we have described the existence of significant NCDs associated with different SUDs. These NCDs have meaningful clinical implications, as they underpin key aspects of addiction psychopathology, i.e. compulsive use, withdrawal and craving, and impact a range of clinical processes and outcomes, i.e. treatment engagement, abstinence or reduction of drug use and quality of life. Specifically, we have provided evidence that NCDs in reward valuation and learning fuel compulsive drug use, NCDs in attention and memory compromise treatment engagement and compliance, respectively, and NCDs in cognitive control and decision-making increase the risk of relapse during and after treatment. In addition, impulsivity/reduced inhibitory control has a generalised negative impact on treatment adherence, abstinence and recovery of quality of life. Given the relevance of NCDs for clinical prognosis and outcomes, clinicians and researchers should collaborate to integrate NCDs-specific assessment and interventions in routine clinical practice. Below, we provide spe-

cific recommendations on how to promote this integration.

Harmonised cognitive assessments The consolidation of addiction-specific NCDs framework should lead to harmonisation of cognitive assessment protocols. At this stage, there is relatively high agreement on the cognitive domains that need to be assessed, but no agreement (in fact remarkably low data comparability) on the assessment tools that need to be used [112]. The Neuroscience Interest Group of the International Society of Addiction Medicine (ISAM-NIG) has been recently created to, among other goals, promote an international expert consensus on a minimum set of harmonised tools that can be uniformly applied on addiction neurocognitive studies globally [101]. This set of tool should measure addiction-relevant mechanistic targets, provide useful feedback to patients and clinicians and be relatively culture-free to facilitate upscaling.

Pragmatic implementation of cognitive assessment in the addiction clinic Cognitive assessment will only be relevant if it is integrated in clinical practice. This way patients and clinicians could benefit from its potential applications, including characterisation of addiction severity (e.g. degree of decision-making impairment), prognosis, triage and cognitive-profiles-matched personalised interventions. The best approach to achieve this goal would be to train machine learning algorithms on predictive data generated from a harmonised tool in the context of international research collaboration studies. Machine learning models can then serve to distil the tools and indices that optimise clinical utility, to derive briefer, pragmatic assessments that can be routinely administered in any clinical setting.

Phase III Randomised Controlled Trials of Neurocognitive Interventions

The majority of the cognitive training and remediation interventions that have shown promising results in proof of concept and exploratory trials have not been tested in Phase III or implementation trials. Given the moderate success of the neuroscience-informed interventions that have been clinically tested, such as cognitive bias modification and mindfulness, Phase III trials involving adjunctive cognitive remediation interventions, including cognitive training of executive functions (e.g. working memory, inhibitory control), Goal Management Training and cognitive rehabilitation + psychoeducation, are warranted and needed.

Key Points

- Neurocognitive deficits in three main domains of positive valence (high saliency attributed to drug-related stimuli), negative valance (intense negative feelings during withdrawal state) and cognitive control (inability to execute inhibition) underlie addiction.
- Heavy cannabis use is specifically linked to episodic and working memory deficits.
- Stimulants and opioids are linked to executive function and decision-making deficits.
- Chronic alcohol use is linked to wide-ranging cognitive deficits.
- Mixed polysubstance use is associated with more severe neurocognitive disorders.
- Neurocognitive deficits change dynamically over time as substance use continues and substance use disorder evolves.
- Pharmacotherapy, cognitive intervention and neuromodulation can target specific neurocognitive deficits associated with substance use disorders in positive valence, negative valance and cognitive control domains.

Contents

Abstract

Infectious diseases account for over 50% of mortality among substance users. About 1.7 million worldwide are known to be infected with HIV and 6.1 million have chronic HCV infection. Skin and soft tissue infections affect 40% or more of active substance users, while more serious bacterial infections (including endocarditis, osteomyelitis, and epidural abscesses) are much more common than in the general population. Addressing them in a systematic manner will be an important part of a worldwide response to the two great pandemics of this era, namely, HIV and HCV infections. Bacterial infections may be the cause of initial presentation to care, which may provide

a unique opportunity to secure engagement in long-term, multidisciplinary programs. If we treat substance users as complex human beings with multiple needs, not only will we treat their infections more effectively, we will also help them become better functioning members of society. This must be our ultimate goal.

82.1 Introduction

Substance use is a global public health problem, affecting over 275 million people, of which 71 million are diagnosed with a drug use disorder [20, 57]. According to the UN World Drug Report, opioid use remains the most prevalent drug used followed by cocaine and amphetamines worldwide. Globally, there are over 12 million injection drug users with the highest proportions concentrated in areas of Eastern Europe (16%), North America (16%), and Southeast Asia (28%) [57]. Many of these individuals (particularly polysubstance users of amphetamines, cocaine, and/or opioids) are at risk for the acquisition of numerous life-threatening infectious diseases. Injection drug use accounts for 10% of global human immunodeficiency virus (HIV) infections (3–4 million individuals) as well as the majority of prevalent and incident cases of hepatitis C virus (HCV) infections in the developed world. Over 50% of the 12 million active injection drug users are living with HCV infection. Transmission of HIV and HCV occurs primarily through sharing of needles and other drug-related paraphernalia, with unsafe sexual practices as another route of disease acquisition, particularly for HIV [12].

Mortality within the substance use population is 2.35 deaths per 100 person-years (PYs) and, using standard mortality ratios, is 14.68 times higher than that seen in a comparable general population [37]. Causes of mortality are listed in Table 82.1, over 50% of which are related to infectious diseases.

Table 82.1 Worldwide deaths/year among substance users [17]

Hepatitis C	~222,000
Overdose deaths	~190,000
HIV/AIDS	~60,000
Self-harm	~29,000

Beyond mortality, there is also a significant morbidity associated with infections in this population, including hospitalizations and costs to the healthcare system. Bacterial infections are frequently implicated in this regard. Of drug users receiving health care in San Francisco, as many as 32% had an abscess, cellulitis, or both on physical examination [21]. Infective endocarditis may occur in 1.5–20 cases per 1000 injection drug users/year [19]. It is also thought that the onset of infections is associated with more unsafe drug use practices and increased consequences of drug use, including accidental overdose deaths. Presentation of an individual into care for management of an infection may represent an opportunity to intervene to prevent such deleterious outcomes.

In this chapter, we will discuss a physiologic basis for an impaired immune response in this population leading to a higher prevalence of infectious complications and the epidemiology as well as the clinical manifestations of the most common viral and bacterial infectious diseases. We will end by proposing an approach to address this aspect of the management of substance use within the context of a multidisciplinary model of care.

82.2 Immunologic Effects of Substance Use

The immunologic effects of substance use are varied, but immune dysregulation and an increased susceptibility to infection are widely described. The effects of substances on the immune system may be due to the presence of substance receptors on immune cells, although the presence of some opioid receptors on immune cells has been debated [1, 18]. Alternatively, the

effects may be caused indirectly through the presence of opioid receptors or the cocaine receptor sigma-1 in cells of the nervous system or through the release of mediators that affect the immune system, as seen with the release of dopamine after amphetamine use [32]. Substances may also affect the normal functioning of the cardiovascular, respiratory, endocrine, and nervous systems, resulting in physiological changes that may in turn dampen normal host responses to infection.

Numerous studies have demonstrated immunomodulation with substance use. The party drug methylenedioxymethamphetamine (MDMA, or ecstasy) decreases neutrophil phagocytosis, inflammatory cytokine production, and circulating lymphocyte levels [11]. Cocaine use has led to decreased antimicrobial activity and altered the release of cytokines [18]. Opioid effects in humans include decreased phagocytosis, chemotaxis, T cell and natural killer cell activity, and decreased antibody-dependent cellular cytotoxicity [16, 18]. In a real-world study examining blood collected from 19 injection drug users in a needle and syringe program, most of whom used multiple drugs (with 26% reporting crack cocaine use, 56% non-crack cocaine use, and 100% heroin use in at least 16 of the previous 90 days), it was found that the injection drug users had more circulating B cells and systemic inflammation when compared to healthy controls [46].

It has also been reported that substances skew the immune response from Th1, favoring cell-mediated immunity, to the humoral Th2 response [18]. A decreased Th1 response impairs the response to viruses and other intracellular pathogens. A study in rhesus macaques demonstrated that animals given morphine had fewer CD4 T cells and increased viral replication after infection with either simian immunodeficiency virus or a modified simian-human immunodeficiency virus [33].

Taken together, these findings demonstrate negative immunomodulation after substance use, leading to a predisposition to microbial infections among substance users. In general terms, there should be a high index of suspicion for infections of all types among substance users engaged in health care.

82.3 HIV Infection: Epidemiologic Considerations

Since the isolation of the virus in 1981, over 77.3 million individuals have been infected with HIV and 35.4 million people have died due to HIV-related complications. Every year there are nearly 1.8 million new cases of HIV infection reported globally [56]. People who inject drugs are nearly 23 times more at risk of acquiring HIV infection as compared to the general population [56]. Injection drug use is the second leading cause of HIV infection and nearly one in eight injection drug users are living with HIV. Nearly 10% of substance users (1.7 million) worldwide are known to be infected with HIV [61]. Reduced inhibitions and increased risky sexual and drug use behaviors contribute to substance user's exposure and prevalence of disease. Today, most regions in the world have demonstrated an overall relative reduction in HIV transmission among substance users as compared to other populations, such as men who have sex with men. In the past few years, the actual incidence of HIV infection among substance users has remained stable. However, with the rise of synthetic opioids, such as fentanyl, there have been pockets of HIV outbreaks within regions of the United States and the rest of North America. The rate of transmission is increased by the lack of availability of needle and syringe exchange programs, increasing the prevalence of risky behaviors favoring HIV acquisition. Globally, HIV among substance users continues to be prevalent in parts of South America, Eastern Europe, and Central and Southeast Asia, for similar reasons [13].

Even among drug users, the incidence of HIV infection tends to be more prevalent among men. This is in part due to enhanced sexual transmission among men who have sex with men, as well as the incidence of injection drug use being higher among men. In those infected with HIV, the presence of another sexually transmitted infection can increase the risk of HIV transmission as the virus tends to shed more effectively when there is an open sore or genital ulcer [48]. This is especially critical among drug users who tend to engage in increased risky sexual behavior

and acquire such concomitant infections that increase the spread of HIV infection if it is already present.

82.4 HIV Infection: Clinical Considerations

HIV causes immune suppression through attacking the body's white blood cells, in particular CD4 T cells. Reductions in CD4 cell counts leave an individual with a weakened immune system and at increased risk for opportunistic infections or cancers. In the first 2–4 weeks following acquisition of the virus, known as the acute stage, symptoms of HIV infection can mirror those of a flu-like illness, with sore throat, fever, chills, and swollen lymph nodes [58]. In a drug user with significant risk factors for disease acquisition, such a presentation should prompt consideration of testing for HIV infection (as well as HCV testing as co-infection will likely be present), with clinical assays for viral detection being positive even at this very early stage. This could allow for immediate initiation of HIV treatment, not only to preserve the patient's immune system but to reduce the amount of HIV in the circulation of an individual who, having recently acquired the infection, is likely engaged in risk behaviors for its onward transmission.

The acute phase is followed by a long asymptomatic period, which may go on for a decade or more. In a drug user of unknown HIV status, this may offer a unique opportunity to establish a diagnosis and initiate antiretroviral therapy as appropriate [58]. Current clinical guidelines suggest that all HIV-infected patients should receive such therapy and that ongoing drug use is not a contraindication to its prescription. Some individuals may naturally never progress to full-blown acquired immunodeficiency syndrome (AIDS) and they are a small percentage (1–5%) of individuals known as "non-progressors." For all others, if left untreated, progression from HIV to AIDS generally occurs within 10–12 years. Progression to AIDS is characterized by a CD4 cell count below 200 cells/mm^3 [10]. From the time of diagnosis of AIDS, mortality generally occurs within 2–3 years.

The advent of highly active antiretroviral therapy (HAART) in 1996, consisting of three medications inhibiting HIV replication administered simultaneously, led to a dramatic decrease in HIV-associated morbidity and mortality. Over the past 20–25 years, treatments have become more effective, simpler, and with few (if any) short- and long-term side effects. Today the life expectancy of an HIV-infected individual adherent to treatment approaches that of the general population [53].

Current regimens that are recommended as part of the initial therapeutic approach generally consist of two nucleoside reverse transcriptase inhibitors (NRTIs) administered with a third agent, most often an integrase strand transfer inhibitor (INSTI). The current preferred combinations, as outlined by the widely accepted US Department of Health and Human Services academic panel, are shown in Table 82.2. For all of these preferred combinations, observational and controlled clinical trials have shown efficacy of over 90% in achieving and maintaining full virologic suppression (undetectable HIV plasma viral load). This is the necessary prerequisite to controlling immune disease progression, preventing the development of AIDS-related complications, and preventing disease transmission [14]. Selection of regimens for drug users should take into account a number of factors including potential adherence barriers, potential drug interactions, and adverse events, with an emphasis on

Table 82.2 What to start: Initial combination regimens for the antiretroviral naïve patient [58]

Regimen	Single tablet regimen	Randomized clinical trial data
Bictegravir/tenofovir alafenamide/emtricitabine	Yes	Yes
Dolutegravir/abacavir/lamivudine	Yes	Yes
Dolutegravir/tenofovir/emtricitabine	No	Yes
Raltegravir/tenofovir/emtricitabine	No	No

liver-related side effects as the majority of HIV-infected substance users are co-infected with HCV.

All of the recommended regimens shown in Table 82.2 can be taken with or without food, addressing an important logistic consideration for the treatment of substance users. Raltegravir has a lower barrier to resistance and some have recommended it not be used in patients who may struggle with adherence to medications. In fact, some have suggested that alternative regimens based on a protease inhibitor (PI) such as darunavir be used rather than an INSTI-based combination, to reduce the likelihood of treatment failure with resistant viral isolates. Finally, tenofovir-based regimens must be used in the presence of HBV co-infection. Other issues are detailed in a number of excellent guideline documents that are updated regularly [58]. Consultation with an expert in the field of HIV medicine should be considered prior to the initiation of lifelong antiretroviral therapy.

Substance users are also at increased risk for HIV disease progression. Many substance users exhibit low or reduced HIV treatment uptake and adherence. As a result, drug users demonstrate suboptimal treatment outcomes and poor virologic response to HIV treatment. Continued drug use, even intermittently, is also associated with a weakened CD4 cell count response as compared to those free of substance use [35]. Various other additional factors contribute to poor HIV outcomes among drug users, such as homelessness and additional psychiatric comorbidities that may independently hinder adherence to therapy [44]. The resulting suboptimal virologic suppression not only reduces treatment efficacy but may also lead to the development of drug resistance. In this context, it will be important for substance users on HIV therapy to be engaged in care so that monitoring of adherence and virologic suppression can be conducted on an ongoing basis. As such, regular monitoring of HIV plasma viral load should be conducted on a quarterly basis at a minimum, more frequently if there are concerns about adherence to therapy.

Substance users living with HIV have a threefold increased risk of death compared to other populations [36]. HIV-/AIDS-related deaths remain the leading cause of mortality in this group. Injection drug use can also decrease the immunological and clinical response to therapy, accounting for part of this observation. Continuous drug use also results in increased risk for opportunistic infections due to the compounding effects of drugs on the immune system of immunocompromised individuals, leaving HIV-infected drug users at increased risk for fatal infections. According to the World Health Organization, nearly one third of AIDS-related deaths are caused by tuberculosis infection, accounting for over 300,000 deaths in 2018, many in substance users who may not be aware of their co-infection status until advanced clinical symptoms develop. HIV-infected substance users are also at increased risk for psychiatric comorbidities and suicide-related mortality. HIV-positive individuals with a history of substance use demonstrate increased rates of suicide [27]. HIV-infected substance users are also overrepresented within the epidemic of overdose deaths, particularly in North America. According to the United States Centers for Diseases Control, overdose deaths among HIV-infected individuals increased by nearly 43% between 2011 and 2015. Increased availability of synthetic opioids and decreased metabolic clearance (due to liver disease) among HIV-infected drug users are considered a major contributing factor to this rapid increase, in addition to a higher prevalence of risky behaviors within this group.

Treatment in HIV substance users requires a multidisciplinary approach in which the individual's medical, social, psychiatric, and addiction-related needs can be addressed in an integrated manner. Peer support, counseling, directly observed treatment, and incentives have been demonstrated as tools to overcome barriers to effective HIV treatment. Co-location of HIV and addiction care has been proven to be an effective tool in addressing HAART adherence and monitoring disease progression. Previous studies have demonstrated the benefits of methadone maintenance therapy (MMT) in HIV treatment adherence and maintenance

[55]. MMT and other opioid agonist therapy (OAT) options have also been demonstrated to be effective tools in primary HIV prevention. Providing harm reduction services is also of critical importance in preventing overdose-related mortality among HIV-infected substance users. A scale-up of multifaceted and integrated treatment approaches are not only the key to success of programs to treat HIV but will also contribute to a more successful approach to the management of addiction itself, including a reduction in the stigma associated with it.

The Joint United Nations Program on HIV/AIDS has set out the 90-90-90 goal for the management of HIV infection in the world, such that 90% of infected individuals are diagnosed, 90% of these linked to care and taking antiretroviral therapy, and 90% of those on therapy exhibit a maximal response to it. However, among substance users in many jurisdictions, suppression rates (the "third" 90%) of 50% or less are achieved [4, 9]. There are many correlates of this lack of success. These include ongoing drug use and poor social conditions, including homelessness. Introducing and scaling-up of evidence-based interventions into the community is critical in addressing HIV among drug users. Interventions such as needle and syringe exchange programs, OAT, and addiction recovery programs must be considered part of the overall approach to HIV infection in substance users. Recent data also show that the provision of HIV pre-exposure prophylaxis (PrEP) to uninfected individuals, shown to be highly effective among men who have sex with men, may also have a role to play among high-risk drug users who are not infected with HIV but are at risk of becoming so. The role of the healthcare practitioner has been stressed as an important tool in mitigating the HIV syndemic among drug users through increased screening and engagement in care [8]. In addition, the design of multidisciplinary programs of care (described below) to attend to the individual's need in a holistic manner may be the key to successful long-term interventions.

82.5 HCV Infection: Epidemiologic Considerations

It is thought that over 71 million people are productively infected with HCV throughout the world [6]. Most people acquired the disease as a result of substance use, with injection drug users being 50 times more likely to become infected as compared to the general population [39]. Most exposure occurs through sharing of needles and syringes, but infection may also occur through pipes, cookers, and other substance use equipment if it is contaminated with blood. In 2014, of the estimated 12 million injection drug users worldwide, six million of those had chronic hepatitis C [41]. According to the World Health Organization, there are about 1.75 million new HCV infections in the world each year, with injecting drug use accounting for 23% of new cases [60]. This is the driving force maintaining this worldwide pandemic. The first few years of injection behavior are particularly important, with up to 40% of individuals acquiring HCV infection during this period of time. In some drug using groups, such as a cohort of drug injectors in St. Petersburg, Russia, prevalence of HCV infection may exceed 90% [43]. Although many people clear the virus spontaneously, as many as 85% will remain productively infected and at risk for the development of cirrhosis and hepatocellular carcinoma (HCC).

Among substance users, a number of factors are associated with the acquisition of HCV infection. The duration of drug use is a key factor, with a meta-analysis showing a 2.4-fold increase in the prevalence of infection with duration of drug use exceeding 5 years [62]. Injection drug use itself confers a tenfold increase in risk of transmission, attesting to the central role played by the injection behavior itself [62]. Sharing of needles/syringes carries a 2.24-fold increase in risk, speaking to the possible benefit of equipment exchange programs in controlling disease spread [62]. A number of social factors play a role, with unemployment, as an example, carrying an independent risk of disease transmission of 1.5-fold [62]. It is likely that other factors such as financial and housing insecurity may be important. Recent incarceration is another key issue, with a meta-analysis showing a

62% increase in HCV acquisition among injection drug users associated with this variable [51]. Finally, it is important to point out the overlap of the HIV and HCV epidemics in the world. An estimated 2.2 million people are co-infected with HIV and HCV and over half of these cases are in people who inject drugs, a fact that must be considered as they are engaged in active medical care.

82.6 HCV Infection: Clinical Considerations

The first 6 months of HCV infection are referred to as acute HCV infection, which is asymptomatic in two-thirds of cases. If symptoms do occur, it will typically occur over a broad period of time after exposure, between 2 weeks to 6 months and usually within 8 weeks. The most common symptoms are jaundice, dark urine/pale stools, nausea, and abdominal pain. In a substance user engaged in care with any or all of these clinical manifestations (particularly jaundice), testing for the presence of HCV infection should be considered. As it may take several months for a positive HCV antibody test to develop, HCV RNA testing should be requested as it is generally positive within weeks of the infection having been acquired. HIV antibody testing should also be requested as 20–25% of individuals may be co-infected. Globally, it is estimated that 9.1% of people who inject drugs are productively infected with HBV, with great geographical variation [13]. It would also be indicated to test for the presence of HBV infection in this context.

Once HCV infection has been diagnosed, the patient must be monitored to determine the outcome of infection, either spontaneous viral clearance or chronic productive infection. Estimates of the frequency of spontaneous clearance vary from 15% to 45% [60]. If this occurs, individuals who continue to use drugs remain susceptible to infection upon re-exposure to HCV and should be re-evaluated accordingly. Some guidelines suggest HCV treatment be considered in patients who have HCV RNA values that remain detectable 12 weeks after the suspected date of exposure. In this setting, a shorter course of treatment may be considered (perhaps only 6 weeks) with a cure being achieved in more than 95% cases. This should only be considered in consultation with a specialist in HCV therapy.

Once chronic infection is established, it is generally asymptomatic for many years. Patients remain viremic and at risk of transmitting the infection to susceptible hosts. Compared to uninfected patients, those with chronic HCV infection are more likely to die at a younger age and from liver-related causes. Disease progression rates among substance users have been well studied. On average, cirrhosis occurs 34 years post-infection, with compensated cirrhosis occurring at 6.6 events/1000 PYs and decompensated cirrhosis at 1.8 events/1000 PYs [50]. HCC occurs at a rate of 0.3 events/1000 PYs [50].

Until 10 years ago, treatment of HCV infection was complex and toxic, with marginal efficacy. The regimen was as long as 48 weeks in duration, including weekly interferon injections, and was curative in only 50% of cases for the most common genotype. Highly effective, well tolerated all-oral agents known as direct-acting antivirals (DAAs) are now the treatment of choice for the vast majority of HCV-infected individuals (Table 82.3). Controlled clinical trials have shown

Table 82.3 Currently available all-oral treatment regimens for the management of HCV infection and their reported efficacy among substance users

Drug name	Genotypes	Studies in substance users	SVR12 (cure) rate
Sofosbuvir/velpatasvir	All genotypes	SIMPLIFY (Ref. [24])	94%
Sofosbuvir/velpatasvir/voxilaprevir	All genotypes	None	—
Glecaprevir/pibrentasvir	All genotypes	MISTRAL (Ref. [45])	98%
Elbasvir/grazoprevir	1, 4	C-EDGE CO-STAR (Ref. [15])	91.5–94%
Ledipasvir/sofosbuvir	1, 4, 5, 6	None	—
Ombitasvir/paritaprevir/ritonavir and dasabuvir	1	D3FEAT (Ref. [23])	91%

them to produce a cure of HCV infection (defined as the absence of detectable HCV RNA in the blood 12 or more weeks after the end of therapy, known as a sustained virologic response, or SVR12) in 95% or more of cases. Several studies including C-EDGE CO-STAR, D3FEAT, and SIMPLIFY, as well as subset analyses of other clinical trials, have examined the use of DAAs in substance users and/or those receiving OAT. These studies have demonstrated high completion and SVR12 rates in these populations [26]. There have also been many "real-world" reports of the successful treatment of HCV infection among substance users. A meta-analysis of DAA treatment studies in substance users reported an overall cure rate of 87.7% [28]. There is great concern about the risk of HCV re-infection after a cure has been achieved in this population. A systematic review found that low-risk patients had a re-infection rate of 1.85/1000 person-years of follow-up (PYFU), while high-risk patients including injection drug users and prisoners had a rate of 22.32/1000 PYFU [49]. In some centers such as ours, the re-infection rate in substance users is as low as 1.05/100 PY [30]. If HCV treatment is contemplated, measures should be taken to mitigate the risk of re-infection as much as possible. Part of the approach includes maintenance of the patient in long-term follow-up. This allows for ongoing discussion of how to reduce risk behaviors for HCV acquisition and to perform repeat HCV RNA testing every 6–12 months to diagnose and treat HCV re-infection at the earliest possible time.

The World Health Organization has set a goal of eliminating HCV infection as a part of the Sustainable Development Goals by 2030 [59]. Active substance users who are infected have been prioritized to receive HCV treatment, not only to cure their own infection but to limit onward transmission of infection in this population that is, essentially, sustaining the HCV epidemic in the developed world. To date, less than 1% of people with HCV have been treated [25]. There is an urgent need to develop systems of care to engage and treat this population in the context of a global HCV elimination plan.

82.7 Selected Bacterial Infections in Substance Users

Acute bacterial infections are commonly seen among substance users. Their pathogenesis relates to direct introduction of pathogens into the skin or bloodstream from contaminated needles, syringes, and other drug paraphernalia. They are a frequent cause for a substance user to seek medical attention, due to the symptoms that may occur. Although often treated with oral antibiotics and local drainage, a systemic infection may occur and produce life-threatening sepsis. Seeding of distant structures including bones, joints, and heart valves is not uncommon and adds to the potential morbidity and complexity of treatment of the infection.

82.7.1 Cellulitis and Abscesses

Skin and soft tissue infections (SSTIs), which include cellulitis and abscesses, are the most frequent infectious complication of substance use. In Tehran, Iran, 40% of injection drug users interviewed reported ever having an injection site infection [42], while a study conducted within two American needle exchange programs found 66% of attendees had experienced an SSTI [52]. In England, a study on hospitalizations caused by infections in opioid users from 1997 to 2016 found 35% of injecting-related admissions were due to abscess and 23% were attributed to cellulitis [34]. However, hospitalizations may not reflect the full extent of SSTIs as many individuals attempt self-treatment [21]. In a study of injection drug users in San Francisco, 27% reported lancing their own abscesses and 16% reported using antibiotics without a prescription [5].

Intramuscular or subcutaneous injection, also called "skin-popping," and the injection of a heroin and cocaine mixture (speedball) have both been associated with an increased risk of abscesses [5, 40]. The most frequent causative agent for SSTIs in substance users is *Staphylococcus aureus*, particularly methicillin-resistant *S. aureus* (MRSA) [32]. Other bacteria

commonly found are streptococci, anaerobic bacteria such as *Fusobacterium* spp., and Gram-negative bacilli such as *Pseudomonas aeruginosa* [16, 32]. Many other bacteria, including ones not commonly associated with infections, can be found in SSTIs in injection drug users, and polymicrobial infections are quite common. The oral bacterium *Eikenella corrodens* is a facultative anaerobe and has caused SSTIs after drug users have licked needles or other injection equipment [16]. In some cases, spore-forming bacteria such as *Bacillus anthracis* and *Clostridium* spp. have been injected, leading to cases of tetanus, anthrax, or wound botulism [32].

The diagnosis of cellulitis or an abscess is usually made upon visual inspection, although for abscesses sometimes CT or MRI scans may be required [16]. The infected site is typically painful and displays erythema and tenderness. It is sometimes accompanied by fever. Both cellulitis and abscesses require antibiotic treatment, and abscesses generally must be drained. Complications of cellulitis and abscesses may include ulcer development, necrosis, and sepsis.

82.7.2 Endocarditis

Infective endocarditis is another common infectious complication of substance use, with estimates ranging from 1.5 to 20 cases per 1000 injection drug users annually [19]. Its incidence is also increasing in substance users, with a study on opioid users in the United States showing a significant increase in hospitalizations from 2002 to 2012, likely related to limited availability of sterile injection supplies [47]. At a Swedish hospital, the incidence rate of *S. aureus* endocarditis related to injection drug use doubled over the course of 10 years, from 0.52/100,000 PYs in 2004–2008 to 0.99/100,000 PYS in 2009–2013 for all adults, with an estimated rate of 249/100,000 PYs in injection drug users in Stockholm [3]. In the general population, left-side endocarditis is predominant, while in injection drug users up to 76% of cases are right-side endocarditis [19]. The difference is likely due to intravenously injected substances reaching the right-side valves first, leading to endothelial damage and/or the aggregation of microbes on the right side of the heart.

Cocaine has a stronger association with endocarditis than other drugs, which may be due to its physiological effects on the circulatory system including vasospasm leading to vasoconstriction and ischemia, along with more frequent injections when compared to heroin due to the shorter half-life of cocaine [19, 21]. The major bacterial causes of endocarditis in substance users are *S. aureus*, streptococci, *P. aeruginosa*, and other Gram-negative bacilli and enterococci, although many other species have been isolated. *S. aureus* accounts for half of the cases involving the right-side tricuspid valve in injection drug users [19], although notably most *S. aureus* involved in endocarditis is methicillin-sensitive. Patients with endocarditis often present with a fever, cough, and chest pain [38]. Antibiotic treatment is vital and surgical intervention may be necessary in some cases, although ongoing injection drug use may complicate the long-term viability of prosthetic valves. Mortality from endocarditis ranges from 5% to 30%, although this risk does not seem to increase in substance users, perhaps because of the inherent lower mortality of right-side endocarditis [38].

82.7.3 Osteomyelitis

Osteomyelitis, or infection of the bone, is an emerging concern in substance users, with one study demonstrating a twofold increase in hospitalizations for osteomyelitis among opioid users from 2002 to 2012 in the United States [47]. The majority of infections are located in the appendicular skeleton, while 2–7% of cases occur in the axial skeleton, although there is evidence that the latter is more common among injection drug users [22, 31]. Osteomyelitis may occur from the spread of SSTIs to the bone or by hematogenous dissemination of bacteria.

S. aureus is the major causative agent of osteomyelitis in this population, with other commonly isolated organisms including *P. aeruginosa* and streptococci [31]. As with SSTIs, less common

etiologic agents (such as *E. corrodens* and other oral bacteria) may be isolated [31].

Osteomyelitis may be difficult to diagnose, particularly when the underlying bone has become infected from an abscess or other SSTI that was initially treated with a shorter course of antibiotics not suitable in duration for a deeper-seated infection. Imaging of the affected area by CT or MRI scan may be needed to make a specific diagnosis. Long courses (typically 6 weeks) of antibiotic therapy are required, and in some cases, surgery is required to remove an infected sequestrum.

82.7.4 Epidural Abscesses

Once considered quite rare, epidural abscesses are increasingly recognized as an infectious complication of substance use. For example, at a tertiary care center in Massachusetts, USA, spinal epidural abscesses significantly increased from 2.5/10,000 admissions in 2005 to 8.0/10,000 admissions in 2015 [2]. Another study in the United States found the number of hospitalizations for epidural abscess in opioid users more than doubled from 2002 to 2012 [47].

The vast majority of epidural abscesses are caused by infections that have spread through the blood from distant infected locations, with one risk factor being a history of localized blunt spinal trauma [54]. A limited number are caused by direct injection of contaminated material. As with other bacterial infections among substance users, the major causative agents are *S. aureus*, streptococci, and Gram-negative bacilli [54].

While back pain is extremely common among substance users and usually quite benign, it is important to consider the possibility of an epidural abscess in patients complaining of back pain, as early diagnosis is key for limiting mortality or long-term sequelae. Patients present with localized pain in the vertebrate in 70–100% of cases, often accompanied with back tenderness and sometimes with fever [7]. Surgical drainage is typically required in combination with antibiotics, perhaps as long as 12 weeks' duration. In some patients where surgical drainage is not possible, antibiotic therapy alone may be used, which may include longer-term prophylactic regimens. If the infection progresses, neurological deficits may occur. Despite all appropriate interventions, the mortality rate of an epidural abscess is approximately 10% [22].

82.7.5 Prevention of Bacterial Infections

The sources of bacterial infection relate to the use of non-sterile drugs and diluents, as well as exposure to the substance user's own microflora during drug use. Harm-reduction strategies are key to reducing the occurrence of such infections. Expanding access to OAT and needle and syringe programs can limit needle sharing and needle reuse and therefore the introduction of microbes. Instruction about sterile injection practices as well as the risks associated with polysubstance use, skin popping, and needle licking may also be helpful.

82.8 A Multidisciplinary Approach to the Care of Infections Among Substance Users

The needs of an individual who is using/injecting drugs are complex and go well beyond the substance use itself. These include many medical, psychiatric, and social concerns, in addition to the addiction-related issues. In designing systems of care to optimally manage potentially life-threatening complications of substance use, a multidisciplinary program of engagement is required. If we think of a "four-legged chair" that will define a patient's needs in a rigorous and systematic way, specific plans of intervention must be developed for each relevant condition. In committing to a plan to deal with the imperatives the patient defines as most important, adherence to treatment regimens that could be life-long (as in the case of HIV infection) could be improved. Addiction-related interventions could also be optimized to allow for safer drug use on the one hand and perhaps commitment to recovery on the other (Fig. 82.1).

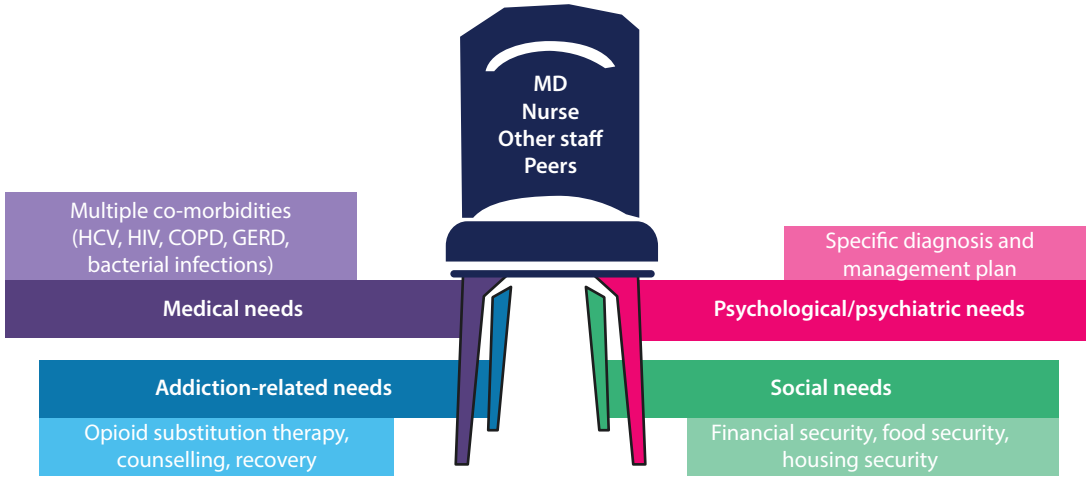

Fig. 82.1 A multidisicplinary program of engagement in care is the key to the long-term management of vulnerable substance users. This can be depicted as a fourlegged chair, to illustrate the need to address medical, psychologic, social, and addiction-related aspects of care [29]

We have designed such a program focused on providing multidisciplinary care. This model aims to address all patient-related needs in an integrated setting. We offer weekly support groups; assistance with housing, income assistance, and nutritional supplement applications; snacks; and education workshops, in addition to medical clinic services with infectious disease specialists. We hold weekly community pop-up outreach events, in which we go to various community sites to provide point-of-care HCV and HIV testing, immediate medical consultation for those who test positive, and linkage to care with incentivized appointment attendance. Our center follows the "three pillars" motto in which we aim to provide engagement, multidisciplinarity, and durability. The engagement pillar entails immediate consultation with a healthcare specialist along with the design of a relevant treatment plan. The second pillar of multidisciplinary ensures that all the patients' needs are addressed in a flexible and accountable manner. Lastly, through the pillar of durability, we strive to ensure a low threshold to care, with incentives for long-term engagement and strategies to mitigate loss to follow-up. Through our program we have been able to provide curative HCV treatment to over 500 substance users as well as lifesaving antiretroviral treatment to over 450 HIV-positive individuals. Our program has had a significant impact on opioid-related deaths. In one analysis, based on local opioid-related deaths, we should have expected over 80 deaths over a period of 18 months in our population, while we have only observed eight. We feel that the engagement we provide leads to safer drug use and a greater commitment to recovery. It is important to note that the initial encounter that led to the design of a durable, multidisciplinary plan of care for a given individual was often an infectious complication of addiction, perhaps something as simple as a bacterial skin infection.

In the practice of addiction medicine, it is essential to individualize and optimize the care plan to manage substance use and the addiction itself. It is equally important to have a systematic program in place for HIV and HCV screening given the prevalence of these two chronic and treatable conditions in this population. In those found to be uninfected (as well as in those who have been cured of HCV infection and exhibit risk behaviors for repeat exposure to the virus), this screening must be incorporated into the long-term management of substance users. In addition to this, an evaluation for the presence of an infectious complication must be incorporated into each clinic visit. Many conditions are easily treated, while some may be life-threatening and may require urgent referral for specialist evaluation.

82.9 Conclusion

Infectious complications of substance use are common and have a significant morbidity and mortality. Addressing them in a systematic manner will be an important part of a worldwide response to the two great pandemics of this era, namely, HIV and HCV infections. Serious bacterial infections are also common in this population. Particular attention must be given to the diagnosis and treatment of these infections when substance users present for medical care. Ultimately, the approach must be a holistic one, based on three pillars: engagement, multidisciplinarity, and durability. If we treat substance users as complex human beings with multiple needs, not only will we treat their infections more effectively, we will also help them become better functioning members of society. This must be our ultimate goal.

Abstract

The overall concept and aim of this chapter is to provide a basic sleep medicine "crash course" with a specific goal of describing a practical approach to treating the patient population afflicted with substance dependence and concomitant sleep complaints.

A sleep medicine overview will be provided, with specific emphasis on sleep physiology, nosology, and psychiatric and addictive disorders associated with sleep concerns. Also, an overview of a diagnostic approach in addiction to treatment options will be presented. The treatment of sleep disorders with both pharmacotherapy and cognitive behavioral therapy approaches will be offered.

The often-heard complaint from our patients of "Doctor, I can't sleep" is not a simple problem, but requires a simple yet comprehensive approach. The addicted population is unique and a unique "skill set" is required from clinicians treating this population.

Treatment settings vary, and the question of "who is going to do what" is important and needs to be clarified prior to approaching optimal treatment strategies. Some treatment settings include physicians from various specialties, sleep specialists, psychologists, therapists, program social workers, and other health professionals. Invoking a multidisciplinary team approach to the diagnosis and treatment of sleep disorders and "insomnia" in particular is crucial.

An evidence-based approach is of paramount importance as we move to superior clinical paradigms and one that should be kept in mind throughout this process.

One can utilize a "sleep assessment package" which should include intake questionnaires, sleep diaries, and other structured assessments. Informed choice of medications for "insomnia" when pharmacotherapy is deemed necessary is required, and this chapter offers practical guidelines and describes other available resources.

It is advisable to screen all patients for primary sleep disorders (i.e., obstructive sleep apnea or periodic leg movement/restless legs disorder), first clinically, and then with sleep studies if indicated. And lastly it is important to link with local sleep clinics or specialists when possible to avail yourself and your patients of a specialist perspective when needed.

83.1 Introduction

People who abuse alcohol and other substances are at high risk for sleep disturbances due to the direct effect of the substance and/or its discontinuation on their sleep. Also, their sleep-wake cycle and its effect on their behavior and daily functioning in-turn impact their daily need for subsequent sleep. Those with substance abuse disorder are 5–10 times more likely to have sleep disorders [26].

83.2 Sleep Disorders

83.2.1 Incidence

It is estimated that up to one third of the adult population have occasional sleep problems. Of these, one third has chronic "insomnia" as a presenting complaint. For example, between midnight and 3 a.m., it has been estimated that on any night, two million Canadians from the total population of 35 million are awake watching television. Many professionals in our current society (including doctors, nurses, EMS workers, and police) work irregular sleep-wake schedules or shift work, often leading to sleep disturbance. Compared with the population at the turn of the century, we are now sleeping 1.5 h less per 24-h period. Epidemiological studies show that EDS (excessive daytime sleepiness) in Westerners is between 5% and 36%. The number one cause of excessive daytime sleepiness is insufficient sleep due to reduced opportunity or ability to sleep given adequate opportunity. In any given year, 20–40% of adults complain of difficulty sleeping and 17% consider it serious [29]. The majority remain unrecognized and untreated. It has been estimated that the average family MD asks two questions before offering a prescription medication to deal with "insomnia." In addition it is well known that many medical school curricula do not spend adequate time in educating young doctors in the area of sleep medicine.

83.2.2 Implications and Consequences of Sleep Problems

There are multiple very well publicized examples of the consequences of sleep insufficiency and the resulting fatigue and excessive daytime sleepiness. Excessive sleepiness has been implicated in the following world catastrophes: Exxon Valdez oil spill, Three Mile Island nuclear accident, Chernobyl nuclear plant disaster, Bhopal chemical explosion in India, and the US Space Shuttle Challenger explosion.

Sleep deprivation studies in animals have clearly shown that "sleep is necessary for survival" [34]. In 1965, a 17-year-old college student tried to set a new world record for staying awake. The resulting clinical scenario was one of frequent micro sleeps, visual and auditory hallucinations, tachycardia, hypotension, psychosis, and profound weakness at 264 h and 12 mins (11 day, 12 mins). Interestingly, he fully recovered after sleeping 14 h and 40 min, just as the Rechtschaffen rat studies.

Sleep-deprived people have nearly as many car accidents as drunk drivers and double the rate of car accidents as the general population. Sleep-deprived people have a higher incidence of infection and other illnesses, as sleep acts as a "host defense" against infection and facilitates the healing process. Sleep plays a critical role in memory consolidation. Disturbed or reduced sleep can have an effect on cognitive functions such as learning and decision-making [9].

Sleep disorders medicine, from a historical and international perspective, is a relatively new field and one which many countries have little access to. The field largely began at Stanford University in 1970 and, as an example, is approximately 25 years old in Canada. In 1981 with the introduction of CPAP (continuous positive airway pressure used to treat obstructive sleep apnea), the field grew exponentially. There are currently available fellowship programs and board certification via the American Board of Sleep Medicine.

83.2.3 NPSG and MSLT

Most sleep laboratories in North America deal primarily with respiratory-related sleep disorders, such as obstructive sleep apnea (OSA), with a significant number providing the full range of sleep disorders diagnosis and treatment. Sleep specialists' backgrounds differ widely and range from those whose primary training is in psychology, general medicine, pulmonology, neurology, and psychiatry, and many then become board certified in sleep disorders medicine as well.

The PSG (polysomnogram, sleep study) is complex and labor intensive, often generating volumes of information which would be equal to 1000 pages of data. A typical overnight sleep study monitors EEG (electroencephalogram), EOG, (electrooculogram), chin EMG (electromyogram), EKG, respiratory effort (chest and abdominal movements), oxygen saturation, and leg movements (EMG), all using noninvasive leads. Some centers also perform daytime MSLTs (multiple sleep latency tests) in diagnosing narcolepsy and documenting excessive daytime sleepiness and MWT (maintenance of wakefulness tests) used in documenting treatment efficacy for the excessive daytime sleepiness associated with a number of sleep disorders.

83.3 Sleep Physiology

83.3.1 Normal Human Sleep

The exact function(s) of sleep is still not precisely known. The "normal" amount of sleep that a healthy adult individual needs is 7–8 hrs and that amount may vary with age or when one is ill or stressed [9]. It is estimated that 20% of the population regularly sleeps less than 6 h and 10% sleeps 9 h or more (long sleepers).

Sleep is characterized by different EEG signals that range from active wake patterns of beta waves to relaxed states with eyes closed and alpha waves. Deeper sleep, defined by higher arousal threshold, is associated with slow theta and high amplitude delta waves. There are two types of sleep: REM (rapid eye movement) and NREM (non-REM). Thus, sleep is not a homogeneous state, but rather a combination and cycling of these two separate and distinct states. These distinct states are characterized by specific behavioral and physiologic changes that occur during these phases of sleep.

83.3.2 NREM

NREM sleep is divided into three stages: stage N1 with low-amplitude mixed-frequency waves (predominantly in the 4–7 Hz theta frequency) and slow rolling eye movements, stage N2 typified by theta frequency waves and the presence of EEG features known as "sleep spindles" and "K-complexes," and stage N3 featuring the emergence of slow (0.5–2 Hz) delta frequency waves. Arousal thresholds are generally lowest in stage N1 and highest in stage N3 sleep.

83.3.3 Rem

Even without any instruments, we can tell if someone is in REM sleep by looking at the movements in their eyes, even when closed. In REM, we will often report dreaming when awakened. Alpha motor neuron activity is suppressed through a number of inhibitory pathways, and our skeletal muscles are paralyzed. REM periods typically occur every 90–120 min, with each successive REM phase getting longer in duration: first, 5 min; second, 10 min; and third, 15 min. Blood flow is directed to the brain (active) and the EEG pattern is that of low-amplitude, mixed-frequency waves, often with the presence of distinct waves with a sawtooth appearance. REM sleep accounts for 20–25% of sleep.

NREM sleep accounts for 75–80% in adult humans and is further divided in three stages, based on EEG criteria:

- Stage N1 sleep ➔ 3–10% of total sleep time
- Stage N2 sleep ➔ 45–55%
- Stage N3 sleep ➔ 15–20%

Sleep normally cycles through the various stages as follows: generally stage N1 ➔ stage N2 ➔ stage N3 ➔ stage N2 ➔ REM ➔ stage N1, N2, or N3. A full sleep cycle consists of a sequence of NREM and REM sleep, typically lasting approximately 90–120 min, and there are generally 4–6 cycles per night. The first two cycles are dominated by SWS (slow-wave sleep), and REM sleep increases as the night progresses, dominating the last 3–5 cycles.

Sleep patterns also change throughout our lifespan, with sleep occupying two thirds of a human newborn's time and REM sleep occupying one half

of total sleep time [9]. The percentage of REM declines rapidly in early childhood, and by the age of 1, the adult percentage of REM sleep is achieved. SWS is minimally present in the newborn but rapidly increases to reach maximum by the age of 10, remaining stable into the 20s and then declining. Arousals during sleep also increase with age.

83.4 Classification of Sleep Disorders

83.4.1 ICSD

The International Classification of Sleep Disorders (ICSD) is a "primary diagnostic, epidemiological and coding resource for clinicians and researchers in the field of sleep medicine" [1], now in its third edition.

The ICSD was published with the goal of standardizing definitions of sleep disorders and creating a systematic approach to diagnosis. It is widely used by clinicians and researchers worldwide, improving research efforts throughout the international community by adhering to a recognized set of standards. The ICSD-3 outlines the following goals:

1. To describe all currently recognized sleep and arousal disorders and to base the description on scientific and clinical evidence
2. To present the sleep and arousal disorders in an overall structure that is rational and scientifically valid
3. To render the sleep and arousal disorders as compatible with ICD-9 and ICD-10 as possible

As a result the ICSD-3 includes 60 specific diagnoses within seven major categories:

1. Insomnia disorder
2. Sleep-related breathing disorders
3. Central disorders of hypersomnolence
4. Circadian rhythm sleep-wake disorders
5. Parasomnia
6. Sleep-related movement disorders
7. Other sleep disorders

83.4.2 Insomnia

Studies of insomnia have been hampered by wide-ranging definitions of the disorder, putting the prevalence rate between 4% and 48% depending on the definition used and sample studied.

The ISCD-3 criteria for insomnia disorder include a report of sleep initiation or maintenance problems, despite adequate opportunity and circumstances to sleep, and daytime consequences. Both the ISCD-3 and the DSM-5 specify a 3-month duration of the sleep problem, as well as a minimum frequency of 3 times a week. However the DSM-5 and ISCD-3 differ in how they classify sleep disturbance in substance use disorders. In DSM-5, insomnia is classified as comorbid with SUD if occurring beyond immediate use of the substance (prior to and after the discontinuation of substance use).

In ICSD-3, a subtype of insomnia is "insomnia due to drugs or substances." The ICSD-3 is making a somewhat stronger causal inference regarding the relation between substance use and sleep disturbance.

Insomnia is an expected aspect of many medical and psychiatric conditions and is the most common sleep diagnosis associated with SUD. Treatment for insomnia occurring with SUD will be discussed later in this chapter.

83.4.3 Other Sleep Disorders

83.4.3.1 Sleep-Related Breathing Disorders

1. Sleep-related breathing disorders are divided into four types: obstructive sleep apnea (OSA), central sleep apnea (CSA) syndromes, sleep-related hypoventilation disorders, and sleep-related hypoxemia disorder. OSA is one of the most common sleep disorders and is caused by partial or complete obstruction of the upper airway. A diagnosis of OSA is evaluated using a PSG or home sleep test and requires 15 or more obstructive events (hypopneas, respiratory event-related arousals, or obstructive or mixed apneas) per hour for severe OSA or ≥ 5 to ≤ 14 for patients with

mild OSA. Symptoms of OSA include excessive daytime sleepiness, observed episodes of breathing cessation during sleep, abrupt awakenings, and loud snoring.

Specific consequences of OSA include high blood pressure, cardiac arrhythmias, cerebrovascular accidents (stroke), myocardial infarction, erectile dysfunction, and fatalities from driving while excessively sleepy. Psychological consequences of sleep apnea include depression and anxiety.

OSA treatments may include weight loss, positional therapy, PAP (positive airway pressure), or surgery.

83.4.3.2 Circadian Rhythm Sleep-Wake Disorders (CRSWD)

1. According to the ISCD-3, this category of disorders includes conditions in which sleep timing is out of alignment with the light-dark cycle. Criteria for CRSWDs include:
   (a) Chronic or recurrent pattern of sleep-wake rhythm disruption primarily caused by an alteration in the endogenous circadian timing system or misalignment between the endogenous circadian rhythm and the sleep-wake schedule desired or require
   (b) A sleep-wake disturbance (i.e., insomnia or excessive sleepiness
   (c) Associated distress or impairment

   CRSW disorders include delayed sleep-wake phase disorder, advanced sleep-wake phase disorder, irregular sleep-wake rhythm disorder, non-24-h sleep-wake rhythm disorder, jet lag, and shift work disorder. Drug use may affect homeostatic and circadian processes involved in sleep-wake regulation. Research on circadian factors linked to drug use has been neglected largely due to attributing the disorder to lifestyle factors, such as erratic sleep schedules and all-night drug binges. However, some studies suggest alcohol consumption leads to moderate melatonin suppression [12, 43], which may also be true for other drugs of abuse. Treatment of CRSWD may include chronotherapy, light/dark exposure, prescription medications, or melatonin.

83.4.3.3 Sleep-Related Movement Disorders

These conditions are characterized by simple movements during sleep and may be associated with excessive daytime sleepiness or insomnia. Drugs like antidepressants and alcohol may exacerbate sleep-related movement disorders.

Periodic limb movement disorder (PLM) is defined by the AASM (American Academy of Sleep Medicine) scoring manual as >15 events/h and must be accompanied by sleep disturbance or other functional impairment.

Restless leg syndrome (RLS) is a disorder of the dopamine system that causes an urge to move the legs. RLS occurs primarily with rest/inactivity, is partially or totally relieved by movements for as long as the movement occurs, and occurs primarily in the evening or night.

Treatment for RLS and PLM usually involves medication that either reduces the movements or helps the individual sleep through the movements. Medications include benzodiazepines, dopaminergic agents, anticonvulsant agents, opioids, and GABA agonists.

83.5 Psychiatric Disorders and Sleep

Almost all mental disorders, as well as their treatments, can have associated sleep disturbance. Insomnia often sets the stage and is a major risk factor in the development of some psychiatric disorders. If we can treat insomnia, it may protect against significant mental illness.

The following section will aim to provide a brief description of the common sleep disturbance/architecture irregularities seen in those major mental disorders most commonly comorbid with SUD.

Mood Disorders: It has been estimated that 90% of cases of major depression have associated symptoms of insomnia or hypersomnia are among the diagnostic criteria. Patients with major depression complain about difficulty fall-

ing asleep, increased awakening during the night, early morning awakening (a unique characteristic), and un-refreshing sleep. While a PSG is not generally done unless a primary sleep disorder is suspected, the PSG reveals unique features including reduced slow-wave sleep, shortened latency to REM sleep, increased REM sleep especially in the first part of the night, and increased density of eye movements per REM time. These are all markers of increased REM pressure. Antidepressants are virtually all REM suppressants and treatment is associated with normalization of these PSG abnormalities.

Generalized Anxiety Disorder (GAD): Patients with GAD report difficulty falling asleep, maintaining sleep, and restless sleep; again these are among the diagnostic criteria. But, the worry of GAD is nonspecific and differs from insomnia in that it is not focused on sleep. The PSG of GAD is unremarkable with the exceptions that stage 1 may be increased and onset to REM sleep may be delayed, not reduced as in depression.

Posttraumatic Stress Disorder (PTSD): One of the "hallmark" features of PTSD is frequent nightmares and insomnia complaints are also common. The PSG findings are not particularly unique with one exception. Given the prominence of nightmares to PTSD, studies have focused on REM sleep. The findings suggest fragmentation of REM sleep with frequent transitions from REM sleep to stage 1 or wake.

83.6 Role of Sleep Disturbance in Initiation, Maintenance, and Relapse in Substance Use Disorders

In some cases insomnia may precede the presence of drug use. Alcohol and marijuana are frequently used to initiate sleep. New emerging data also suggest that an age-corrected deficiency in slow-wave sleep, possibly premorbid, is associated with the likelihood of use of alcohol as a sleep aid. Alcohol does initially enhance slow-wave sleep in the presence of a deficiency [38, 40]. Tolerance to these "beneficial" drug effects develops leading to increased use.

In those who abuse stimulants, continued stimulant use is reinforced as the alerting effects of the stimulant decreases the sleepiness and fatigue caused by the drug-associated disturbance of sleep, allowing the individual to function on a "normal" level and hence maintaining the stimulant use [5, 6, 37]. In opiate use disorder, based on animal studies, the timing of sleep and wake and NREM-REM cycling is linked to the timing of the opiate self-administration pattern, irrespective of the light-dark cycle [31].

The relationship between sleep and substance use appears to be bidirectional, in that use of drugs or alcohol may directly cause sleep disturbances, and difficulty sleeping may induce relapse to substance use. In alcoholics, disturbed sleep is a significant predictor of relapse and the severity of alcohol dependence and relapse is greater in individuals with insomnia versus those without insomnia at baseline [21]. Higher levels of REM sleep or shortened REM latency predicted relapse within 3 months after hospital discharge in 80% of patients. In other studies, those who eventually relapsed exhibited a higher proportion of REM and a lower proportion of SWS at baseline [37]. The same has been shown in cocaine use disorder; slow-wave sleep deficiency is predictive of relapse.

If sleep problems lead to relapse, then treatment of those problems should improve relapse rates. As yet, behavioral and pharmacological treatments targeting sleep disturbance have not definitively shown that *sleep improvement (treatments are generally associated with sleep improvement)* is associated with relapse reduction.

83.7 Contributing Medications and Substances Causing Sleep Problems

The majority of people with substance abuse or dependence experience some form of sleep disorder. While the effects of alcohol have been most studied, there is sufficient evidence on the direct

Table 83.1 Common medications and substances contributing to sleep problems

Category	
Antidepressants	SSRI (fluoxetine, paroxetine, sertraline, citalopram, escitalopram, fluvoxamine), venlafaxine, duloxetine, MAO inhibitors
Stimulants	Caffeine, methylphenidate, amphetamine derivatives, ephedrine and derivatives, cocaine
Decongestants	Pseudoephedrine, phenylephrine, phenylpropanolamine
Narcotic analgesics	Oxycodone, codeine, morphine, propoxyphene, methadone
Cardiovascular	Beta-blockers, alpha agonists and antagonists, diuretics, lipid-lowering agents
Pulmonary	Theophylline, albuterol

effects on sleep continuity and architecture parameters by a great variety of substances (see Table 83.1 below).

83.7.1 Stimulants

Nicotine, caffeine, amphetamines, and cocaine can all cause increased arousal and disruption of sleep acutely and then subsequently cause hypersomnia and fatigue or sleepiness upon discontinuation.

83.7.2 CNS Depressants

Anxiolytic benzodiazepines, alcohol, and opioids may all cause excessive daytime sleepiness and fatigue acutely, while alcohol and opioids cause insomnia upon discontinuation. The effects of these drugs, as well as their discontinuation, require close monitoring and caution in patients with a history of substance dependence [10].

83.7.3 Opiates

Opiates/heroin causes a decrease in stage 3 and 4 sleep and decrease in REM sleep with frequent awakenings. Discontinuation typically has been shown to cause a REM rebound and more frequent nightmares. Individuals receiving treatment for opiate/heroin dependence using methadone or buprenorphine have shown an increased risk of sleep-related breathing disorders [14, 45].

83.7.4 Alcohol

Acute effects of alcohol intake in the evening include increased sleepiness approximately 30 min after ingestion leading to reduced sleep latency, increased SWS (if a deficiency exits), and decrease in awakenings for the first 4 h but increased awakenings for the last 4 h and an increase in REM sleep [4, 7].

Chronic effects of alcohol use include increased sleep fragmentation and shorter SWS (slow-wave sleep) interrupted by brief arousals. An increase in alcohol intake improves the above symptoms, which typically leads to a worsening problem [23].

Insomnia is a common feature for alcoholism with prevalence rates of 36–72%. Alcohol has also been shown to exacerbate or induce OSA in those at risk (obstructive sleep apnea) [19].

83.7.5 Cannabinoids

Short-term marijuana use results in minimal sleep disruption, characterized by a slight decrease in REM sleep. Chronic use of THC is associated with reduced levels of SWS. During marijuana discontinuation, users show lower total sleep times, less slow-wave sleep, worse sleep efficiency, longer sleep onset, and shorter REM latency when compared to healthy controls [3].

83.8 Diagnosis of Sleep Disorders

The goal of this section is to provide a brief overview of the approach to diagnosis of a variety of sleep disorders, with a specific emphasis to substance use disorder patients. This section will cover initial sleep intake history and physical

examination, sleep diary or log, and sleep questionnaires.

83.8.1 Intake History and Physical Examination

Much like with any other medical conditions, it is of paramount importance to obtain a full medical and psychiatric history. Specific to sleep disorders, it is important to include a bed partner or caregiver interview. Discussion about the patient's sleep habits and daytime functioning should be undertaken. Specific and detailed analysis of substance use or abuse is crucial. This should include both licit (e.g., tobacco, caffeine, alcohol) and illicit substances, as these can all have an effect on sleep.

The physical examination should be targeted at ruling out specific diagnosis but should typically include a mental status examination (e.g., mini-mental status), as well as a cardiovascular, respiratory, and neurologic examination.

Specific details on a "typical" night's sleep should be obtained and should include the following:

- Time to bed
- Pre-sleep activitie
- Delay to onset of sleep
- Specific symptoms or behaviors delaying sleep onset
- Awakenings – number, duration, and cause if known
- Time of final awakening
- Time out of bed
- Total estimated duration of sleep (total sleep time (TST))
- Nocturnal behaviors, e.g., eating, smoking, and nocturia
- Napping behavior during daytime
- Sleeping environment, noise, light, and temperature

The details above can be tabulated in detailed notes or by the use of a sleep "diary" or "log."

A variety of standardized sleep questionnaires exist that can be used to provide an objective characterization of specific sleep parameters, depending on the clinical situation at hand. The table below includes the most commonly used questionnaires, and here we provide a brief description of some (Table 83.2).

Table 83.2 Examples of insomnia questionnaires used in baseline and treatment outcome assessment

Questionnaire	Description
Epworth sleepiness scale	ESS is an 8-item self-report questionnaire used to assess subjective sleepiness (score range: 0–24; normal <10)
Insomnia severity index	ISI is a 7-item rating used to assess the patient's perception of insomnia [0–7, no insomnia, 8–14 subthreshold, 15–21 clinical insomnia (moderate), 22–28 clinical insomnia (severe)]
Pittsburgh sleep quality index	PSQI is a 24-item self-report measure of sleep quality (poor sleep: global score >5)
Beck depression inventory	BDI (or BDI-II) is a 21-item self-report inventory used to measure depression (minimal or no depression: BDI <10; moderate to severe: BDI >18)
State-trait anxiety inventory-form Y trait scale	STAI is a 20-item self-report inventory used to measure anxiety (score range: 20–80; minimum anxiety: T score <50; significant anxiety: T score >70)
Fatigue severity scale	FSS is a 9-item patient rating of daytime fatigue
Short form health survey (SF-36)	SF-36 is a 36-item self-report inventory that generically measures quality of life for any disorder (range from 0 (poorest) to 100 (well-being))
Dysfunctional beliefs and attitudes about sleep questionnaire	DBAS is a self-rating of 28 statements that is used to assess negative cognitions about sleep

83.8.2 Sleep Questionnaires

The Epworth Sleepiness Scale is a widely used and accepted questionnaire that a patient can complete in a few minutes and can help assess the patient's subjective sleepiness (excessive daytime sleepiness). This is of particular importance

to assess daytime effects of sleep disorders. The scale is copyright protected but is available for private clinical use free of charge and can be accessed at the following web address: http://epworthsleepinessscale.com.

The Insomnia Severity Index is an index used to document the severity of insomnia on which the patient rates (not at all to very much) their difficulty falling asleep and maintaining sleep and its impact on their daytime function. It also can be used to assess the effect of treatment.

83.9 Treatment of Insomnia

The aim of this section is to provide a brief overview to an approach to deal with insomnia complaints in the substance use population. This is by no means an exhaustive account of each technique used, but rather a "primer" to introduce each modality.

The overall approach is that of identifying and treating the underlying condition, as well as perpetuating factors. One can then utilize a combination of behavioral, psychological, and pharmacological modalities, depending on the specific clinical presentation and patient needs.

Predisposing factors to insomnia typically include varying tendencies toward psychological, emotional, or cognitive arousal that promotes insomnia but are insufficient to cause insomnia without the presence of other factors.

Precipitating factors are often identifiable events that initiate insomnia and can be major (e.g., bereavement) or minor (e.g., sleeping in unfamiliar bed). These also depend on the predisposing arousal level of the individual.

Perpetuating factors include poor sleep habits that develop during episodes of insomnia such as erratic sleep-wake schedules, nocturnal eating, and excessive worry about sleep.

83.10 Treatment of Chronic Insomnia: An Overview

The overall approach is to identify and treat underlying condition(s) and to identify and treat perpetuating factor(s). This is best achieved with a combined approach which includes behavioral, psychological, and pharmacological strategies.

83.10.1 Behavioral/Psychological

83.10.1.1 Sleep Hygiene Therapy

Sleep hygiene therapy typically makes an attempt to educate the patient about healthy sleep habits, exercise, caffeine consumption, eating behaviors, and sleep environment.

These suggestions may be ineffective alone in yielding results; they are usually a part of most behavioral treatments for insomnia. Below is an example of a list of sleep hygiene "rules" that can be utilized for this approach (Table 83.3).

You may choose to focus on two or three of the above recommendations at a time and reeval-

Table 83.3 Sleep hygiene rules: the dos and don'ts of a good night's sleep

1.	Keep a regular schedule. Go to sleep and wake up roughly at the same time each day, even on weekends
2.	Exercise regularly, in the morning or afternoon. Don't exercise in the late evening
3.	Have a comfortable bed in a quiet, dark room. Don't have your bedroom too hot or too col
4.	If hungry before bed, eat a light snack or have a glass of milk. Don't eat a heavy meal before retiring
5.	Schedule a relaxing period before retiring
6.	Keep the bedroom just for sleeping, sickness, and sex (3-S's), not as an all-purpose activity area
7.	Don't use alcoholic beverages or recreational drugs as sedatives.
8.	Don't try too hard to fall asleep. Get out of bed and return to bed only when you feel sleepy (30 min rule)
9.	Don't nap during the day
10.	Don't smoke or drink caffeinated beverages or eat foods for several hours before bedtime
11.	Use an alarm clock to wake you at your regular time, but position it away from you so you don't "clock watch" which can cause unnecessary tension
12.	If worrying keeps you awake or you are awake in the middle of the night and can't return to sleep because of worries, set aside a 15-min "worry" period to occur at the same time, perhaps after dinner, and in the same place every day. Writing down a "problem" list may help to relieve stress associated with worrying about forgetting certain things

uate your sleep habits every few weeks. And remember, a consistent sleep schedule works best.

83.10.1.2 Behavioral Therapy

Behavioral therapies for insomnia that are empirically supported include stimulus control, progressive muscle relaxation, and paradoxical intention, with sleep restriction, biofeedback, and multifaceted cognitive behavioral therapy for insomnia [2].

83.10.1.3 Stimulus Control Therapy

Based on the theory that cues in the bedroom precipitate and perpetuate arousal. The therapy involves instructions such as the following: "go to bed only when sleepy," "establish standard wake up time," "avoid using the bedroom as an all-purpose activity area, restricting behaviors to the 3 S's (sleep, sickness, sex)," leave the bedroom when lying in bed for greater than 20 min," and "refrain from napping during the day."

83.10.1.4 Sleep Restriction Therapy

The therapy restricts time allotted for sleep each night. First a "sleep log or diary" is maintained for 2 weeks and then an initial TIB (time in bed) prescription is set at a minimum of 5 h total bed time. This is followed by an expansion of a 15–30 min sleep at the beginning of the sleep phase (i.e., desired bedtime time), every few days. This is carried out over a few visits, with fine-tuning as needed.

83.10.1.5 Progressive Muscle Relaxation

Based on the theory that mental relaxation will be a natural outcome of physical relaxation leading to sleep, the patient is instructed to tense or tighten muscles, one at a time in a specific order. A greater degree of muscle tension is attempted, and subsequently when muscle tension is released, the patient learns the sensation of relaxation.

83.10.1.6 Paradoxical Intention

Performance anxiety contributes to preventing proper sleep. The patient is encouraged to stay awake (the feared behavior). As the patient stops trying to fall asleep, the performance anxiety related to attempting to fall asleep is reduced.

83.10.1.7 Biofeedback

Teaches patients to facilitate increased slow wave brain activity (and thus facilitate falling asleep) by using electroencephalographic (EEG) monitoring of brain waves. Eventually this skill can be applied without the EEG.

83.10.1.8 Multifaceted Cognitive Behavioral Therapy

The goal is to identify dysfunctional beliefs and attitudes about sleep and replace them with more adaptive substitutes.

The treatment targets the following: unrealistic sleep expectations ("I must get eight hours of sleep per night"), misconceptions regarding causes of insomnia ("My insomnia is due to a chemical imbalance"), amplification of consequences of insomnia ("I can do nothing after a bad night's sleep"), and performance anxiety due to excessive attempts at controlling the sleep process.

This is also referred to as CBT-I (cognitive behavioral therapy for insomnia) and involves a combination of cognitive and behavioral modalities.

Topics commonly addressed are an array of cognitive, circadian, and sleep-inhibitory factors that affect primary insomnia.

The combination of SCT (stimulus control therapy) and SRT (sleep restriction therapy) has proven most efficacious [44].

Cognitive behavioral therapy enhances sleep-related self-efficacy and reduces depressive and anxiety symptoms. It has also been shown to correct dysfunctional beliefs about sleep and to reduce the use of sleep medications, with an overall improvement in insomnia-related sleep-wake symptoms.

CBT-I should be the standard treatment for many insomnia patients, as comparative data suggest that CBT-I is associated with a more durable benefit in patients with insomnia disorder than pharmacologic therapy and may have an indirect effect of preventing drug dependence and relapse

[22], although that has not been shown (see discussion below).

83.10.2 Pharmacotherapy of Insomnia in the Addiction Population

People who abuse alcohol and other substances are at a high risk for sleep disturbances due to the direct effect of the substance or its discontinuation on their sleep continuity and architecture and their sleep-wake cycle. The drug effect on their behavior and daily functioning, which in turn impacts their daily need for sleep, is also paramount [37].

See Table 83.4 for a listing of those sedative/hypnotics approved for sleep by the US FDA. Benzodiazepine receptor agonists are the most commonly used prescription medication with good evidence of their effectiveness in insomnia, both objectively and subjectively. However, in those with a history of substance abuse, the potential for abuse of these substances is heightened.

In this population, alternative indicated medications such as melatonin receptor agonists (for sleep-onset insomnia), histamine-1 antagonists (for sleep maintenance insomnia), or the newly approved orexin antagonist hypnotic for sleep onset and sleep maintenance may be preferred due to their low risk of abuse. Over-the-counter medications and off-label uses of antidepressant medications (unless there is comorbid depression) should *not* be considered because there is limited evidence on efficacy, dosage, and safety.

Table 83.4 US FDA-approved hypnotics

Generic name	Dose (mg)	T max(h)	T ½ (h)
Benzodiazepine receptor agonist			
Flurazepam	15, 30	0.5–1.0	48–120
Triazolam	0.125, 0.25	2	2-4
Temazepam	7.5, 15, 30	1.2–1.6	8-20
Estazolam	1, 2	0.5–6	8-24
Quazepam	7.5, 30	2	48-120
Nonbenzodiazepine benzodiazepine	*Receptor agonist*		
Zolpidem	5, 10	1.6	1.5-2.4
Zaleplon	5, 10, 20	1	1
Eszopiclone	1, 2, 3	1	5-7
Zolpidem ER	6.25, 12.5	1.5	2.8-2.9
Zolpidem (sublingual)	1.75, 3.5	0.5–0.75	2.1-2.4
Zolpidem (oral spray)	5.10	0.8-2.6	1.5-2.4
MT agonist			
Ramelteon	8	0.75	1.0–2.6
Histamine antagonist			
Doxepin	3, 6	3.5	15
Orexin antagonist			
Suvorexant	5, 10, 20	2	8–14

83.10.2.1 OTC

The most commonly used medications in this class are diphenhydramine and dimenhydrinate. The problem with these OTCs is that there is little or no placebo-controlled evidence that they are effective in insomnia, much less the comorbid insomnia of substance abuse.

1. Diphenhydramine

   Some of the more commonly available brand names are sold as Excedrin PM, Benadryl, Tylenol Allergy Sinus, Tylenol Flue Nighttime Max Strength Power, and Tylenol PM.

   These drugs work as antihistaminic agents, to decrease sleep latency (sleep onset). The anticholinergic effect in the morning leads to drowsiness, especially in higher doses [27]. The potential for diphenhydramine-related toxicity and drug-drug interactions is substantial [24], and tolerance to its sleep-inducing effects occurs within a few days [35], suggesting that diphenhydramine and related compounds such as dimenhydrinate should not represent a viable treatment strategy for long-term sleep maintenance in chronic insomnia.
2. Valerian

   This older compound had been used for many years, in a variety of preparations and

forms depending on country of origin. While there is some subjective improvement in the quality of sleep, there is little scientific evidence documented in clinical trials [17] and doses used vary widely from 75 to 3000 mg.

3. Melatonin

   Melatonin is a hormone naturally produced in the pineal gland which regulates the circadian cycle and is thought to promote sleep through its circadian activity. In the early evening at dusk, melatonin levels rise and remain high throughout the night. Some studies have reported a positive effect of OTC melatonin administration, while others have reported little or no effect on sleep parameters [42]. Inconsistency of results may be due to dose and timing of administration.

83.10.2.2 Prescription Drugs

1. Benzodiazepine and Non-benzodiazepine Receptor Agonists (BzRA)

   The BzRAs are the most commonly prescribed class of medications used for insomnia. Some have a benzodiazepine chemical structure (i.e., estazolam, flurazepam, temazepam, triazolam) and some do not (i.e., "z drugs"). They all are GABA-ergic agonists with effects at the benzodiazepine site on the GABA receptor complex. There are subunits on the site which are associated with specific pharmacological/behavioral effects, and the BzRAs do differ in their subunit specificity. Commonly available and prescribed medications are the "z-drugs" zolpidem (Ambien), zolpidem ER (Ambien CR), zaleplon (Sonata), zoplicone (Imovane), and eszopiclone (Lunesta). Eszopiclone and zolpidem ER are BzRA hypnotics that are FDA approved without a specified time limit on the duration of prescription, and clinical trials indicate they remain effective for 1 year of nightly use (Table 83.4). This probably does not reflect differential activity of these medications, but rather the FDA recognition that insomnia is a chronic disorder and hence the need for chronic therapy.

   The hypnotic efficacy of BzRAs has been well documented using objective measures and patient reports of sleep induction, maintenance, and duration in clinical trials, as well as in meta-analyses [18]. Thus, it can be concluded that they are effective.

   Adverse reactions to BzRA hypnotics include residual effects, which can be related to the half-life and dose of the specific hypnotic, falls in the elderly, amnesia, rebound insomnia, amnesic parasomnia episodes, and potential for abuse. The FDA has recently (April 30, 2019) issued a "black box" warning around the "z-drugs" regarding the possibility of amnesic parasomnia episodes and cautioned regarding the need to select the lowest available dose.

   Dependence has been noted in daily and long-term use of anxiolytic BzRAs, as opposed to short-acting hypnotic use (1 dose/24 h). Short-term studies (<2 weeks) [39] and a long-term study (12 months) [41] of hypnotic use did not indicate dose escalation, rebound insomnia, or withdrawal symptoms on discontinuation.

   The FDA has designated BzRA hypnotics as controlled substances, giving them a schedule IV designation, which indicates these drugs have a known abuse liability in at-risk populations, and thus this must be a particular concern when prescribing these hypnotics to a patient with a history of substance abuse.

2. Melatonin Receptor Agonist: Ramelteon

   Ramelteon has an FDA indication for sleep-onset insomnia, supported by patient reports and objective studies showing that sleep onset is hastened along in a dosage range of 4–32 mg [11, 13].

   Adverse events reported include somnolence, fatigue, dizziness, and nausea, all occurring at rate <5%, and based on behavioral assessments of abuse liability, no liability was seen [16].

3. Histamine-1 Antagonist: Low-Dose Doxepin

   Doxepin is a tricyclic antidepressant that is frequently used off-label as a hypnotic in antidepressant doses (26–150 mg). At the doses approved for insomnia (3–6 mg), doxepin is thought to be a relatively pure H1 histaminic receptor antagonist, which, when antago-

nized, produces sedating effects, without anticholinergic, antiserotonergic, and antiadrenergic activity. Doxepin has been shown in both adults and the elderly to maintain sleep, particularly in the last 2 h of the night, unlike the BzRAs, without producing residual effects. Doxepin is not a scheduled drug and is considered not to have an abuse liability; however, more evidence on this is required due to evidence for behavioral dependence of H1 antihistamines. As the clinical trials have all been short and intermediate term (<=3 months), the issue of dependence must be more fully studied before caution of low-dose doxepin is lifted.

4. Suvorexant

Suvorexant is a dual orexin receptor antagonist which acts to block the binding of wake-promoting neuropeptides and promotes sleep. In the treatment of insomnia, suvorexant has been shown to improve subjective and objective total sleep time, wake after sleep onset, and latency to persistent sleep without altering sleep architecture [33]. At doses of 20 mg or less, suvorexant is relatively safe and effective for the treatment of sleep onset and sleep maintenance in insomnia disorder, although it has not been evaluated in the substance abuse population.

Additionally, orexin neurons have an established role in modulating reward pathways. This suggests an antagonist could be a novel treatment for drug addiction by blocking reward signals. Although not explored in humans, animal studies have shown suvorexant can attenuate motivational and hedonic properties of cocaine and decrease alcohol drinking, self-administration, and reinstatement [15, 30].

5. Other Off-Label Drugs

(a) Antidepressants: Trazodone, Amitriptyline, and Mirtazapine

The most commonly used off-label drugs for insomnia are antidepressants used at "lower doses" for insomnia than their standard antidepressant doses. Trazodone, amitriptyline, and mirtazapine are three of the most widely used antidepressants for insomnia. There is limited information regarding the dose range over which these drugs improve sleep and their safety at those doses. No studies of amitriptyline and mirtazapine on primary insomnia were found in literature, and two studies of trazodone gave mixed results with improvements at lower doses giving reduced sleep latency and increased total sleep time; however, these effects lasted for only 1 week.

The dosage generally recommended for sleep is lower than the antidepressant dosage, and it is not known where potential serious side effects documented at higher doses – suicidality, residual effects, anticholinergic effects (i.e., dry mouth, urinary retention, weight gain, and hallucinations) to orthostatic hypotension, priapism, cardiac arrhythmias, and conduction abnormalities – would occur at these low doses. Given that there is no clear understanding in regard to the dose range for the hypnotic efficacy and safety of these drugs, it is recommended they not be used as hypnotics.

There is currently no data available on antidepressants for use in sleep disorders among patients with substance use disorders.

Proper diagnosis of comorbid mood disorder may indicate that a single medication can be helpful to treat both conditions.

(b) Atypical Antipsychotics: Olanzapine and Quetiapine

These medications include "off-label use" of such drugs as olanzapine (Zyprexa) and quetiapine (Seroquel) for their effect on sleep problems.

These agents have shown improvement in self-reported sleep measures [36]; however, the concern for the use of these drugs, as with other off-label drugs, is that there is limited information regarding efficacious and safe doses, and their use as hypnotics is not recommended [32]. There is currently no data available on

olanzapine or quetiapine among patients with substance use disorders.

(c) Off-Label BzRAs: Clonazepam, Alprazolam, and Lorazepam

Anxiolytic BzRAs are also often used as hypnotics, with clonazepam, alprazolam, and lorazepam as the most commonly used off-label BzRAs. These share the same hypnotic mechanism of action of the indicated BzRAs and were used previously due to no limitations on long-term use; however, their hypnotic dose is unknown, and due to the availability of BzRAs approved hypnotics as discussed above, there is no advantage to their use. In fact, there may be increased risk as discussed below.

(d) Gabapentin

Gabapentin is an anticonvulsant used to treat seizures, neuropathic pain, and restless legs syndrome. It has been used off label to treat insomnia with polysomnographic studies showing increased sleep efficiency and slow-wave sleep and decreased wake after sleep onset and spontaneous arousal index [25]. The dose for most patients is 600 mg. In those with alcohol dependence, gabapentin significantly improved rates of abstinence as well as relapse-related symptoms of insomnia [8, 28]. When used alone, there is little abuse potential, but if used in conjunction with muscle relaxants, opioids, or anxiety medications, a euphoric effect (i.e., "high") may be produced and thereby abuse potential is increased.

83.11 Medications and Potential for Abuse

83.11.1 Abuse Liability Signs

There is abuse liability associated with the BzRA hypnotics. The non-BzRAs that are not scheduled have limitations in regard to their indications, ramelteon being only for sleep-onset and doxepin only for sleep maintenance insomnia. The orexin antagonist, suvorexant, carries a schedule IV designation. Therefore, if a scheduled drug is prescribed, the following important signs have been identified regarding potential abuse liability of BzRAs [20]:

1. Dose escalation beyond the indicated clinical hypnotic dose within the first week of treatment
2. Use during daytime outside of the sleep period

These patterns suggest nonhypnotic drug effects that were being sought and guidance to closely monitor the patient during the first week of use, and not allowing patient-initiated dose adjustments is recommended.

83.11.2 Precautions and Contraindications

Patients who have histories of drug or alcohol abuse with difficulty sleeping, particularly sleep maintenance, which is the chief complaint among abstinent alcohol and drug abuse patients, require precautions. These sleep disturbances can continue for a year or more. The non-BzRA, low-dose doxepin or the orexin antagonist, suvorexant, may be options, although further studies are required to fully understand their benefit-risk profile in SUD patients.

If the physician considers the use of a BzRA hypnotic in an outpatient setting, the patient must be monitored closely beyond the initial week of use. Within the alcohol and drug abuse treatment community, stress-induced relapse is a well-recognized phenomenon that can occur after months of successful abstinence. In such cases, the experience of new life stresses can induce a relapse to drug and alcohol abuse. When alcohol is used concurrent with *any* hypnotic, there is potential for additive sedative effects and the occurrence of any of the aforementioned adverse effects.

In prescribing sedative hypnotics in substance use disorder patients, there are specific cautions and guidance that should be followed. We provide these principles in Table 83.5. Several points should be noted. Sedative/hypnotics can potentially have additive effects with other sedative drugs, exacerbate respiratory disturbance, require

Table 83.5 Guidelines for prescribing sedative/hypnotics

Initiate hypnotic use after identifying and addressing specific behaviors, circumstances, and underlying Guidelines disorders contributing to insomnia
Prescribe the lowest effective dose of the hypnoti
Avoid hypnotic use or exercise caution if the patient has a history of substance abuse, myasthenia gravis, respiratory impairment, sleep apnea, or acute cerebrovascular accident
Normally one prescribes for short-term use, but in SUD patients where sleep disturbance is 3 months and longer, long-term use may be required
Watch for requests for escalating doses or use during the daytime
Hypnotics should be discontinued gradually (i.e., tapered); the physician should be alert for adverse effects (especially rebound insomnia) and withdrawal phenomena if higher, super-therapeutic doses are in use
General Comments About Sedatives/Hypnotics
Administration on an empty stomach is advised to maximize effectiveness
Not recommended during pregnancy or when nursing
Caution is advised if signs/symptoms of depression, compromised respiratory function (e.g., asthma, COPD, sleep apnea), or hepatic heart failure are present
Caution and downward dosage adjustment is advised in the elderl
Safety/effectiveness in patients <18 years not established
Additive effect on psychomotor performance with concomitant CNS depressants and/or alcohol use
Certain antidepressants (amitriptyline, doxepin, mirtazapine, paroxetine, trazodone) are employed in lower than antidepressant therapeutic dosages for the treatment of insomnia. These medications are not FDA approved for insomnia and their efficacy for this indication is not well established

lower doses in elderly and women, should be used with caution in patients with liver disease, and should be avoided in pregnant and nursing woman.

83.12 Conclusion

Insomnia is a prevalent symptom in those with chemical dependency, and it may be a predictor of relapse. The key is proper assessment and diagnosis of the underlying cause. Treatment with pharmacotherapy and behavioral therapy is likely the best option. As of this writing, there is still significant need for further research.

It is crucial to remember that not all "insomnias" are the same. The complaint of insomnia is extremely common, with significant implications and with a high rate for concurrent disorders: medical, psychiatric, and substance use disorder. There is a need for a simple yet comprehensive approach for the diagnosis and treatment of sleep disorders in the substance-abusing population, which should involve a multidisciplinary team approach to care.

Sleep disorders medicine is a fascinating and rapidly growing field. Think about sleep disorders when patients complain of fatigue or EDS (excessive daytime sedation). Think about the possibility of OSA (obstructive sleep apnea) if the patient presents with snoring with fatigue, and they are also overweight or have hypertension or diabetes. It is prudent to stay away from benzodiazepines for insomnia as the first "treatment."

Key Points

1. People who abuse alcohol and other substances are at high risk for sleep disturbances due to the direct sleep effects of the substance or its discontinuation.
2. Disturbed and insufficient sleep can have significant behavioral and health consequences including car and industrial accidents, impairment of memory and decision-making, exacerbation of illnesses, and notably for the addiction medicine practitioner is predictive of relapse.
3. The physiology of normal human sleep is firmly established and classification of sleep disorders has been developed, now in its third revision.
4. The most frequently occurring sleep disorders comorbid with addictions are insomnia, sleep apnea, and restless legs/periodic leg movement disorders.
5. Treatment of sleep disorders in addiction includes behavioral/psychological treatments, pharmacotherapy, and mechanical ventilator devices.

Clinical Relevance

Clinicians can potentially improve outcomes and avoid potential risk by appropriately identifying sleep disorders in their patients with substance use disorder. Sleep problems can contribute to the initiation, maintenance, and relapse of substance use disorders. Consultation with a sleep disorders specialist should be sought when help in identifying and treating the sleep disorder is needed. Newer pharmacological treatment options, without the abuse liability of benzodiazepine-acting hypnotics, are now becoming available and availability of specialists in behavioral insomnia treatment is expanding.

Abstract

Endocrine manifestations of substance use disorders can result from the direct effect of the addictive substance, chronic and acute toxicological phenomena, or more indirectly due to long-term disturbances of delicate hormonal feedback loops. Although the existing data is largely based on case reports and ani-

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment*, https://doi.org/10.1007/978-3-030-36391-8_84

mal studies, emerging evidence suggests that addiction can result in physiological disturbances to multiple hormonal pathways. This can result in overt or subtle clinical syndromes and may often be overlooked in addiction patients who frequently have other biopsychosocial factors at play. Chronic opioid use may lead to hypothalamic-pituitary suppression with resultant hypoadrenalism and hypogonadism. Alcohol-induced hypercortisolaemia (previously termed pseudo-Cushing's syndrome) remains under-recognised, with alcohol-related hepatic dysfunction further compounding metabolic risk factors in dependent patients. Human studies of tobacco and cannabis smoking on hormone homeostasis have yielded incongruous results in human studies but remain important modifiable risk factors for osteoporosis and metabolic syndrome. This chapter aims to highlight the clinically important endocrine disturbances associated with drugs of addiction, as well as touching on related metabolic considerations that are vital in holistic patient management.

84.1 Introduction

Endocrinopathies and hormonal disturbances associated with addiction are widespread and can manifest in a diverse spectrum of clinical syndromes. They can mimic intoxication or withdrawal and if left undetected can result in significant morbidity or mortality from disruption of hormonal axes. Drugs of addiction may be overlooked as potential causes of endocrinopathies, just as hormonal disturbances can be omitted from the differential diagnoses of patients who appear to present with a toxidrome. Comorbid endocrinopathy may also have the potential to lead to exacerbation of a substance use disorder typically via disturbance of mood or quality of life. Clinical questions emerge regarding the treatment of these disturbances and whether hormone replacement may be required above and beyond treatment of the addiction. This chapter primarily addresses hormonal disturbance associated with alcohol and opioid dependence and also touches on the effects of other substances of abuse.

84.2 Hormones and Addiction

Often termed the 'master' gland, the pituitary gland sits in the bony sella turcica and is connected to the hypothalamus by a stalk called the infundibulum. The hypothalamus receives messages from the cortex and signals the pituitary to secrete or inhibit hormones in response to several biochemical, psychological and environmental stimuli. Via this tightly regulated system, the hypothalamic-pituitary axis signals the thyroid, gonads and adrenal glands, with other pituitary hormones and neuropeptides acting on a variety of target tissues. Drugs of addiction, as well as the cycles of intoxication and withdrawal, can alter the biochemical and psychological homeostasis of hormones, both directly and indirectly. Hypothalamic-pituitary dysfunction may result in times of critical illness, with acute and chronic effects of addictive substances becoming increasingly recognised.

84.2.1 Hypothalamic-Pituitary-Adrenal Axis

The effect of addictive substances on the physiological stress response system can be seen at the level of the hypothalamus (corticotrophin-releasing factor), the anterior pituitary (adrenocorticotropic hormone or ACTH) and the adrenal gland. Psychological or physiological stress from

intoxication may contribute to addictive behaviours and ultimately lead to disrupted stress response in chronic use. The effects of exogenous opioids, alcohol and other addictive substances on the hypothalamic-pituitary-adrenal (HPA) axis are discussed here.

84.2.1.1 Action of Opioids

Beta-endorphin is an endogenous opioid which is produced upon the cleavage of proopiomelanocortin (POMC) to ACTH and beta-lipotropin, working on μ-opioid receptors to modulate pain and stress response in normal subjects [67]. Exogenous opioids, both prescription and illicit, are increasingly recognised as contributing to the dysfunction of the hypothalamic-pituitary-adrenal axis with potentially life-threatening adverse effects. G-coupled opioid receptors exist in the hypothalamus and pituitary gland [35] and may be subject to suppression with administration of exogenous opioids.

It is thought that endogenous opioids have a physiological *inhibitory* effect on the HPA axis, with studies of healthy volunteers demonstrating augmented corticotrophin release and increased cortisol levels in response to opioid receptor antagonism with intravenous naloxone [22]. These data suggested opioid receptor agonists should have the opposite effect, but human results of studies have been conflicting. Chronic opioid use in human studies has demonstrated varying degrees of hypothalamic/pituitary suppression [1, 25]. One recent cross-sectional study comparing pituitary function, quality of life and sexual function in chronic opioid users suggested a dose-dependent effect with secondary adrenal insufficiency identified in 22.5% of chronic opioid users versus normal controls [87]. In addition opioids may exert direct toxic effects on the adrenal glands mediated via μ- and κ-opioid receptors leading to a diminished adrenal response to ACTH [87]. The clinical significance of the latter remains unclear.

84.2.1.2 Adrenal Insufficiency

The prevalence of opioid-induced adrenal insufficiency is estimated to range from 9% to 29% of chronic users [25], although epidemiological studies to date have been small in numbers. Postulated risk factors include a higher dose of opioid and long-acting formulations [12] although this has yet to be studied prospectively. Clinical implications including possible adrenal crisis are becoming increasingly recognised in long-term opioid-dependent patients and rarely may result in a frank hypoadrenalism in times of increased physiological stress [23]. Signs of adrenal insufficiency may be non-specific and include fatigue, weight loss, vomiting, dizziness and myalgia, as well as hypoglycaemia. Hyperpigmentation as seen in primary adrenal pathology is absent. In the acutely unwell opioid-using patient, high suspicion for adrenal insufficiency and appropriate steroid replacement are crucial to avoid an adrenal crisis.

A diagnosis of adrenal insufficiency should be made by measuring baseline ACTH and serum cortisol levels, with an early morning serum cortisol of <300 nmol/L raising suspicion for the diagnosis [13]. A corresponding low serum ACTH is suggestive of secondary (pituitary) or tertiary (hypothalamic) adrenal insufficiency. Confirmation via dynamic testing is then necessary. The insulin tolerance test remains the gold standard for the diagnosis of adrenal insufficiency, although it is contraindicated in patients with a history of seizures, ischaemic heart disease or severe panhypopituitarism [31]. Short synthetic ACTH stimulation test may be performed with subsequent assessment of adrenal response via serum cortisol. Limitations to these tests in this population should be expected particularly in patients with abnormalities of albumin or cortisol-binding globulin (CBG), such as cirrhosis or nephrotic syndrome. In addition, short synthetic ACTH stimulation test will not detect acute hypoadrenalism developing across 1–2 weeks, including that due to opioids.

Once the diagnosis of hypoadrenalism is established, glucocorticoid replacement therapy should be commenced in affected patients; mineralocorticoid replacement is not required in secondary adrenal insufficiency. Replacement dosage of 15–25 mg per day of oral hydrocortisone in adults is recommended in divided doses, titrating to patient symptoms. A recent double-blinded randomised control

trial assessing low-dose glucocorticoid therapy in chronic pain patients with hypoadrenalism taking opioids suggested an improvement in pain scores and vitality compared with placebo [74]. The role of replacement and role in prevention of relapse warrant further studies. Education regarding sick day management and stress dosing of hydrocortisone in times of increased physiological stress is necessary. Cessation of opioids should also be considered, as case reports indicate the pathology may be reversible [61, 78].

84.2.2 Alcohol-Related Hypercortisolaemia

Hypercortisolaemia associated with both acute and chronic alcohol use has been well documented. The proposed mechanisms include increased ACTH release [93], decreased cortisol binding to albumin and cortisol binding globulin and impaired hepatic metabolism of cortisol due to liver dysfunction. Patients with hypercortisolaemia secondary to alcohol use may be less likely to exhibit the classic cutaneous and muscular signs of Cushing's syndrome [6], and clinicians should be vigilant and refer for screening tests (midnight salivary cortisol and 24-hour urinary free cortisol) in all suspected cases. Signs of hypercortisolaemia can be non-specific and include central adiposity, glucose intolerance, moon-like facies, proximal myopathy, skin thickening, hypertension and hirsutism in women. Initial screening tests may result in false positives and differentiating between causes of hypercortisolaemia can be difficult. Furthermore, a low-dose overnight dexamethasone suppression test may yield inconsistent results in the alcohol-dependent population, with alterations in cortisol binding globulins leading to false negatives, and thus the dexamethasone/CRH suppression test may be more specific. Abstinence from alcohol will result in normalisation of serum cortisol levels [75].

84.2.3 Other Drugs and the HPA Axis

Repetitive exposure to methamphetamine may also lead to chronic activation of the HPA axis resulting in increased release of cortisol. Persistent activation of the HPA axis in this manner may be partially responsible for changes in the reward pathway, making abstinence more difficult to achieve [99]. Similarly, over-activation of the HPA axis is seen in both animals and humans who chronically use cocaine, although the clinical relevance of this remains unclear [68].

Cannabis has been postulated to affect HPA axis function as the endocannabinoid signalling pathway is involved in regulation via hypothalamic CB1 receptors. Again, the real-life effect of THC use on this pathway is unknown and remains an area for further study [72].

84.2.4 Gonadal, Sexual and Reproductive Function

Male hypogonadism secondary to both chronic alcohol and opioid use is well documented, with studies among female subjects yielding heterogeneous results. Hypogonadism can present as low energy, depression, poor libido and erectile dysfunction (or menstrual disturbance in women) with long-term complications, such as osteoporosis discussed later in this chapter. Gonadotropic-releasing hormone (GnRH) from the hypothalamus acts on the anterior pituitary to produce luteinising hormone (LH) and follicle-stimulating hormone (FSH). FSH and LH in turn act on the gonads to produce oestrogen and testosterone. A recent meta-analysis demonstrated low serum testosterone is associated with an increase in all-cause mortality although this association is unlikely causal and is more a reflection of overall health status [46]. Acquired hypogonadotropic hypogonadism has been documented in both alcohol- and opioid-dependent patients [37]. Elevated prolactin may further contribute, as hyperprolactinemia suppresses GnRH and FSH/LH release. Sex hormone replacement therapy may be prescribed following careful consideration of symptoms, quality of life, complications of prolonged hypogonadism and contraindications.

84.2.5 Alcohol and Hypogonadism

Alcohol can impact circulating gonadotropins both directly and indirectly. Numerous animal and human studies describe direct toxic effects on the testes with histological, anatomical and biochemical disturbances. A recent rodent study showed that abstinence did not reverse alcohol-induced testicular damage as measured by sperm count and testicular weight [27], yet there was some biochemical recovery in testosterone level with alcohol abstinence. Secondary hypogonadism indicated by low serum testosterone without corresponding elevation of LH or FSH is seen following acute ethanol ingestion.

Chronic alcohol use, with or without cirrhosis, can lead to feminisation including gynaecomastia and may be a cosmetic concern to male patients. This appears to be multifactorial, with elevated oestradiol, androstenedione and serum hormone-binding globulin (SHBG), but reduced DHEAS, free and total testosterone concentrations. These changes appear to be related to the stage of cirrhosis and hypogonadism and appear to be of hypothalamic origin [76]. Alcohol-induced hypogonadism has been reported to resolve after withdrawal of alcohol use.

The relationship between hypothalamic-pituitary-gonadal function and alcohol use in females is less clear. Following acute ingestion of alcohol, oestradiol levels have shown a positive relationship compared to placebo [69]. Moreover chronic heavy alcohol consumers, compared to occasional or social drinkers, appear to have a higher incidence of menstrual disturbances [70]. In long-term use, elevated FSH and decreased ovarian reserve have been shown [66]. No conclusive evidence regarding progesterone levels and alcohol use has been observed to date, although decreased catabolism of circulating sex hormones has been hypothesised [85].

Higher levels of alcohol consumption appear to adversely impact fertility in both men and women. However, a safe level of consumption has yet to be established with studies thus far yielding heterogeneous results. In men, abnormalities in gonadal function, testosterone levels and spermatogenesis in heavy alcohol use may further hinder any desired conception. Semen quality and decreased spermatogenesis appear to be associated with alcohol use; one large systematic review showed decreased semen volume and impaired morphology in daily drinkers compared to non-drinkers, but no conclusive results regarding overall sperm quality [82]. Furthermore, daily drinkers appeared to have more marked alterations than occasional consumers. This finding was echoed in the cannabis-using population, with a study of 1215 Danish men demonstrating 28% reduction in sperm concentration and 29% reduction in sperm count. A recent meta-analysis and systematic review evaluating daily alcohol dose and chance of conception in women suggested a linear association between decreased fecundity and each additional 12.5 gram of alcohol per day compared to non-drinkers [32]. Alcohol use may also lead to hyperprolactinemia [21] that may further suppress gonadotropin secretion and impaired testicular or ovarian function.

84.2.6 Opioids and Hypogonadism

First recognised among heroin-addicted patients and later among methadone maintenance patients, opioid-induced hypogonadism remains an under-recognised phenomenon [71]. In chronic pain patients receiving intrathecal morphine, hypogonadism was found in both men and women [34]. Chronic administration of opioids may cause hypogonadotropic hypogonadism with reduced pulsatile secretion of GnRH [1] resulting in lower circulating levels of oestrogen and androgens. The increased sex hormone-binding globulin (SHBG) production seen in chronic opiate users leads to a further reduction in testosterone levels. In one large retrospective cohort study, men on long-acting opioids were over three times more likely to develop hypogonadism than men taking short-acting opioids [84]. Interestingly not all opioids appear to have the same effect; with buprenorphine [11] and more recently tapentadol [29] appearing to have less significant effects than pure opioid analgesics on testosterone levels in men. The same effects have not been consis-

tently replicated in female chronic opioid users with one cross-sectional study demonstrating much lower rates of opioid-related hypogonadism in female subjects [38].

84.2.6.1 Clinical Considerations

The role of sex hormone replacement in opioid- or alcohol-related hypogonadism is not clearly established in guidelines. Hormone replacement may be indicated where opioid therapy is required in long term, symptoms of hypogonadism are onerous and complications of hypogonadism have developed or are affecting treatment adherence.

In men, a diagnosis of hypogonadism may be made with consistently low serum total testosterone concentrations, on two separate occasions measured on early morning fasting biochemistry. Clinicians should also be aware that recent opioid use may result in low testosterone levels [10]. Important differentials for hypogonadism (particularly primary pituitary pathology) must be excluded prior to commencing replacement therapy. Although a recognised complication of long-term opioid therapy, prescribing guidelines for testosterone replacement vary internationally. In Australia, androgen deficiency caused by drugs is an exclusion criterion for federal subsidy, which limits access to testosterone replacement in many cases.

Testosterone therapy in a hypogonadal man has been shown to improve mood, sexual function, areal bone mineral density, fat-free mass and muscle strength [36]. Contraindications to therapy include prostate or breast cancer, elevated haematocrit, poorly controlled congestive cardiac failure or desire for fertility. Common adverse effects include mood or behaviour disturbance, erythrocytosis, acne, reduced spermatogenesis and prostatism. One recent retrospective analysis of 27 men demonstrated that with opioid-induced hypogonadism, testosterone replacement therapy reduced opioid requirement in patients with chronic pain [81]. Studies to date have been underpowered to establish definitive data regarding cardiovascular risk or prostate events in the testosterone replacement population [7]. A frank discussion with patients outlining possible risks and benefits, as well as routine monitoring while on therapy, is necessary. Diagnosis of hypogonadism in premenopausal women may be suspected with a clinical history of menstrual disturbance but may go undetected for some time. Biochemical evaluation of FSH, LH, oestradiol and prolactin may be useful; however, there is no current consensus for diagnosis. Treatment with oestrogen and progesterone replacement may be warranted. Oral and transdermal preparations are widely available, including the oral contraceptive pill.

84.2.7 Thyroid Function and Addiction

The hypothalamic-pituitary-thyroid (HPT) axis is responsible for maintaining normal levels of circulating thyroid hormones: thyroxine (T4) and its active form, triiodothyronine (T3). T4 and T3 circulate in both a protein-bound inactive form and a free, readily available active form. When the hypothalamus detects reduced circulating levels of thyroid hormones, it responds by releasing thyrotropin-releasing hormone (TRH), which in turn stimulates the anterior pituitary to secrete thyroid-stimulating hormone (TSH). Thyroid hormones are responsible for setting the basal metabolic rate, growth and protein synthesis, among other functions [24].

Thyroid dysfunction is an important differential in the addiction population. Disturbance to thyroid hormone levels can be seen in any cause of acute illness, the so-called sick euthyroid state. True hyper- or hypothyroid states can mimic conditions of both intoxication and withdrawal with symptoms ranging from non-specific fatigue or mood changes to rare life-threatening thyroid emergencies. Overt clinical thyroid syndromes associated with addictive substances are rare; however, both animal and human studies have shown that acute intoxication, withdrawal and abstinence periods may affect the thyroid hormone axis. This may occur at the level of the pituitary and thyroid gland or affect the peripheral conversion of T4.

84.2.8 Thyroid and Alcohol

The relationship between alcohol use and thyroid disturbance remains unclear. Acute alcohol exposure appears to have little effect on the HPT axis. In contrast, chronic alcohol use appears to have several effects. Chronic exposure of adult male rats to ethanol for 40 days induced a significant decrease in total T4 and T3, free T4 and T3 as well as basal TSH levels [80]. In human studies a blunted TSH response to TRH can be seen that may persist into abstinence [88]. Inconsistent data exists regarding levels of circulating thyroid hormone in the alcohol-dependent patient; however, levels of both T4 and T3 are observed to be lower in people with alcohol use disorder during withdrawal and early abstinence than in healthy control subjects [47]. Following long-term abstinence, thyroid dysfunction has been reported to recover [79] although dysfunction may recur if alcohol use is recommenced [48]. A positive correlation between higher free T3 levels and increased alcohol cravings has been demonstrated in a small study, generating some interest that this may demonstrate a link between thyroid dysfunction and alcohol dependence [3].

84.2.9 Thyroid and Tobacco

Tobacco smoking is unambiguously associated with an increased risk of Graves' disease [19]. The association between Graves' ophthalmopathy and smoking is even stronger. In a meta-analysis investigating the association between thyroid disorders and smoking, the odds ratio for developing Graves' ophthalmopathy was 4.40 (95% CI: 2.88–6.73) in patients who had ever smoked compared to never smokers [92]. Furthermore, Graves' ophthalmopathy severity is positively related to smoking amount in tobacco smokers [16]. Interestingly, there appears to be a lower prevalence of thyroid autoantibodies and subclinical hypothyroidism among smokers, although the clinical significance of this is unclear [58].

84.2.9.1 Thyroid Function and Other Drugs

Opioid use and thyroid dysfunction have yet to be conclusively studied. In general opioids do not appear to alter primary thyroid function [56] but may interfere with levels due to changes in thyroid-binding globulin and hypothalamic action via K-receptors [44]. Early studies examining clinically euthyroid methadone-maintained patients revealed elevations of *total* T3 and T4 and thyroxine-binding globulin compared with normal controls; however, *free* T3 and T4 and thyroid-stimulating hormone (TSH) were normal [30]. Neither cannabis nor psychostimulants have been associated with increased prevalence of thyroid disorders. Acute methamphetamine intoxication is an important differential diagnosis in cases of thyroid storm, as both present with agitation, tachycardia, fever and symptoms of catecholamine excess.

It may be reasonable to assess for other causes of thyroid dysfunction, prior to attributing causality to substance use exclusively. Screening for dysfunction via thyroid function tests (TSH, free T4 and free T3 levels) may be prudent where there is any clinical suspicion, proceeding to antithyroid autoantibody testing and imaging where appropriate.

84.3 Weight, Glucose Metabolism and Appetite in Addiction

Although addictive disorders are most frequently associated with malnutrition [83], metabolic complications and labile blood glucose levels are not uncommon. Substance-related sympathomimetic effects may result in elevated serum cortisol and catecholamines, with a subsequent increase in hepatic gluconeogenesis and glycogenolysis [62]. Prolonged malnutrition may deplete hepatic glycogen stores further altering energy homeostasis. Maladaptive eating patterns and neurobiochemical similarities to addiction have become areas of increasing interest for developing therapies in addiction, eating disorders and obesity.

84.3.1 Opioids

Chronic opioid use is associated with weight gain, hyperglycaemia and worsening glycaemic control in people with diabetes, postulated to be due to a central action via the sympathetic nervous system and impaired insulin secretion [14]. Data also suggests that opioids play a role in regulating food intake and food choice as well as the reward system associated with good-tasting foods. Interestingly, there appears to be an association between opioid use and taste preference for sweet foods over and above increased caloric intake [42]. It is likely that there is significant overlap between reward pathways associated with food consumption and addiction. The observed weight gain in opioid users may also be related to decreased gastric motility and slowed absorption of glucose, resulting in a delayed release of insulin. Furthermore, the suppression of growth hormone during hyperglycaemia appears to be impaired in the opioid-using population compared to controls [40] with other studies postulating opioids may stimulate hypothalamic GH secretion via the mu-opioid receptor [97]. Abnormalities in growth hormone secretion may further contribute to body composition changes.

84.3.2 Alcohol

The relationship among alcohol use, weight gain and cardiometabolic complications including diabetes mellitus is complex and appears to be dose dependent [59]. Frequent but low-level daily use of alcohol may have a protective metabolic effect [73]. A study in nondiabetic postmenopausal women demonstrated lower serum insulin and triglyceride levels in those who drank 30 g of alcohol daily than in those who were abstinent [20]. This effect has been hypothesised to explain the lower frequency of type 2 diabetes mellitus in moderate users of alcohol. The protective effect of moderate alcohol use (<30 g daily) against type 2 diabetes is obviated in those who drink above 48 g daily [50]. Moderate alcohol use in known patients with diabetes is associated with a reduction in cardiac disease although further studies are needed to clarify this effect.

Data detailing the relationship between weight gain and alcohol use is conflicting. While alcohol may account for a large proportion of caloric intake, this has not been consistently observed to correlate with weight gain ([86], p.). Men and those drinking primarily beer as opposed to other forms of alcohol may be more susceptible to gaining central adiposity [98]. Alcohol use disorder, particularly with variable levels of consumption, complicates the management of established diabetes due to the impact on carbohydrate metabolism and treatment adherence. Alcohol-related pancreatitis leading to insulin deficiency, non-adherence to prescribed diabetic therapies and high risk of hypoglycaemia should all factor into the holistic management of patients with comorbid diabetes and substance disorder. Acute alcohol-induced ketosis and lactic acidosis are common acute entities and may lead to acid-base disturbances in the critically unwell patient. In addition, alcohol excess may contribute to euglycaemic diabetic ketoacidosis in patients prescribed the newer SGLT2 inhibitor agents.

There is anecdotal evidence that alcohol may cause increased post-prandial hypoglycaemia, which has been inconsistently replicated in small studies [77]. Hepatic impairment due to alcohol use will also impair gluconeogenesis and therefore patients with liver disease are at risk of hypoglycaemia if inadequate caloric intake occurs. This is especially important clinically in people with type 1 diabetes, where alcohol binges can contribute to the precipitation of severe nocturnal hypoglycaemia. In a different setting, malnutrition is frequently observed in heavy alcohol users and may contribute to this effect.

84.3.3 Tobacco

Tobacco smoking is associated with an increased risk of developing type 2 diabetes, thought to be due to nicotine impairing glucose sensitivity [95]. Both tobacco smoking and nicotine replacement therapy are associated with increased insulin resistance [17]. Smoking reduces body weight

by multiple potential mechanisms including via uncoupling protein-1 induction in subcutaneous fat. The association between smoking cessation and weight gain is well known and remains a barrier to quitting for many patients (Filozof 2004 Obes rev). The average weight gain following cessation of smoking is 3–5 kg, although some patients may gain considerably more [96]. This effect may be attenuated by the use of bupropion, nicotine replacement therapy, fluoxetine or varenicline; however, only exercise interventions have shown convincing benefit [33].

84.3.4 Cannabis

The metabolic role of the endocannabinoid system remains an ongoing area of interest, with both peripheral and central cannabinoid receptors likely playing some role in appetite, weight and energy homeostasis. CB1 receptors in the hypothalamus may mediate food intake, with peripheral CB1 expression on adipocytes and skeletal muscle demonstrated [8]. In trials of cannabinoid receptor-1 antagonist, promising metabolic benefits such as decreased waist circumference, insulin resistance and triglyceride levels raised particular interest as a target for weight loss. However increased suicidality and mood disturbances halted further development and use [39].

84.3.5 Appetite Factors

Regulation of hunger involves multiple neurobiochemical signals stimulated by the gastrointestinal tract, incretins and serum glucose levels. Current evidence suggests that gut hormones responsible for the regulation of food intake also affect dopaminergic neurotransmission in the mesolimbic reward pathways in the brain. Hunger is regulated by several gastric peptide hormones, including ghrelin, amylin, leptin and GLP-1.

During fasting the appetite-stimulating peptide ghrelin is secreted producing hunger signals as well as reward centre activation following food and alcohol intake. It is therefore relevant in alcohol abstinence, as increased ghrelin has been shown to correlate with cravings in early abstinence in alcoholic men [63], making this hormone a potential target for intervention.

Leptin regulates satiety, with leptin resistance developing in obesity. Despite high levels of circulating leptin and high-energy stores, patients with leptin resistance are unable to feel satiated (Pan H 2004 Physiology and behaviour). In animal models, leptin appears important in mediating dopaminergic reward pathways in alcohol, cocaine and amphetamine use [53]. Female, but not male, tobacco smokers with pathological eating behaviours also had evidence of raised leptin levels [64].

Glucagon-like peptide-1 is an incretin and is released in response to food intake, acting to enhance glucose-dependent secretion of insulin shortly after meals. GLP-1 agonist therapies have proven successful in the treatment of obesity. Emerging animal studies suggest central GLP-1 activation may attenuate addictive behaviours via inhibition of the mesolimbic dopamine reward system [91]. Commandeering the mesolimbic dopaminergic reward pathways may potentially lead to targeted treatment for substance addiction in the future, but warrants further prospective studies. The opioid receptor antagonist naltrexone combined with the dopamine and norepinephrine reuptake inhibitor bupropion has demonstrated positive weight loss effects in post-marketing data. In combination, the agents are thought to act on hypothalamic hunger centres and modulate food cravings through an effect on reward pathways [5].

Interestingly, there appears to be a significant overlap between the eating disorder population and substance use population, with 27% of anorexia nervosa patients having comorbid substance use [51]. Chronic starvation, leading to hypothalamic-pituitary suppression, profound electrolyte disturbances, hypogonadism, osteoporosis and cardiac arrhythmias are common in the terminal stage of the condition. Neurobiochemical, genetic and environmental factors appear to all contribute to maladaptive eating behaviours, although precise aetiology warrants further investigation. In addition, patients with schizophrenia have high rates of

tobacco smoking well over 50% and multiple-fold the general population; the cause of this high-frequency relationship may be both behavioural and physiologically based.

84.4 Bone and Skeletal Metabolism

Skeletal homeostasis results from a continuous process of bone turnover, mediated by osteoclasts resorbing bone and osteoblasts forming new bone. This does not occur only as a response to injury but is a continual process mediated by multiple hormonal regulatory pathways. Bone pathology, including osteoporosis and osteopenia, results from an imbalance between the activity of osteoclasts and osteoblasts. In addition, calcium hydroxyapatite is the primary building block of the bone matrix laid down by osteoblasts, and therefore normal calcium homeostasis is essential to this process. Adequate vitamin D is critical to allow bone mineralisation, maintain dietary calcium absorption, promote bone resorption, maintain calcium and phosphate levels and allow adequate parathyroid hormone function. These pathways are all susceptible both to the disturbance by the direct toxicological effect of substances and to lifestyle changes.

84.4.1 Alcohol and Bone

Alcohol is a risk factor for fracture independent of bone density which may be in part attributable to increased fall risk [55]. In addition to fall risk, alcohol produces changes in bone homeostasis resulting in net bone loss. Animal studies have demonstrated that the effect of alcohol on bone homeostasis is mediated via action on osteoblasts [41]. Osteoblast function and numbers are reduced in chronic alcohol ingestion disrupting osteoblast gene expression and bone matrix synthesis. Rodent studies suggest that even moderate levels of alcohol consumption may reduce bone turnover and have detrimental effects on the skeleton. The results from human observational studies in this area have been heterogeneous due to extensive confounding factors; however an increased risk of fractures was seen in patients with an intake of greater than two units of alcohol daily [55]. Part of the mechanism may be related to alcohol-induced hypercortisolaemia, described earlier in this review. A large meta-analysis observed a definitive increase in fracture risk in men consuming alcohol daily or greater than ten drinks per week [28]. Interestingly, another study demonstrated those consuming 0.5–1 unit of alcohol daily had a lower risk of fractures than abstinent patients [9].

As previously discussed, chronic alcohol ingestion may cause pituitary suppression, hypercortisolaemia and hypogonadism further contributing to low bone mineral density. Nutritional considerations, exocrine pancreatic dysfunction and malabsorption of fat-soluble vitamin D may lead to further bone loss.

84.4.1.1 Tobacco Smoking and Bone

Many mechanisms have been proposed for the effect of tobacco smoking on bone health. Nicotine has a direct inhibitory effect on osteogenesis and decreases osteoblast cell production, with cigarette smokers having lower serum concentrations of RANK ligand and osteoprotegerin than non-smokers ([60], p.). In one in vivo study, bone healing was impaired in nicotine-exposed rabbits, leading to an upregulation of vascular endothelial growth factor and hypoxia-inducible factor 1-alpha, yet decreased levels of bone healing factors [26].

Tobacco smoking is a well-recognised risk factor for osteoporosis. This effect appears to remain even after adjustment for confounders such as weight, age and level of physical activity, involves all skeletal sites and appears to be dose dependent [94]. One large meta-analysis demonstrated increased risk of fracture in smokers compared with non-smokers [54]. A twin study of discordant tobacco use demonstrated that smoking one pack per day of cigarettes throughout adulthood resulted in approximately 5–10% reduction in bone mass [49]. The risk of osteoporosis remains elevated even after cessation of smoking, although not as high as in current smokers, suggesting that bone health can improve with

smoking cessation. Anti-oestrogenic effects caused by smoking may also contribute to accelerated bone loss. This effect may be particularly important in postmenopausal women on hormone replacement therapy, as tobacco smoking may increase the metabolism of exogenous oestrogen, further contributing to bone loss in this high-risk population [2].

84.4.1.2 Opioids and Bone

Accelerated bone loss and increased fracture risk have long been observed in the chronic opioid-using population. The net bone loss seen in this population is likely a cumulative effect of disturbed systemic hormone levels and direct opioid inhibition of bone formation via opioid receptors on osteoblasts [18]. Interestingly, in one recent in vivo study, increased bone density was seen in mice administered with opioid receptor antagonist naltrexone [89]. Bone mineral density is lower than normal at all sites in men but not women on methadone maintenance therapy [45]. In one cross-sectional study of men on long-term opioid maintenance therapy, BMD was significantly lower in the lumbar spine but not at the hip compared with age and BMI-matched controls. This appeared to correlate directly with lower serum free testosterone [43]. Moreover, the decreased bone mineral density correlates with an increase in fracture risk as demonstrated in a large case-control study of over 100,000 patients [65, 66]. The purported mechanisms of increased fracture risk in this study are twofold and relate primarily to increased fall risk and the aforementioned hypogonadism.

84.4.1.3 Other Drugs and Bone

The relationship between bone health and other drugs of addiction is less well defined. Endocannabinoids and their associated receptors have been shown to be involved in signalling pathways relating to bone development and remodelling. This suggests THC use may have an effect on skeletal homeostasis, but further study is required [4]. There is little literature relating to the effect of methamphetamine and cocaine use on bone mineral density. A small study of 46 hospitalised methamphetamine users demonstrated lower BMD than in matched controls although the differences were not statistically significant in all age groups [57].

84.4.1.4 Clinical Management

All patients who are at risk of osteoporosis should be screened and commenced on therapy if warranted. Classical risk factors for osteoporosis include hypogonadal states, low body weight, chronic illness and malabsorption syndromes. In the addiction population, one should be especially vigilant and have a low threshold to screen for poor bone health. Patients who use alcohol, tobacco or opioids should be carefully assessed given that these substances may be associated with increased risk. Minimising fracture risk in this cohort should be prioritised even in the context of continuing substance use.

If there is suspicion of poor bone health, a dual-energy X-ray absorptiometry (DXA) bone mineral density scan should be performed. A diagnosis of osteoporosis can be made with a T-score of less than −2.5 or following a minimal trauma fracture with a T-score less than −1.5. If osteoporosis is confirmed, screening for secondary causes should be undertaken. If hypogonadism is suspected, screening via measurement of gonadotropins (FSH, LH, SHBG and testosterone) should be performed. Calculation of fracture risk via fracture calculation tools may be useful in stratifying patients at risk, with WHO estimates showing cost-benefit for treatment when ten-year major osteoporotic fracture risk exceeds 3% [90].

Ensuring adequate dietary calcium (1200 mg of calcium) is paramount to good bone health, with supplementation necessary if dietary intake cannot be maintained. Vitamin D3 (approximately 800 IU daily) is essential for calcium absorption and bone mineralisation [52]. A low threshold should be maintained for vitamin D deficiency in this at-risk population who may not have adequate UVB exposure. A 25-hydroxyvitamin D level equal to or greater than 50 nmol/L is considered sufficient. If levels fail to rise with adequate supplementation, screening for malabsorption syndromes is warranted.

Once a diagnosis of osteoporosis is made, referral to a specialist physician may be prudent in patients with addiction, with advantages and disadvantages of all the available treatment options to be considered. In the hypogonadal cohort, testosterone replacement therapy can be considered in those who are deficient. Combined oestrogen/progesterone or oestrogen monotherapy reduces fractures in postmenopausal women with efficacy equivalent to that of other specific antiresorptive therapies [15]. The minimal effective dose for bone protection has yet to be established and assessment of cancer, cardiovascular and thrombotic risk should be considered prior to commencing these agents.

Antiresorptive therapies (bisphosphonates, denosumab) are beneficial in reducing fracture risk and bone loss in the addiction patient with confirmed poor bone health. Bisphosphonates have proven efficacious for fracture reduction and are available in oral and parenteral forms. Denosumab, a monoclonal antibody that targets RANK-L, is given via subcutaneous injection and has also proven efficacious for fracture reduction. Teriparatide, a PTH analogue given daily, leads to an increase in bone mineral density as well as significant decrease in fracture risk and may also be considered in those with severe osteoporosis or ongoing fractures despite antiresorptive therapy.

84.5 Key Points and Conclusions

- Chronic alcohol use can lead to hypercortisolaemia, hypogonadism and poor bone health. Comorbid hepatic dysfunction may contribute to altered hormone-binding globulins and disrupted glucose homeostasis.
- Opioids are increasingly recognised as having an inhibitory effect on the hypothalamic-pituitary axes, with resultant hypogonadism and hypoadrenalism.
- Tobacco smoking increases the risk of Graves' disease and associated ophthalmopathy and remains an important modifiable risk factor in the management of metabolic syndrome and osteoporosis.
- Disruption of hormonal homeostasis is less well understood in the stimulant-using population and warrants further studies.
- Endocannabinoid antagonists have demonstrated promising metabolic effects, with cannabinoid receptors in the hypothalamus and peripheral tissues an ongoing target of therapeutic development. Cannabis use leads to impaired spermatogenesis compared to non-users.

Disturbances of delicate hormonal balances in the addiction population are becoming increasingly recognised phenomena. Delicate biochemical and hormonal homeostasis may be altered by numerous stimuli including addictive substances and cycles of addiction and withdrawal. An index of suspicion linked to careful assessment of comorbid endocrinopathy in these patients is crucial. Although overt clinical syndromes remain uncommon, subtle disturbances appear to be common. Furthermore, complications of prolonged disturbances may persist in abstinence and should be carefully evaluated in chronic care. Whether these disturbances could perpetuate addictive behaviours requires further study, with guidelines for screening and treatment yet to reach consensus. Nevertheless, any neurohormonal process that may lead to relapse or chronic comorbidity warrants consideration in this population.

Sexual Function and Alcohol and Other Drug Use

85

Richard Hallinan

Contents

Abstract

Alcohol and other drugs have actions in limbic-hypothalamic hedonic motivational pathways that subserve basic biological functions including sexual behaviors. They may also have a range of other physiological and psychological effects on sexual function.

Psychoactive drugs are often used to facilitate or enhance sexual behaviors, but they can also cause sexual dysfunction. Their use can be associated with risky or harmful sexual behaviors.

Pharmacotherapies commonly used in addiction treatment, including opioid pharmacotherapies, sedative/hypnotics, antidepressants, and antipsychotics, can negatively affect sexual function, with implications for treatment adherence and effectiveness. Further, common psychological and physical comor-

bidities in people with substance use disorders may cause sexual dysfunction.

An understanding of these issues can help clinicians working in the field of addiction better to appreciate motivations for continuing or reducing drug use, can inform motivational and harm reduction interventions, and can improve understanding of issues around treatment adherence. While there are challenges for clinicians in speaking about sexuality with their patients, this may be an important part of comprehensive assessment and treatment planning. The clinical benefits of addressing these issues, ranging from reducing sexual risk behavior to improving the quality of life of people receiving pharmacotherapies, can be substantial.

85.1 Introduction

The impact of alcohol and other drugs (AODs) on human sexuality can be considered across three domains: (1) the deliberate use of alcohol and drugs to facilitate or enhance sexual behaviors, (2) their association with risky or harmful sexual behaviors, and (3) their association with sexual dysfunction [85].

Human sexuality and its disorders are complex and there are uncertainties even in the definitions of normality and dysfunction in human sexuality, differing between males and females, across the human lifespan, within and across cultures. One must distinguish between acute effects and chronic effects in heavy or dependent users of alcohol and other drugs. Epidemiologically, moreover, there are three distinct types of study populations for AOD-related sexual dysfunctions:

1. Populations with sexual dysfunctions
2. Clinical populations with substance use disorders
3. Population studies, which generally shed light only on commonly used substances

85.2 Substances and Sexual Dysfunction

85.2.1 Models and Neurochemical Substrates of Normal Sexual Function

In order to understand the effects of alcohol and other drugs on sexual function and to identify and manage sexual dysfunction where it occurs, it is important to have an idea of what is normal.

Since Masters and Johnson in the 1960s and with various amendments (Kaplan, Lief, and Levine, among others), the human sexual response has been described as proceeding in linear fashion through phases of desire, excitement, orgasm, and resolution. Progressive editions of DSM and ICD correspondingly defined disorders of reduced or impaired desire, arousal, and orgasm, adding premature ejaculation (PE) in the case of men and dyspareunia and vaginismus in women.

The linear model has been challenged for women and a cyclic model proposed instead, with overlap between phases, especially desire and arousal, reflecting the complexity of sexual motivation, the importance of intimacy, and a broader view of sexual satisfaction [13]. In DSM-V, desire and arousal disorders are merged for women but not men, while they remain distinct for both sexes in ICD-11 [96]. Hypersexual disorder was rejected for DSM-V but compulsive sexual disorder was included in ICD-11 under impulse control disorders.

A model for sexual responsiveness in mammals including humans posits a dynamic balance of excitatory and inhibitory forces, across all domains of sexual function [57, 87]. There are commonalities among the neurochemical substrates of reward and reinforcement of the essential biological functions of feeding and sexual activity, and those of drugs and alcohol, which most clearly increased dopamine activity in the nucleus accumbens [66, 82].

Sexual excitatory factors include dopaminergic pathways which control attention to incentive stimuli, behavioral responses, and parasympathetic outflow to genital areas, melanocortin, the "bonding hormone" oxytocin, and noradrenaline, which has an "inverted U"-shaped relationship with sexual behavior, whereby states of fear or anxiety reduce excitation. There are complex interplays among these factors, and their tone is influenced hormonally by estradiol and testosterone and also by gonadotropins directly. Testosterone is important for sexual desire and arousal in both men and women, and estrogen for arousal in women, including genital swelling and lubrication. Peripherally these hormones modulate mechanisms involving nitric oxide synthase, vasoactive peptides, prostaglandins, and serotonin, which act to increase genital blood supply [87].

The evolutionary value of the inhibition of mammalian sexual function is likely dual: to allow refractory periods and to avoid conflict within the species. Inhibition can be divided into two aspects, satiety and executive (prefrontal) inhibition. Evidence from the feeding literature suggested serotonergic mediation of satiety. Opioids may have a dose-related rewarding function, inducing satiety at higher doses. Endocannabinoids also appear to have a role in sedation after orgasm. Sedation in itself is likely to play a role in sexual responsiveness.

The central role of dopaminergic, serotonergic, and opioid-mediated processes in normal human sexuality points to the potential effects of prescribed and nonprescribed psychoactive substances in human sexuality.

85.2.2 How Common Is Sexual Dysfunction? Evidence from Population Studies

Population studies show high prevalence of sexual difficulties in women and men. Approximately two thirds of women report difficulty with sexual desire, one third difficulty with orgasm, one third difficulty with arousal, and a quarter of sexual pain [53]. However, only a proportion of the women were distressed by these difficulties, and symptoms were often not persistent [102]. Difficulties with erection are reported by 30–40% of men, with premature ejaculation by 10–20% and delayed orgasm being less common. In general, while the prevalence of sexual difficulties increases with age in both men and women, associated distress declines with age [33].

85.2.3 Deliberate Use of Psychoactive Substances in Sexual Behavior

Population studies show that drugs and alcohol are often used for sex-related purposes. There are differences among drugs in their perceived effects and uses: cocaine to prolong sex, alcohol to facilitate encounters, and MDMA to increase desire, closeness, and satisfaction but which may reduce erection and delay orgasm [7, 71, 122]. Opiate users are less likely than other drug users to attribute positive sexual effects to their drug [95]. Amphetamines and cocaine are most commonly reported to be pro-sexual, but some people report the opposite.

It should be borne in mind that childhood abuse, especially sexual abuse, is a risk factor for the development of substance use disorders and also for risky sexual behaviors [5, 11].

Both perceived effects and expectancies about drug use vary by demographics, gender, and context; women may believe or perceive the effects of drugs in men to be different from their own [38, 95]. Some evidence suggests the use of drugs as self-medication for sexual difficulties, which may be an important factor in the initiation of drug use [67, 75].

The term sexualized drug use "refers to the use of drugs in a sexual context…." "Chemsex" has been defined as "the use of drugs…before or during planned sexual activity to sustain, enhance, disinhibit or facilitate the experience" [37]. These include methamphetamine, GHB/GBL, mephedrone, phosphodiesterase type 5 inhibitors (PDE5-I), ketamine, and alkyl nitrites (such as amyl nitrate or "poppers") [47].

Recreational drug use and binge drinking have been associated with risky sexual behaviors including condomless sex and having partners of unknown HIV serostatus [71, 97]. People using stimulants, including nonmedical users of prescription stimulants, are reported as having higher numbers of sexual partners, higher rates of providing sex for money or drugs, and higher rates of sexual risk behavior [49, 68, 76, 116]. Risky sexual behaviors among people who use drugs and alcohol may reflect impulsivity, disinhibition, and impaired judgement and capacity for consent. While sedative/hypnotics and GBH are sometimes implicated in "date rape" cases, the most commonly identified substance is alcohol [85].

Oral erectile dysfunction (ED) agents are commonly used by recreational and dependent users of alcohol [90]. Among men who have sex with men, the use of sildenafil is associated with increased HIV risk; the combined use of methamphetamine and sildenafil is especially of high risk [42]. People who inject drugs reporting same-sex activity had substantially higher odds of chemsex use than those reporting heterosexual activity [54]. Higher sexual risk is not limited to sexual minorities, as suggested by increasing heterosexual syphilis transmission among persons who use methamphetamine in the USA [61]. In Africa and the Middle East, numerous groups are identified at higher risk of HIV, including people who use drugs, especially people who inject them, women in general, and female sex workers and their clients [77, 86].

85.2.4 Understanding the Etiology of Sexual Dysfunction in General

Assessment and management of sexual dysfunction in any clinical context require a consideration of its numerous possible causes.

85.2.4.1 Hormonal Factors

In women, testosterone and DHEAS peak in early adulthood and decline rapidly and progressively after such that levels are halved by age 40 [31]. By contrast, decline of testosterone in men is progressive from about age 40. Men have 10–16 times the level of testosterone compared to women, so the slow decline with age does not impact on hormonal drive and libido until older ages.

Androgen deficiency is common in men presenting with erectile dysfunction (ED) [62] and androgen replacement is beneficial for sexual function in hypogonadal men [8, 9], though not for the normal testosterone decline of aging. A large population-based cohort of older men showed no association of testosterone with ED, except in men with increased luteinizing hormone (LH) levels suggesting primary testicular disease [64].

Although androgen deficiency has not been unequivocally associated with female sexual dysfunction, several studies have shown the benefit of testosterone therapy on sexual desire, arousal, orgasm, and satisfaction in naturally or surgically menopausal women [31]. There is a challenge in understanding changes with menopause as distinct from aging itself: declining estrogen after menopause is a cause of vaginal dryness and dyspareunia [32]. Postmenopausal status increased the risk of sexual dysfunction in middle-aged women, while postmenopausal hormone replacement use was protective [17].

Hyperprolactinemia and hypothyroidism are also potential causes of sexual dysfunction in both men and women. While hyperprolactinemia commonly manifests with sexual dysfunction, hyperprolactinemia is an uncommon cause of male sexual dysfunction, which is not necessarily mediated by reduced testosterone [8, 16].

85.2.4.2 Vascular and Neural Factors

Normal sexual function requires intact vascular and neural function to the genital areas. Neuropathy may include autonomic or reduced tactile sensation, especially in genital areas. Endothelial disease is a common cause of erectile dysfunction in men [8]. Sexual dysfunction in diabetes is probably mediated by both vascular disease and neuropathy and multiple sclerosis through neuropathy.

85.2.4.3 Bodyweight, Obesity, Sleep Apnea, and Exercise

Overweight and obesity are increasingly implicated as risk factors for male sexual dysfunction, principally erectile dysfunction [106]. ED has a U-shaped relationship with weight (i.e., underweight is also a risk factor) and abdominal obesity and physical inactivity were associated with ED independent of body mass index, while physical activity itself appears protective against ED and female sexual dysfunction [2, 20, 56].

Obstructive sleep apnea is also independently associated with ED [15] as it disturbs REM sleep, which is the time during sleep when most nocturnal erections occur. Fewer nocturnal erections are a factor in the development of chronic diffuse corporeal fibrosis, leading to ED. This is preventable with early CPAP.

85.2.4.4 Other Medical Illnesses

Numerous other medical illnesses can cause sexual dysfunction, especially those affecting general constitution and fitness, such as chronic heart disease and lung disease. Chronic liver disease, especially liver failure, is related to sexual dysfunction independent of alcohol use [36].

85.2.4.5 Psychological Factors

Distress from sexual dysfunction appears to be dependent not only on age but also on relationship. Postmenopausal status and presence of sexual dysfunction in the male partner increased the risk of sexual dysfunction in middle-aged women, while partner faithfulness and menopausal hormone replacement use were protective [17]. In men, self-esteem and depression mediate the effect of erectile dysfunction on quality of life [89]. Continued alcohol use by alcohol-dependent men had negative impacts on sexual intimacy in the relationship which improved with abstinence [80]. Marital conflict may be an important factor in reported sexual dysfunction in male alcoholics [81].

85.2.4.6 Psychiatric Disorders and Their Treatment

A key issue is distinguishing between *preexisting and treatment-emergent* sexual dysfunction in people with mood, anxiety, and psychotic disorders, who may be prescribed with psychotropic medications. In each of these groups of disorders, there are high rates of sexual dysfunction, generally in the direction of hypofunction [25]. Anxiety and depression are also associated with premature ejaculation in men [92]. As with opioid pharmacotherapies (see below), sexual emergent side effects can affect psychiatric treatment adherence [104].

While SSRIs appear mainly to affect orgasm and antipsychotics primarily desire, all phases of sexual function can be affected by psychotropic medications. There appears to be a hierarchy among antidepressants regarding treatment-emergent sexual dysfunction with prevalence ranging from 25% to 80%. Among SSRI/SNRIs, sertraline, venlafaxine, and citalopram have higher prevalence of sexual dysfunction than escitalopram and fluvoxamine. Several other types of, primarily non-serotonergic, antidepressants (including agomelatine, bupropion, moclobemide, mirtazapine, and nefazodone) do not significantly differ from placebo [50, 103].

Sexual dysfunction is also common in people treated with antipsychotic agents, with no significant difference found among risperidone, quetiapine, and olanzapine [78]; these drugs are commonly associated with hyperprolactinemia, but hyperprolactinemia and sexual dysfunction were not correlated with each other [59].

For benzodiazepines and mood stabilizers, evidence of effect on sexual function is relatively lacking [25, 65]. Diazepam, clonazepam, and alprazolam have been associated with treatment-emergent male sexual dysfunction [44].

85.2.5 Sexual Dysfunction Related to Substance Use and Dependence

85.2.5.1 Tobacco and Cannabis

In men, tobacco smoking is a clear risk for vasculogenic ED, cumulative with packet years of smoking and persisting in former smokers [22, 72, 112]. Evidence is lacking for specific effects of tobacco smoking on arousal in women, though

other risks/indicators of endothelial disease (metabolic syndrome, obesity, diabetes, and coronary heart disease) are associated with female sexual dysfunction [74].

Daily cannabis use was associated in one study with difficulty achieving orgasm in men, but not sexual dysfunction in women [108], in another study with inhibited orgasm and dyspareunia [60], and in other studies with the beneficial effects of cannabis for erectile function [105]. The effects of cannabis use on sexual function are hard to disentangle from those of tobacco, as tobacco is often mixed with cannabis when the latter is smoked, and where cannabis is used in other ways than smoking, tobacco smoking is typically also common.

85.2.5.2 Alcohol

Low to moderate alcohol use in men may confer protection from erectile dysfunction [2, 22, 72].

Heavy alcohol use and alcohol dependence are common in clinical populations with sexual dysfunction, and alcohol-dependent men have been reported in studies in a range of countries to have sexual dysfunction including premature ejaculation, ED, and reduced desire [3, 35, 39]. Sexual dysfunction is also reported for alcoholic women, though evidence is less [58].

Pach et al. [83] found high prevalence of ED in alcohol-dependent men, which was not associated with testosterone or prolactin concentrations, but to higher gonadotropin levels, consistent with a toxic effect of ethanol on the testes. In the absence of severe liver disease or hypogonadism, male sexual dysfunction improves with abstinence [114].

Autonomic neuropathy commonly goes unrecognized in alcoholics and appears to be dose related and potentially reversible on abstinence; in heavy male alcohol users, erectile dysfunction may be the only symptom of parasympathetic neuropathy [94].

85.2.5.3 Opioids

Chronic users of opioids including heroin, and opioid pharmacotherapies for dependence and for chronic pain, have high prevalence of sexual dysfunction, consisting in hypoactive sexual desire and arousal difficulties in both genders, and increased ejaculatory latency in men [29, 88].

There is strong evidence of sexual dysfunction in both treated and untreated opioid-dependent men, including numerous studies in heroin users from a range of countries and cultures and several studies of opioid substitution treatment [6, 10, 52, 79, 91, 115]. Erectile dysfunction may be less common in men on buprenorphine than on methadone for the treatment of opioid dependence [119]. The smaller published evidence for women suggests reduced libido, emotional arousal, and orgasm satisfaction in women using opioids [12, 115, 101].

Early studies of methadone maintenance treatment (MMT) found either improvement or little change in sexual function in opioid-dependent women and men compared with their prior heroin use [45, 117]. Garbutt and Goldstein [45] prospectively studied 120 entrants into MMT, and while average "climax" and "impotence" scores improved at 27 weeks, compared with baseline, the majority of the 30% who dropped out of treatment reported loss of sexual function as a major reason. More recent studies of men on MMT and buprenorphine maintenance treatment (BMT) have given mixed results for erectile dysfunction with opioid pharmacotherapy showing improvement [4, 24], deterioration [123], or no change [19] compared with prior heroin use. By contrast with heroin users entering opioid pharmacotherapy, where prior sexual dysfunction is common, sexual dysfunction in men treated with opioids for chronic pain is more clearly treatment emergent [29].

Cross-sectional studies of the relationship between methadone dose and sexual dysfunction have given mixed results [21, 52, 79]. This may reflect the large interindividual variation in the pharmacokinetic and pharmacodynamics of methadone. Clinical experience is that methadone dose reductions may improve sexual dysfunction. The relationship between testosterone levels and erectile dysfunction has not consistently been shown in cross-sectional studies of opioid users [23, 46, 120].

Numerous other correlates of sexual dysfunction in opioid users have been variously, if inconstantly, identified. These include marriage status, depression, MMT duration, age, sleep quality, unemployment, education level, and tobacco smoking [21, 34, 70, 113, 119].

Most reported studies identifying orgasmic difficulties in men do not distinguish between premature ejaculation and delayed orgasm. Where it has been studied, premature ejaculation is found to be more common in men using heroin and on methadone treatment than in general community studies, and opioids may be used deliberately by some men to manage this problem [1, 18]. Although opioid antagonists have been trialed as treatment for erectile dysfunction, the only study available of sexual dysfunction in men on naltrexone maintenance treatment found high prevalence of erectile dysfunction, comparable with buprenorphine maintenance. However, premature ejaculation was the most common dysfunction in these men [93].

Increasing literature in recent times points to significant impacts of sexual dysfunction in patients injecting opioids or receiving opioid pharmacotherapy on quality of life and psychological distress [21, 70, 113]. Gerra et al. [46] found evidence suggesting psychiatric symptom load and neglect history may actually mediate opioid effects on sexual function.

85.2.5.4 Stimulants

In contrast to population studies finding the use of stimulants to improve sexual function, in clinical populations with substance use disorders, cocaine use was commonly associated with impaired desire and sexual, especially orgasmic, function [63, 95, 116]. Amphetamine users had high rates of sexual dysfunction, though less than those of dependent opiate, mostly injecting, users [48, 6] reporting IIEF scores of men shortly after their entry into a compulsory drug treatment facility, found odds ratios for erectile dysfunction were significantly higher relative to controls for heroin (4.8) and amphetamines (3.2), but not for MDMA users. While 23% of amphetamine users reported increased sexual desire, the sexual desire scores of this subgroup were still significantly lower than those of controls. The heterogeneous nature of actual or perceived drug effects is further reflected in the fact that about half of the men in this study reported increased, while about 15% decreased, ejaculatory latency.

85.2.6 Sexual Function and Alcohol and Other Drug Use: Clinical Assessment and Management

Assessment of sexual dysfunction in people with substance use disorders is based on the understanding that there may be multiple contributing factors:

1. The actions of the substances themselves
2. Psychiatric and medical comorbidities, as described above
3. The psychosocial context including partner status, self-esteem, and relationship issues
4. The effects of treatments, especially with dopamine antagonists, serotonergic agents, and opioids, but also non-psychotropic medications such as beta-blockers, antihistamines, NSAIDs, and thiazide diuretics

Few patients may volunteer information about the impact of substance-related sexual disturbance on their lives, and few clinicians may ask [19, 101, 118]. Low sexual desire may not constitute a symptom – if anyone complains, it may be the partners. Clinical presentation can be indirect, with depression, relationship problems, underdosing of or poor treatment adherence with opioids and other medications, and even dropping out of treatment.

Clinicians can develop skills to incorporate inquiry about sexual matters as part of comprehensive assessment and ongoing assessment in a way that puts patients at their ease. For example, it may be helpful to inquire about sexual dysfunction as one of other common medication-associated symptoms: in the case of opioids, these include sweating, constipation, and disturbances of menstruation.

It should be clarified which phases of sexual response are involved, desire, arousal, and orgasm, as this may determine the focus of management. Also important in assessment are the effect that sexual dysfunction is having on their lives and whether it is affecting their attitude to treatment in any way. Unless there is distress, sexual dysfunction may not need specific management.

Drug treatment services and other settings where brief interventions can be carried out provide opportunities for discussing drug-related sexual risks and promoting safe sex. For people continuing to use drugs or alcohol, discussion of sexual function may be important in motivational interventions. Abstinence may come at a perceived or actual cost to one's sex life. Equally, sexual dysfunction resulting from alcohol or drug use may be a salient motivation toward abstinence [84]. Sexual contexts, cues, and triggers may be important, for the risk of relapse, to be considered in relapse prevention strategies [95].

Where "self-medication" of premature ejaculation with alcohol or other drugs is causing problems, discussion of alternatives might reduce harms and risk of dependence or relapse. The SSRIs fluoxetine, paroxetine, and citalopram, and also tramadol have shown benefit for the treatment of premature ejaculation, and the short-acting SSRI dapoxetine has been approved in a number of countries specifically for the indication on premature ejaculation. Other treatments include local anesthetics such as topical lignocaine and the Masters and Johnson "squeeze technique."

Small open-label studies reported the benefit of the serotonin antagonist and reuptake inhibitor trazodone for erectile dysfunction in men on MMT [111] and of the dopamine agonist bromocriptine to treat sexual dysfunction in MMT on the hypothesis of possible hyperprolactinemia [107] – however hyperprolactinemia is uncommon in men on MMT and unrelated to sexual dysfunction [52, 119]. Small randomized controlled trials have shown promise for Damascus rose oil for sexual dysfunction in both men and women on MMT [40, 41] and for bupropion for erectile dysfunction in men on MMT [99, 121]. There are a few reports of improvement in sexual function with androgen replacement in men receiving opioid treatment for chronic pain (see [27] for a review) and buprenorphine for opioid dependence [26].

Otherwise there is limited specific evidence to guide the treatment of sexual dysfunctions arising out of substance use and its disorders. In the absence of such evidence, the clinician must integrate more general evidence into clinical practice.

85.2.7 Treating Sexual Dysfunction

85.2.7.1 The Example of Opioid Pharmacotherapy

Where sexual dysfunction is identified in the setting of opioid pharmacotherapy, management is likely to be multifaceted, with consideration of:

- Mood, anxiety, and psychotic disorders and related psychotropic medication use including antipsychotics, "antidepressants," and sedative/hypnotics
- Other potentially treatable or reversible risk factors for sexual dysfunction including tobacco smoking, alcohol and other drug use, sleep apnea, and obesity (noting that exercise may be protective against sexual dysfunction)
- Issues related to poor self-esteem, including obesity and poor dentition
- Hormonal status, especially hypogonadism
- Partner status and relationship issues

Sexual dysfunction attributed to methadone treatment may cause patients to drop out of treatment [45, 101]. Set within the larger issue of treatment planning, people may be prepared to tolerate the side effects of pharmacotherapies if these are discussed, and their identification may provide a rational and structured context for goals in treatment.

Pharmacological strategies for hypoactive sexual desire include hormone replacement where there is hypogonadism. The centrally acting dopaminergic agent apomorphine is limited by side effects especially nausea [73]. Centrally

acting pro-dopaminergic and anti-serotonergic medications are the foci of ongoing research [109]; see also Sect. 85.2.7.2. Such treatments usually involve consultation with an endocrinologist or sexual health physician.

In both men and women with sexual dysfunction emergent with opioid, antidepressant, or antipsychotic therapy, dose reduction, changing medications to alternatives with lower reported rates of sexual side effects, timing of medication in relation to planned sexual activity, and addition of phosphodiesterase type 5 inhibitors (PDE5-I) are all plausible strategies, though studies of these approaches are lacking [98, 100]. As well as having favorable profiles for sexual side effects in monotherapy, the antidepressants bupropion, trazodone, and mirtazapine have shown benefit as add-on treatment to SSRIs for depression.

Despite the lack of a consistent dose relationship of sexual dysfunction to methadone dose in cross-sectional studies, it is likely that sexual dysfunction is dose related in any one individual and that dose reductions can help, provided this does not lead to relapse into other opioid use. With the same caveats, cross-sectional studies showing less prevalent sexual dysfunction in men on buprenorphine than methadone suggest possible benefit of switching medication.

How is the clinician to understand the inconsistencies in the epidemiological literature as to the role of opioid medication, dose, other drug use, and demographic and clinical correlates in sexual dysfunction? They may reflect the complexity of human sexuality, the large number of factors involved, and interindividual variation in these factors. It may be that a correspondingly individual approach is the most practicable clinical approach. In practical terms, that means considering all of the potentially relevant issues and seeking pragmatic individual solutions.

85.2.7.2 Some Specific Issues for Women

Systemic testosterone may have a role for hypoactive sexual desire in surgically and naturally postmenopausal women. It is only approved for limited indications in a few European countries, although off-label use is common [30, 43]. Side effects include hirsutism, deepening of the voice (the latter can be irreversible), male pattern alopecia, and clitoromegaly, and longer-term concerns include possible increase in cardiovascular disease and breast cancer.

Systemic estrogens with or without progestins can improve menopause-related symptoms, including reduced genital arousal and lack of vaginal lubrication. Topical estrogens may be preferred for equal efficacy and the absence of systemic side effects and lower risk of breast cancer. Evidence does not support benefit for estrogen treatment to increase sexual desire [30]; indeed, estrogens might reduce sexual desire.

The PDE5-I sildenafil, in lower doses than are used in men, shows benefit for female sexual dysfunction related to multiple sclerosis, spinal cord injury, and diabetes, secondary to antidepressant use [14].

Two medications have now been approved in the USA for treatment of hypoactive sexual desire disorder, both showing significant but modest effects. Flibanserin is functionally characterized as a noradrenaline and dopamine disinhibitor [110] and is marketed for daily use. It has had a small market uptake so far, possibly owing to its side effect profile and interactions with alcohol and medications. Bremelanotide, a melanocortin receptor agonist, is marketed as an injection for on-demand use by injection. Limited study populations led to corresponding limitations in drug labeling and drug subsidy. The need for research in "additional study in diverse populations" [69] and the redefinition of arousal and sexual desire disorders add to the uncertainty in the use of these medications.

85.2.7.3 Some Specific Issues for Men

PDE5-I are effective for erectile dysfunction of a broad range of etiologies. They may be beneficial where erectile dysfunction is a side effect of opioid pharmacotherapy and where opioid dose reductions are likely to be counterproductive. They have advantages including on-demand effectiveness and absence of long-term side effects. However, some men who have erectile dysfunction do not respond at all, or if so not longer term, to PDE-5 inhibitors, and for some, these

drugs are contraindicated. Currently available alternatives include intracavernosal injections.

In counseling, one should bear in mind that orgasmic dysfunction itself may contribute to erectile dysfunction in men, and loss of confidence and relationship stress can play a large role in perpetuating erectile dysfunction. Involvement of the partner in counseling may be helpful, and nondrug aids such as penile rings and vacuum devices are cheap and easily available or can be improvised, though not without their risks.

Opioid-induced androgen deficiency can be managed by dose reduction, medication switch, or androgen replacement [55] and weight loss where there is obesity. It is questionable whether androgen replacement should be considered where heavy alcohol use or unprescribed opioid use continues. The decision for androgen replacement should be informed by the possibility of placebo response and the possibility that initial benefit for sexual symptoms may not be sustained [28]. Concerns about excessive or otherwise inappropriate use of androgens can be minimized by prescribing transdermal formulations or limited supply and supervised administration of injected formulations.

85.2.7.4 Setting the Management of Sexual Dysfunction Within the Social Context

Relationship conflict can be a contributing factor in sexual dysfunction. In management, it can be helpful to place the sexual problem within the context of the relationship rather than the individual. At the same time, it must be recognized that people with AOD problems often have high levels of social dislocation, including disrupted or lacking intimate relationships. Economic factors, low self-esteem, poor dentition, tobacco smoking, and obesity are all factors to which the social context is relevant; none can simply be solved with a prescription.

85.2.8 International and Public Health Perspectives

Research into the nexus of sexuality and AOD use is increasing. Where research was previously mostly from Western societies, the increasing published literature from Asia, the Middle East, and South America indicates that issues of sexuality are important across a range of societies and cultures.

Numerous screening and research instruments for sexual dysfunction are available for both men and women, of which some are widely validated in different cultures/languages. That single question instrument have shown utility in identifying sexual problems in research settings suggests that simple methods of enquiry may also have clinical utility. For clinicians, the challenge in any setting is to develop sensitive and culturally appropriate techniques of inquiry. Eliciting information about sexual experiences other than heterosexual intercourse, "self-pleasure" (masturbation), and sexualized drug use may be challenging in all cultures.

Given the public health concerns related to AOD and sexually transmitted diseases, it may be that addiction medicine clinicians should pay attention to their patients' sexual lives no less than do sexual health clinicians. There is a need for interventions to reduce health risks related to sexual behaviors, including sexualized drug use, which are informed by understanding social and cultural contexts. These may include the impact of gender/sex identity, sexual orientation, sexual venue, relationship dynamics, and socioeconomic factors such as poverty, stigma, and marginalization.

85.3 Clinical Relevance

This chapter encompasses three main theses relevant to the clinical practice of addiction medicine, namely:

1. Human sexuality can be a major motivational factor in the initiation and continuation of alcohol and other drug use and may entail high-risk sexual behaviors.
2. Alcohol and other drug use might have both adverse and positive (whether actual or perceived) effects on people's sexual lives.

3. Pharmacological treatments used in addiction treatment may (mostly adversely) affect people's sexual function, and this has implications for treatment acceptability and adherence.

The overarching proposition is that awareness of these issues can inform both clinical practice and public health policy. The clinical implication is that enquiry about sexual experience and function can be an important element of assessment in AOD contexts, from general practice to the specialist addiction treatment facility, providing opportunities for informed counseling around risky sexual behaviors and improving access to and adherence to treatments.

At face value it seems no more remarkable to propose that clinicians should ask about matters of human sexuality than that they should ask about the clinically important matter of bowel function (which can have considerable health impacts; [51]). This proposal comes with some caveats: that enquiry about sexual matters ought to be culturally appropriate, that it be sensitive to the high prevalence of abuse including childhood sexual abuse in AOD clinical populations [5, 11], and that examination of genitalia be considered in the light of a possible abuse history and where necessary referred to another clinician.

85.4 Conclusion

Human sexuality and its disorders are complex, involving a wide range of physiological, pathological, psychological, and societal factors. The benefits of addressing these issues in AOD settings, from reducing sexual risk behavior to improving the quality of life of people receiving pharmacotherapies, can be substantial. Better understanding of the relationship between sexuality and AOD use might enable more effective prevention, treatment, and harm reduction for AOD use and is the focus of ongoing diverse research endeavors.

Abstract

This chapter outlines the problems that may arise when patients with a substance use disorder present for surgery, including the social, psychological and biomedical aspects. The assessment and management of patients and the factors that may affect anaesthesia and perioperative pain management are covered.

Keywords

Substance use disorder · Anaesthesia
Acute pain

86.1 Introduction

Much of the literature on the effect of substance use disorder (SUD) and perioperative care focus on the biomedical effect of any substances used on the patient's physiology and on interactions with pharmacological agents. Social and psychological factors may cause more difficulty in providing the best medical care to people with substance use disorders and addiction. The patient has a different focus when presenting for surgery than when attending addiction services. Having surgery and anaesthesia carries a set of meanings: fear of pain, complications or death, worry about diagnosis and prognosis, being in the alien environment of the hospital, among others. For the patient with SUD, there is also the anxiety of being unable to access their substance and the value judgements that they feel may be made about them. The perioperative setting is an opportunity for brief intervention. An open, empathic approach is essential to avoid triggering an antagonistic confrontation. The priority is to ensure quality and safety in perioperative care and a successful outcome from surgery.

86.2 Social and Psychological Factors

When patients with SUD or addiction are admitted to hospital for surgery or when acute pain management is required, there can be problems with establishing a good therapeutic relationship between the patient and healthcare professionals (HCPs). There may be a perception by the HCP that SUD or addiction is a character defect or a lifestyle decision, rather than a neurobiological condition, with complex predisposing and perpetuating factors. HCPs involved in perioperative care may have limited knowledge or understanding of the underlying causes and treatment of the condition.

Societal and cultural differences between the HCP and patient may make establishing a trusting relationship more challenging.

From the patient's perspective, there may be lack of trust in HCPs due to previous negative experiences, feeling judged and not believed in, when reporting pain and other symptoms. The perceived stigma of addiction and feelings of guilt or shame may lead patients to withhold information. Sometimes, symptoms can be exaggerated by the patient, in an attempt to ensure that

they are taken seriously by the HCP. The social circumstances of the patient may foster feelings of alienation from the HCP and there may be attempts to mislead, deceive or manipulate, which can lead to further loss of trust. Intoxication, withdrawal symptoms or mental health problems, such as personality disorders, can deter the establishment of therapeutic alliance. Patients may be anxious or fearful of undertreatment of pain or of withdrawal symptoms if they are not able to access tobacco, alcohol or other substances. Those on opioid substitution therapy (OST) may worry that they will not be able to access it. Illicit drugs can be taken in addition to prescribed treatment, or the patient can take discharge against medical advice, due to anxiety, among many other factors.

Frequently, these factors can lead to a perpetuation of the cycle of negative experience on the part of the patient and the perception of patients with SUD as difficult to help or not deserving of care from the perspective of HCPs.

The development of an open, empathic and non-judgemental approach, as well as being able to understand more of the underlying issues for the patient, is key to ensuring a more humane and patient-centred care in the perioperative period, as well as contributing to more effective and safe management of acute pain.

Reassurance that pain and withdrawal will be managed as well as can be is the first step while recognising that pain cannot be completely eliminated and is sometimes more difficult to manage, due to factors such as tolerance and opioid-induced hyperalgesia. The development of a realistic agreement with the patient and emphasising that mutual respect and honesty are expected are important in ensuring safe and effective medical care.

86.3 General Assessment of SUD

Gaining the patient's confidence is important in the assessment of what substances may have been abused and whether intoxication, withdrawal or social, psychological and behavioural problems might affect their care in the perioperative period.

In many countries, particularly in more prosperous nations, substances that are liable to cause dependence or to be abused are more likely to be prescribed medication, such as opioids, benzodiazepines and gabapentinoids, than illicit drugs [1]. When taking a history, problematic or aberrant drug use can be elicited by asking about the quantity prescribed at a time, whether the prescription has run out before it was due for renewal and whether the patient has taken more than was prescribed or has overdosed. Corroborating information with the prescriber, pharmacist and prescribing monitoring schemes can construct a more accurate picture of whether to expect tolerance, withdrawal or problematic behaviour.

Over the recent years, the demographics of persistent opioid use has changed, with more liberal prescription of strong opioids for persistent or chronic pain. This increase in prescribing has resulted in rising rates of harm [2]. The numbers of patients coming to harm from prescribed opioids has exceeded those taking illicit drugs. The initial medical enthusiasm, in the 1990s and 2000s for using the principles of the analgesic ladder in chronic non-cancer pain, was based on the experience of success in being able to manage 85% of patients with cancer pain with oral opioids [3]. There was a widespread belief that patients with pain are unlikely to develop addiction. Unfortunately, the evidence that has emerged subsequently failed to show improved pain relief, quality of life or likelihood of recovery from chronic non-cancer pain. At the same time, there is increasing evidence of harms associated with prescribed opioids [4].

There is a complex interplay of pharmacological, biomedical, social and psychological factors in patients taking prescribed opioids as well as in healthcare practitioners caring for them. Often patients will be presenting for orthopaedic or neurosurgical treatment for the condition which has led to them being prescribed with opioids. In the case of back and neck pain, this can be especially problematic, with little evidence that either opioids or surgery are helpful in managing the

patients' pain [5, 6]. When assessing patients for care in the perioperative period, those taking prescribed opioids will outnumber those taking illicit drugs.

86.4 Societal Factors

Opioids have been the mainstay of pain management for thousands of years. Widespread use and misuse among veterans following the American Civil War led to an international treaty to restrict the availability of opioids in 1914. There followed many years of "opiophobia", with the belief that the use of opioids for treatment, even of terminal cancer pain, would lead to the rapid development of tolerance and addiction. As a result, it was advised not to prescribe opioids even in terminal cancer until the last few days of life. The introduction of the World Health Organisation "Analgesic Ladder" in 1986 [3] led to the establishment of the principle of treating the patient's pain based on their subjective rating of severity and relief with treatment. The publication of an observational letter and a small trial in patients with back pain led to an advocacy for the use of the analgesic ladder in patients with non-cancer pain in 1990 [7]. These influential publications in combination with promotion of better pain management, in which the pharmaceutical industry was involved, led to a marked rise in opioid prescribing, particularly in North America, the UK and Australia.

When considering the DSM criteria for substance use disorder, many patients taking opioids for persistent pain fulfil the criteria for mild SUD at least [8] (Table 86.1).

Illicit drug use or aberrant use of prescription medication can be explored after enquiring about alcohol and smoking, which are more socially acceptable for patients [9]. It can help to know about the local drug scene (e.g. gabapentinoids are much more commonly abused in prisoners); information can be gathered from addiction services, law enforcement and drug intelligence networks. The features that may affect the HCP involved in perioperative care are as follows (Table 86.2):

Table 86.1 DSM-5 criteria for SUD: mild, 2–3; moderate, 4–5; severe, 6 and greater

1.	Taking the substance in larger amounts or for longer than you're meant to
2.	Wanting to cut down or stop using the substance but not managing to
3.	Spending a lot of time getting, using or recovering from use of the substance
4.	Cravings and urges to use the substance
5.	Not managing to do what you should at work, home or school because of substance use
6.	Continuing to use, even when it causes problems in relationships
7.	Giving up important social, occupational or recreational activities because of substance use
8.	Using substances again and again, even when it puts you in danger
9.	Continuing to use, even when you know you have a physical or psychological problem that could have been caused or made worse by the substance
10.	Needing more of the substance to get the effect you want (tolerance)
11.	Development of withdrawal symptoms, which can be relieved by taking more of the substance

Table 86.2 Assessment of SUD and common problems

Cannabis Party drugs Synthetic cannabinoids – spice, etc.	Whether under the influence History of psychosis or other behavioural problems Vascular disease (myocardial ischaemia, cerebrovascular disease) Respiratory disease, COPD, cough and liability to laryngospasm
Stimulants – cocaine, methamphetamine, ice	Liable to cardiovascular depression with anaesthetic agents when wearing off – cautious dosing Hypertension, MI and CVA
Heroin or other opioids	Whether opioids – interaction with perioperative analgesics causing depression of respiration and conscious level How much and how often? Whether injected How long can they be without? Are there unpleasant withdrawal symptoms? Opioid substitution therapy; methadone or buprenorphine
Other problems associated with drug or alcohol use	Infections Malnutrition, vitamin deficiencies, hepatic dysfunction and coagulation abnormalities Problems with venous access Blood-borne viruses and associated immunosuppression or liver disease Mental health problems Involvement with police or prisons Social work and child welfare

86.5 Alcohol

86.5.1 Alcohol's Impact on Operative Outcomes

Around 20% of surgical patients have alcohol use disorder (AUD) [10]. Alcohol misuse has an impact on virtually every organ system. Uncontrolled use may lead to severe complications summarised in Fig. 86.1; Table 86.3.

Patients with AUD have up to 2–5 times increased risk of post-operative morbidity [11] and increased hospital stay [12]. Many of ethanol's effects contribute to increased adverse outcomes such as modulation of immune function [13], delayed wound healing [14], reduced cardiac function and altered haemostatic balance. The increased risk applies across all types of surgeries [15].

Post-operative alcohol withdrawal can be difficult to manage and be confused with delirium of other causes. Untreated withdrawal may lead to confusion, hallucinations or seizures. Other alcohol withdrawal symptoms include anxiety, tremors, headaches, sweating, nausea, vomiting, increased heart rate and blood pressure. Alcohol withdrawal symptoms may appear as soon as blood ethanol starts falling. Most severe withdrawal symptoms typically appear on day 3 of alcohol cessation and may worsen over the course of 5–7 days.

Wernicke's encephalopathy from thiamine (vitamin B1) deficiency may result from malabsorption and malnutrition in patients with chronic alcohol issues. All three of the classic Wernicke's triad (see Table 86.4) might only be present in 10–16% of patients with Wernicke's encephalopathy [16]. Caine suggested the addition of dietary deficiencies to the triad and requiring only two out of four criteria to diagnose Wernicke's encephalopathy. This increased the sensitivity to 58% and specificity to 100% [17]. Untreated thiamine deficiency may lead to irreversible Korsakoff's syndrome. This is characterised by long-term memory impairment. A key characteristic of patients with Korsakoff's syndrome is confabulation (Table 86.4).

Despite these known complications and impact on surgical outcomes, screening and intervention for AUD are often neglected [18]. A short duration of abstinence may have significant benefits. Two weeks of abstinence improves delayed-type hypersensitivity (DTH) and haemostatic balance [19]. Four weeks of abstinence reduces stress response.

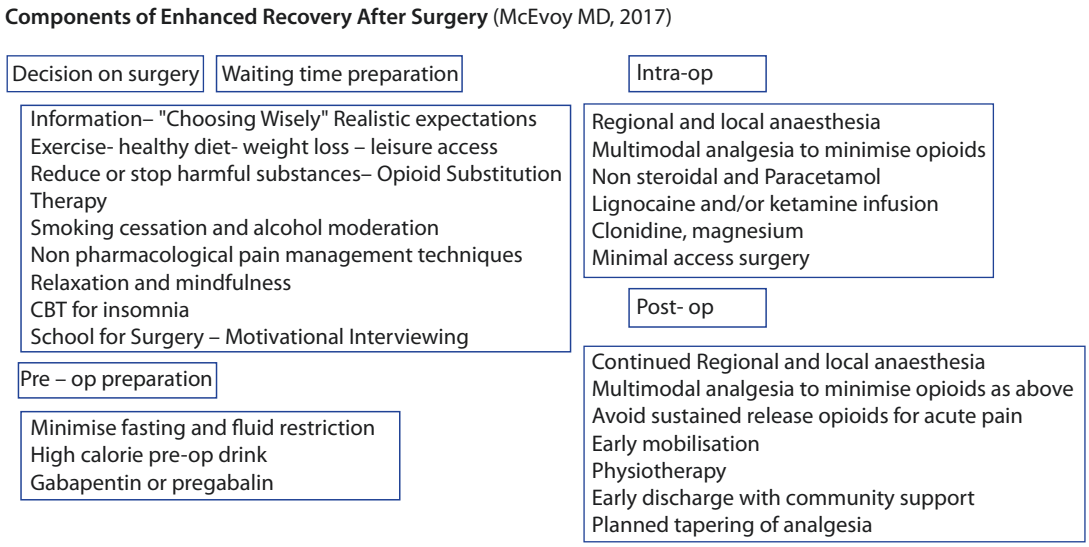

Fig. 86.1 Components of an ERAS programme. The waiting time preparation opportunities are not widely utilised. Many of these measures would benefit people with SUD

Table 86.3 Complications associated with chronic alcohol use

Cardiovascular	Dysrhythmias Cardiomyopathy Hypertension
Gastrointestinal	Esophagitis Gastritis Hepatic cirrhosis and fibrosis Alcoholic hepatitis Pancreatitis
Endocrine	Decreased testosterone Decreased gluconeogenesis Hypalbuminaemia Hypomagnesemia
Haematologic	Thrombocytopenia Leukopenia Anaemia
Neurologic	Peripheral neuropathy Cerebellar degeneration Cerebral atrophy Cognitive impairment including confusion and amnesia (Wernicke-Korsakoff's syndrome)
Psychiatric	Depression Anxiety Hallucinations Insomnia

Table 86.4 Signs of Wernicke's encephalopathy

Ophthalmoplegia	Nystagmus, papilledema, gaze palsies
Cerebellar dysfunction	Dysdiadochokinesia, ataxia, motor skill impairment
Mental state changes	Confusion, agitated delirium, decreased consciousness, memory impairment

86.5.2 Preoperative Considerations and Management

Routine screening using questionnaires is recommended. The ten-item Alcohol Use Disorder Identification Test (AUDIT) [20] can be used and takes less than 5 minutes to complete. History regarding alcohol use should be mandatory preoperatively. End-organ damage from chronic alcohol use should be evaluated via physical examinations.

Investigations such as mean corpuscular red cell volume (MCV), gamma-glutamyl transpeptidase (GGT), aspartate transaminases (AST) or alanine aminotransferase (ALT) and carbohydrate-deficient transferrin (CDT) may be useful in confirming suspicions of AUD. Blood alcohol level (BAL) may be considered in trauma situations.

A 2018 Cochrane review of perioperative alcohol cessation revealed that intensive preoperative alcohol cessation interventions reduced the number of post-operative complications [21]. These interventions lasted from four to eight weeks and incorporated pharmacotherapy such as thiamine, disulfiram and chlordiazepoxide. The intense interventions often included motivational counselling, as well as phone support. The high levels of resources required for these intensive preoperative interventions aimed at abstinence may not be easily available to most hospital systems.

Two other Cochrane reviews have confirmed that brief intervention, with or without pharmacotherapy in primary care [22] and hospital wards [23], is effective in reducing alcohol consumption. It is recommended that brief psychoeducation, as well as motivational counselling, should be attempted for all patients with AUD.

86.5.3 Management of Perioperative Alcohol Withdrawal

Recognition of AUD and withdrawal symptoms allows early treatment. Delay or inadequate treatment will result in worse prognosis. Severity of alcohol withdrawal should be assessed regularly using an objective scale such as the Alcohol Withdrawal Scale (AWS) or Clinical Institute of Withdrawal Assessment for Alcohol (CIWA-Ar) [24]. Any other causes of delirium such as infections or metabolic dysfunction should be ruled out. Basic pathology monitoring full blood count, electrolytes (including potassium and magnesium), liver function and coagulation function should be mandatory.

Main treatment consists of long-acting benzodiazepines (e.g. diazepam, lorazepam) with special consideration for any liver dysfunction. Benzodiazepines should be given aggressively at the recognition of withdrawal symptoms.

Symptom triggered as per-required regime should be used along with regular doses of benzodiazepines. Dosage should be adjusted according to the severity of alcohol use and withdrawal symptoms.

Symptomatic treatment should be considered, such as antipsychotics for hallucinations and agitation (e.g. haloperidol), antiemetics for vomiting (e.g. metoclopramide) and fluids for dehydration. Common non-pharmacotherapy for managing confused or agitated patients such as a low-stimulus environment and increased nursing care may help.

Thiamine replacement is vital to preventing Korsakoff's syndrome. Parenteral thiamine is preferred, as oral absorption is impaired in those with severe alcohol use disorder. A total of 300–500 mg IV three times daily should be considered and be given until improvement of cognition.

86.6 Nicotine

86.6.1 Tobacco's Impact on Operative Outcome

Tobacco users are more likely to suffer from perioperative complications [25]. Tobacco inhalation produces carbon monoxide, which binds strongly to haemoglobin and reduces its capability to carry oxygen. This decreases the tissue oxygen availability by 3–12% [26]. Nicotine also activates sympathetic activity and increases heart rate, blood pressure and vascular resistance. The combination of reduced oxygen supply and increased oxygen demand results in escalated risk of perioperative complications.

Current smokers are 1.38 times more like to die perioperatively than non-smokers [27]. Tobacco users also have increased risks of pulmonary complications (pneumonia, unplanned intubation, mechanical intubation) and cardiovascular complications (cardiac arrests, myocardial infarctions and stroke), as well as increased likelihood of wound healing and infections [28]. As a result, tobacco smokers tend to have longer hospital stays and be more likely to require intensive care [29].

86.6.2 Management of Preoperative Tobacco Use

There is expert consensus to support smoking cessation before surgery. Longer duration of quitting is associated with increased benefits. Cessation for one day can improve tissue oxygen delivery [30]. Abstinence of at least three weeks can improve wound healing [31]. Six to eight weeks of stopping improves pulmonary function [32] and decreases cardiovascular and wound complications [33]. Six months of abstinence restores immune functions [34].

Surgical patients may be more receptive to cessation advice. Patients' odds of quitting increases by 30% if undergoing minor surgical procedure. When faced with major surgery, patients might be twice as likely to quit [35]. This suggests possible intervention points at times of health crisis. Despite increased rates of success, provision of preoperative cessation advice is often low from both surgeons and anaesthetists in general [36, 37]. Brief interventions such as offering a quit advice before surgery may double the chance of smoking cessation [38]. Intensive interventions (dedicated consultation with follow-up in 4 weeks and nicotine replacement) reduce post-operative complications by 60% and improve abstinence rates by ten times [39].

Nicotine replacement should be a first-line treatment, followed by nicotine partial agonist such as varenicline and bupropion. Transdermal nicotine substitution does not increase opioid use or post-operative pain [40].

86.7 Opioids

Patients on chronic opioids will have developed tolerance to their effects and be liable to withdrawal symptoms if they are ceased. Autonomic disturbances associated with withdrawal can be treated with clonidine either given orally, transdermally or intravenously.

Patients on preoperative opioids are at higher risk of more severe post-operative pain. It is unclear whether this is a result of tolerance or the development of opioid-induced hyperalgesia

[41]. Both tolerance and hyperalgesia are thought to result from the internalisation of opioid receptors and alterations in intracellular processes. Tolerance can be overcome by increasing the dose of opioid, except in the case of buprenorphine, where other opioids have less affinity for the μ-receptor. Hyperalgesia also seems to involve mechanisms in the spinal cord, where NMDA receptors lead to wind-up. In the central nervous system, alteration in the balance between endorphin and dynorphin may play a role. Opioid-induced hyperalgesia can occur acutely. It was hoped that pre-emptive analgesia, with opioids given before surgical incision, would reduce post-operative pain, but the opposite has been found [42]. A clear demonstration of opioid-induced hyperalgesia is seen in patients who receive remifentanil, an ultra-short-acting opioid, as part of their anaesthetic. There is a higher incidence of pain post-operatively and increasing doses of opiates seem to lead to greater hyperalgesia and pain experience.There is some evidence that this phenomenon can be reduced by ketamine, in low doses of 0.2–0.4 mg/kg [43].

Those on higher doses of opiates may be at risk of opioid-induced ventilatory impairment, especially with doses of opiates above 100 mg oral morphine equivalent daily dose (OMEDD), in combination with benzodiazepines, gabapentinoids and quetiapine. Other factors that increase the risk are obesity, obstructive sleep apnoea, smoking, chronic lung disease and other sedatives such as alcohol. Patients who have been on opioid substitution treatment (OST) or long-acting opioids should be monitored closely in the post-operative period, where the residual effects of their normal medication can combine with post-operative opioids, anaesthetics and the negative effects of surgery on respiration, particularly in the case of thoracic and abdominal surgery.

86.7.1 Illicit Opioids

Those taking illicit opioids may be liable to be treated more judgementally by healthcare professionals than those on prescribed opioids. The actual opioid content of illicit drugs is more variable [44]. The opioid may be adulterated, "cut" with inactive substances, which may contribute to tissue damage and infection if they are injected. More recently, the adulteration of heroin with fentanyl and carfentanil has led to an increase in overdoses, especially in North America.

86.7.2 Prescribed Opioids

The dose of prescribed medication should be verified with the patient's normal prescriber or dispensing pharmacist. Prescribing monitoring schemes can identify patients who have multiple prescribers or dispensing pharmacies, which may indicate aberrant drug use. The possibility of patients having diverted their prescribed medication should be borne in mind if they become sedated when given their normal stated dose. In some situations, urine drug screening is a low-cost and rapid method of confirming the presence or absence of expected opioids. Urine drug screen may also reveal additional substances such as benzodiazepines. To obtain a more accurate screen, chromatography may be considered.

86.8 Opioid Substitution Therapy (OST)

There are different considerations for patients on methadone or buprenorphine (usually prescribed in combination with naloxone sublingually), and there is some debate about the recommendations for buprenorphine. Buprenorphine is a partial μ- and κ-agonist and it has a higher affinity for the μ-receptor than other opioids. This prevents patients from obtaining any euphoric effects, but may also prevent any analgesic benefit from additional opioids. It has a long duration of effect; 24–72 hours can make post-operative pain management particularly problematic [45].

Patients on buprenorphine have been found to be hyperalgesic in response to the cold pressor test and to not respond to morphine [46]. Recommendations are based on case reports, ret-

Table 86.5 Recommendation on buprenorphine OST

Recommendations on pain management in patients on buprenorphine OST	
Recommendation	Benefits and limitations
Use higher doses of short-acting opioids + OST [47]	Single case report, risk of respiratory depression and poorly controlled pain
Continue OST with PCA [48]	Retrospective study
Increase OST dose [49]	Ceiling effect at 32 mg buprenorphine daily
Reduce OST dose by 2 mg every 2–3 days to completely discontinue 3 days before surgery	Risk of relapse in use of illicit opioids, expert consensus
Substitute methadone 30–40 mg, can be increased to manage withdrawal symptoms	Expert consensus
Divide OST to 3 daily doses	Expert consensus

rospective case series and expert opinion (Table 86.5).

Patients on methadone can continue their normal maintenance treatment. This can be split into three times a day, although this is not supported by any evidence, and the rationale is unclear in view of its long durations of action. Patients on methadone may have prolongation of the QT interval, which should be screened for with an ECG. Other drugs affecting the QT interval, such as ondansetron and droperidol, should be avoided or used with caution. In common with patients on buprenorphine, there may be opioid-induced hyperalgesia and an increased risk of respiratory depression.

86.9 Intoxication

The main features of acute intoxication are respiratory depression and reduced conscious level, which respond to the administration of naloxone. Initial administration of small amounts, incrementally, such as 20–40 micrograms at a time, is usually sufficient to restore adequate respiratory drive and improve conscious level, without precipitating withdrawal. Of course, naloxone has a short duration of 30–60 minutes, so an infusion should be started and the patient cared for in a high-dependency environment, where their condition can be closely monitored. The infusion rate will normally be between 0.5 and 0.75 of the initial effective bolus per hour. It might be necessary to admit the patient to an intensive care unit for airway and ventilation management.

86.10 Withdrawal

Opiate withdrawal is uncomfortable but has not been documented to be fatal. Reassurance and an empathic non-judgemental approach can help the patient settle. Clonidine, hyoscine, loperamide and benzodiazepines can be helpful.

86.11 Assessment of the Patient for Anaesthesia

86.11.1 Physical

Venous access may be difficult and the patient may be the best guide of where to find a patent vein. The use of ultrasound to locate vessels can be very helpful. If a general anaesthetic is planned, an inhalational induction with volatile anaesthetic can be used.

Patients may have coexisting cardiorespiratory disease and often have an irritable airway, due to smoking. Dentition may be poor, with broken or fragile teeth.

86.11.2 Infections

Universal precautions should be used, where there is a possibility of previous intravenous drug use, in case of hepatitis, HIV or other bloodborne viruses. Assessment should include the consideration of the possibility of endocarditis, heart valve damage, immunosuppression and opportunistic infections. Osteomyelitis is not uncommon and vertebral osteomyelitis can spread to abscess formation in the epidural space which may compromise the spinal cord and inter-

fere with spinal or epidural anaesthesia. In the cervical spine, there may be an increase in pressure on the spinal cord with positioning for laryngoscopy.

86.11.3 Perioperative Pain Management

Pain is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of tissue damage. The management of pain has evolved to recognise that the distress and suffering as well as social and psychological factors are at least, if not more, important than biomedical ones [50].

Wherever possible, the use of regional and local anaesthetic techniques can avoid most of the problems associated with these patients. Single-injection local anaesthetics have a limited duration of action to a maximum of 24 hours, and there can be difficulty controlling pain when the block wears off, often in the middle of the night. For this reason, the use of a nerve catheter and local anaesthetic infusion for 3 days postoperatively is advisable.

Multimodal analgesia with paracetamol and nonsteroidal anti-inflammatory drugs reduces opioid requirements. NSAIDs have better analgesic effect for dental and musculoskeletal pain than opioids.

The use of adjuvants such as ketamine, clonidine and lignocaine has evidence for improving perioperative pain management [51, 52]. Gabapentin and pregabalin have shown some evidence of benefit in acute pain management [53].

86.12 Prediction of Poorly Controlled Post-operative Pain

Studies of the relative risk factors have used heterogenous study design and methods of determining risk. The following table is derived from a recent systematic review and meta-analysis [54] (Table 86.6).

Table 86.6 Risk factors for poorly controlled post-operative pain

Predictive factor	Increase in risk
Sleep difficulties	OR 2.32 [95% CI 1.46 to 3.69]
History of depressive symptoms	OR 1.71 [95% CI 1.32 to 2.22]
Use of preoperative analgesia	OR 1.54 [95% CI 1.18 to 2.03]
Smoking	OR 1.33 [95% CI 1.09 to 1.61]
Female sex	OR 1.29 [95% CI 1.17 to 1.43]
History of anxiety symptoms	OR 1.22 [95% CI 1.09 to 1.36]
Presence of preoperative pain	OR 1.21 [95% CI 1.10 to 1.32]
Young age	OR 1.18 [95% CI 1.05 to 1.32]
Higher BMI	OR 1.02 [95% CI 1.01 to 1.03]

86.13 Other Substances Cannabis

Legalisation and increasing social acceptability have led cannabis to be widely used. Often patients have a tachycardia, and drugs which might exacerbate this, such as ephedrine and ketamine, should be used cautiously [55]. The airway may be irritable with an increased risk of coughing and laryngeal spasm and patients are liable to have COPD and other smoking-related diseases. There has been inconclusive evidence of any benefit in the use of cannabis or cannabinoids in the treatment of pain. In a recent review of chronic pain, the number needed to treat for obtaining 30% relief of pain was 24 and the number needed to harm was 6 [56].

The selective breeding of cannabis plants with a higher concentration of THC (skunk) has led to an increase in dysphoric and psychotic symptoms.

86.14 Synthetic Cannabinoids

These compounds are a diverse group of chemicals which act to the CB1 and anandamide receptors. They can cause negative symptoms such as nausea, vomiting, palpitations, anxiety, confu-

sion, coordination problems and convulsions. Deaths have occurred directly and also due to adulteration with brodifacoum, rat poison, thought to extend the duration of effect.

86.15 Cocaine, Amphetamines and Methamphetamine

The main problems in the perioperative period are due to sympathetic overactivity, caused by inhibition of the presynaptic reuptake of dopamine, noradrenaline and serotonin. Hypertension and tachycardia can cause myocardial ischaemia. Use of β-blockers can lead to unopposed α-effects causing coronary vasoconstriction. Propranolol is not recommended and there is debate about the safety of esmolol and labetalol. Nitroglycerine, phentolamine, verapamil, benzodiazepines and aspirin have been used. Dexmedetomidate may be useful in reducing the risk of cocaine-induced seizure.

Thrombocytopaenia can occur due to vasoconstriction and increased platelet aggregation. Renal failure has been reported, possibly due to vasoconstriction or to rhabdomyolysis.

Patients should be advised to abstain from cocaine for at least one week before an elective operation.

86.16 Hallucinogens, Ecstasy and Other Club Drugs

Psilocybin, mescaline, lysergic acid diethylamide (LSD) and phencyclidine (PCP) are hallucinogens, inducing hallucinations, distortion of perception and anxiety. They can cause sympathetic overactivity with hypertension and tachycardia. PCP can induce coma with muscle rigidity and nystagmus.

3,4-Methylenedioxymethamphetamine (MDMA) is also known as ecstasy. Sympathetic overactivity, with dehydration, hyperthermia, renal, hepatic and cardiac problems, can ensue.

γ-hydroxybutyrate (GHB) was used as an anaesthetic in the past, but was abandoned due to side effects. It produces ecstasy-like symptoms.

Ketamine is derived from PCP. The main features that are seen are sympathetic activation and reduction in conscious level, which will interact with anaesthetic actions.

86.17 Factors That May Improve Post-operative Care for Individuals with Substance Use Disorder

The evidence for a particular approach to the perioperative management of people with substance use disorder seems to be based on consensus and expert opinion, rather than research evidence. The main consideration should be safety and minimising the risk of exacerbating substance use. For all patients, a multimodal analgesic technique with the use of non-pharmacological strategies has the best results [54]. Preoperative preparation of patients, improving physical fitness and addressing psychosocial factors, is showing promising results, but instituting this takes a cultural shift in attitudes which has been difficult to achieve [57].

86.18 Components of Enhanced Recovery After Surgery [58]

86.19 Conclusion

The focus in managing patients with substance use disorder, presenting for anaesthesia and acute pain management should be on how to provide the safest and best care for patients who are in a vulnerable and fearful situation.

Addiction specialists have a clear understanding of the role that traumatic experiences, social circumstances, mental health issues and genetic predisposition have in leading to the complex neurobiological condition of SUD or addiction. HCPs involved in anaesthesiology and acute care may see the patient with SUD in a less favourable light than patients with other mental health conditions. We hope that this brief overview of the

subject will inspire clinicians to learn more and to know what to do to improve the patient's experience [59].

Key Points

- Substance use disorders may have biomedical and pharmacological implications for patient care in the perioperative period.
- Social and psychological factors may also affect care.
- The priorities should be to ensure patient safety and a successful outcome from surgery.

Clinical Relevance

Having an understanding of substance use will help clinicians provide more humane and patient-centred care. For more in-depth details of post-operative pain management, we would refer the reader to *Acute Pain Management: A Practical Guide*, Macintyre P and Schug S. Fourth Edition, 2014.

Abstract

Chronic or persistent pain is a common problem, affecting around 20% of the population. It can be complex; social, psychological and biological factors are entwined in its causes and effects. The societal factors leading to the increased recognition and demands for treatment of chronic pain have focused on the biomedical aspects and the use of the WHO analgesic ladder, which was intended for treatment of cancer pain. Despite initial optimism, the treatment of chronic non-malignant pain, in the same way as cancer pain, has been found to be ineffective for pain management or improvement in quality of life. Indeed, the opposite effects of increasing disability and dependence seem to be the result, with the epidemic of opioid-related deaths being the tip of the iceberg.

This chapter briefly outlines the underlying mechanisms of pain and dependence, but the main focus is on possible strategies to reduce the potential harms arising from the pharmacological treatment of chronic pain.

Keywords

Chronic · Persistent · Pain · Opioids Dependence

87.1 Introduction

Pain is defined by the International Association for the Study of Pain (IASP) as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or expressed in terms of such damage' [1]. Chronic or persistent pain has been defined as pain that has been present for more than 12 weeks or 3 months. This is a largely pragmatic definition as, when conducting research on treatments for pain, we might expect tissue healing and natural resolution of pain within 6–8 weeks. Hence, the natural course of events, where pain resolves due to healing of the tissues, might confound whether improvement was due to a treatment. Another perspective is to define pain as chronic, when it has persisted after we would normally have expected tissue healing to be complete. There is debate about whether to use chronic or persistent as a description. ICD 11 has used chronic in its classification [2].

Epidemiological studies have found that 20% of the population lives with chronic pain and it is severe and disabling in around 8% [3]. In the Lancet Global Burden of Disease survey, back pain and headache were the two leading causes of years lived with disability. It was noted that there was a 38% increase in opioid use disorder from 1990 to the 2017 survey [4].

Over the last 60 years, there have been great advances in the understanding of the underlying neurobiology which contributes to the experience of pain. The biological causes of pain, are entwined with social and psychological factors, which have a strong influence on the experience, suffering, disability and the persistence of chronic pain. This understanding has been expressed as the biopsychosocial or sociopsychobiomedical model of pain [5].

87.2 Nature of Chronic Pain

Pain can be classified as nociceptive, neuropathic or nociplastic (see Table 87.1).

87.3 Nociceptive Pain

Healthcare training and the general societal understanding of pain have focused on nociceptive pain, with the perception that pain is usually the symptom of tissue damage or an underlying disease. Advances in medical science have enabled diagnosis and treatment, but at the same time have led to increased detection of incidental findings on investigations. One of the areas where this is most problematic is in imaging for back and neck pain. Changes in MRI scans are found in the majority of the population as they age; for instance, 'disc degeneration' is found in 80% of

Table 87.1 Pain classification

Nociceptive	Neuropathic	Nociplastic
Due to activation of nociceptors Signals tissue damage or protects from potential tissue damage	Due to a lesion or a disease of the somatosensory nervous system Continues due to abnormal nerve function Not protective	Due to altered activity in an intact nervous system – formerly called *central sensitisation* Non-noxious stimulation causes pain due to gain of function Overprotective
Tissue damage Noxious heat or cold Noxious pressure Noxious chemical stimulation Inflammatory mediators	Neurological symptoms Plausible cause of nerve damage Abnormal neurological examination Findings on investigations such as nerve conduction tests, MRI and nerve biopsy	Allodynia and hyperalgesia No evidence of actual or threatened tissue damage causing the activation of peripheral nociceptors or evidence for disease or lesion of the somatosensory system causing the pain

asymptomatic people in their 50s [6]. This can lead to attribution of a condition such as back pain to underlying tissue damage, although there is conclusive evidence that biomedical treatment is often useless or even harmful [7]. In the case of true nociceptive pain, due to tissue damage, such as a fractured bone, cancer [8] or post-operative pain [9], analgesic drugs are reasonably effective in the majority of patients. Of course, detection and treatment of treatable pathology are important. The use of 'Red Flags' in back pain can help to avoid masking of a treatable disease, but it is most important to maintain an open and unbiased mindset, rather than a checklist or screening approach [10, 11].

87.4 Neuropathic Pain

Pain due to a lesion or disease of the somatosensory nervous system accounts for a minority of all chronic pain. A systematic review found a wide range of estimates of prevalence from 1% to 17% of the general population [12]. This variability may be due to a change in the definition of neuropathic pain from dysfunction to damage, and the diagnosis may be overestimated by relying solely on questionnaires. It can be classified as possible, probable or definite, by assessing the history, examination and investigations as illustrated in Fig. 87.1.

Most back pain is musculoskeletal – Red flags are to make us think "is there something else I should consider or investigate?"
May not need immediate action – Look for improvement with low back pain MSK treatment or evolution of symptoms with time
Previous history malignancy (however long ago)
Age < 16 or > 50 with new-onset pain
Weight loss (unexplained)
Previous longstanding steroid use
Recent serious illness
Recent significant infection – IV drug use, HIV, TB
Nonmechanical pain – Worse at rest or lying down
Thoracic pain
Fever, rigors or night sweats
General malaise
CAUDA EQUINA SYNDROME IS A SURGICAL EMERGENCY REQUIRING URGENT IMAGING AND SURGICAL OPINION.

87.5 Nociplastic Pain

The majority of chronic pain is nociplastic in nature. Stimuli that would not normally be painful (non-noxious), such as light pressure, changes in temperature and sitting or standing for too long, cause pain. Previously this was termed central sensitisation, and the IASP adopted the new terminology, nociplastic, in 2017 [14].

The details of the mechanism behind this phenomenon have been elucidated to an extent. There is increased activity in the nervous system, descending facilitation and wind-up of pain mechanisms. Biological, psychological and social factors are all important in the development and maintenance of this chronic pain condition. Unfortunately, although pharmacological treatment has limited effect, this has been found to be the first strategy employed in several studies [15].

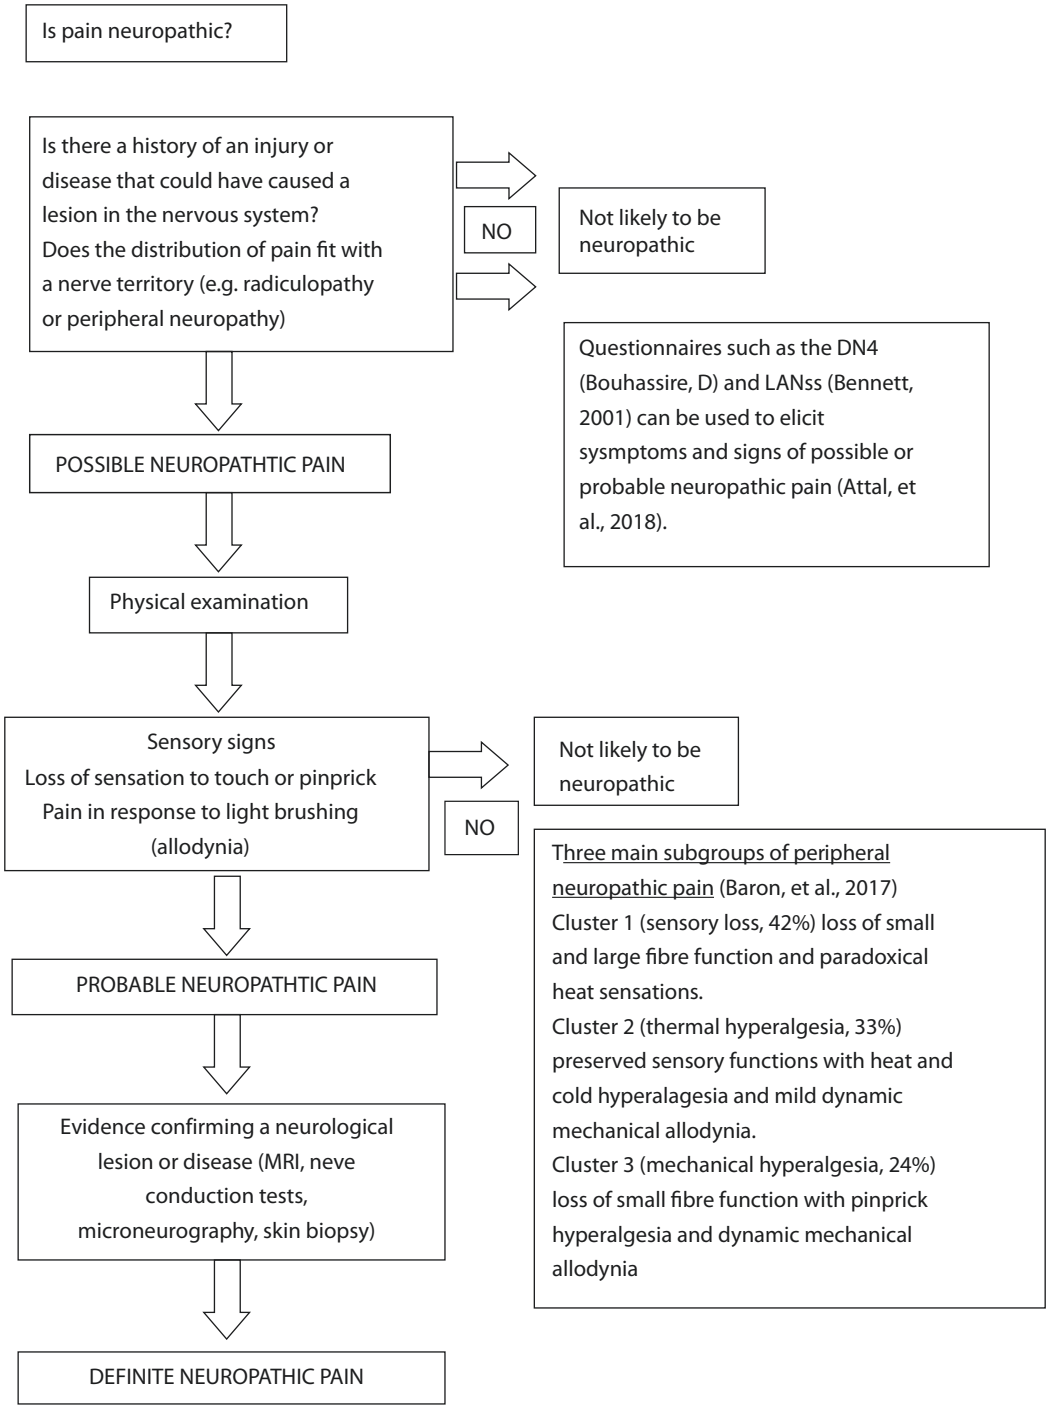

Fig. 87.1 Diagnosis of neuropathic pain [13]

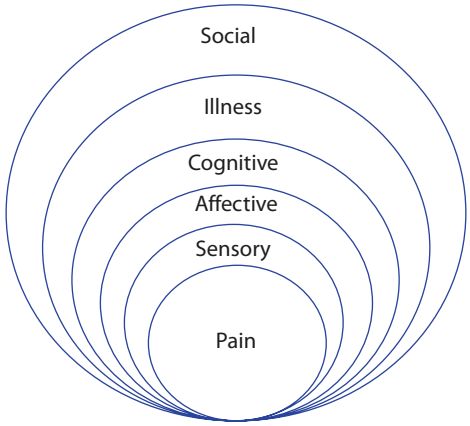

Fig. 87.2 The biopsychosocial model of pain

87.6 Biopsychosocial or Sociopsychobiomedical Model

The onion diagram of the biopsychosocial model was introduced by Engel in 1977. The main factors in the development of persistent and disabling pain seem to be psychosocial. This research was formulated into the "Yellow Flags" approach to identify the psychosocial risk factors for chronicity, which was revised in 2011 to incorporate orange, blue and black flags [16].

The aim of the flags system is to address psychosocial factors early; however, the Lancet Back Pain papers of 2018 identified that the majority of healthcare professionals preferentially take a biomedical approach [7].

The flags can be assessed in primary care and risk factors, which are amenable to modification, and are identified and addressed. The flags can be remembered by the mnemonic 'ABCDEFW' (Fig. 87.2).

- *Attitudes and Beliefs:* feeling they have something serious causing their problem. Thinking the pain has to be completely gone before they can start getting back to normal activities. These beliefs can lead to catastrophisation, a negative mental set, comprising magnification, rumination and helplessness.
- *Behaviours:* development of disability role, rest and passive rather than active treatments, with external locus of control, use and abuse of medication, continually seeking medical opinions and treatments.
- *Compensation**: work-related accidents, compensation and perceived injustice can create a conflicted mindset, where there is an adversarial system in which the person has to prove how much suffering and disability the pain has caused. Multiple medical and legal opinions are often confusing, not necessarily taking the patients' long-term interest as the first priority.
- *Diagnosis:* often healthcare professionals can give confusing and conflicting information about the likely cause of the pain. There is widespread belief that tissue damage or 'degenerative' changes are the cause of musculoskeletal pain, such as low back pain. Imaging reports are often worrying for patients and poorly understood by healthcare professionals.
- *Emotions**: patients with other emotional difficulties such as ongoing depression and/or anxiety states are at a high risk of developing chronic pain. It is natural that isolation from normal social contact leads to mood changes.
- *Family**: those close to the patient may be fearful or catastrophising, being overprotective and solicitous. Often people with pain feel they are not believed, leading to breakdown in relationships and compassion fatigue in the family and friends.
- *Work**: if there are difficulties, people are more likely to develop chronic problems.

*In the revised flag system.

- *Black Flags*: compensation, family, legislation restricting return to work and heavy work or duties that cannot be modified.
- *Blue Flags*: Work which is perceived to be too onerous or likely to cause further injury; belief that supervisors or colleagues are unsupportive or unsympathetic.
- *Orange Flags*: psychiatric conditions such as clinical depression or personality disorders.

Identification of significant psychosocial factors has been simplified to detect those at higher risk with the STarT Back questionnaire [17] (Fig. 87.3).

Low Risk: one-off consultation, examination and reassurance to promote self-management. Avoid unhelpful language, provide written information.

Medium Risk: building on the above, with the aim to restore function, including work. Course of physiotherapy. Some patients may need specialist referral.

High Risk: builds on the above, with the aims to reduce pain and improve functioning. More skilled physio, with additional training enabling them to elicit and address more complex psychosocial issues.

The Keele Start Back Screening Tool		
Thinking about the **last 2 weeks** tick your responses to the following questions	Disagree 0	Agree 1
1. My back pain has spread down my legs at some time in the last 2 weeks.		
2. I have had pain in the shoulder or neck at some time in the last 2 weeks.		
3. I have only walked short distances because of my back pain.		
4. In the past 2 weeks I have dressed more slowly because of back pain.		
5. It's not really safe for a person with a condition like mine to be physically active.		
6. Worrying thoughts have been going through my mind a lot of the time.		
7. I feel my back pain is terrible and it's never going to get better.		
8. In general I have not enjoyed all the things I used to enjoy.		

Overall, how bothersome has your back pain been **in the last 2 weeks?**

Not at all	Slightly	Moderately	Very much	Extremely

The use of this approach was found to allow the identification of higher-risk patients and more effective and economical treatment.

87.7 Elements of the Problems Leading to Increased Prescribing and Dependence in Chronic Pain

As outlined in the chapter on perioperative issues and acute pain, there was a societal change in attitudes towards the treatment of chronic non-cancer pain following some influential publications in the 1980s and 1990s [18, 19]. There was increased awareness of the prevalence of chronic pain and the development of campaigns to recognise chronic pain as a vital sign or a disease as well as the perception of pain relief (i.e. the analgesic ladder) as a human right [20]. The resulting increase in prescription of opioid and other pain medications was augmented by influence from the pharmaceutical industry, which claimed that addiction or dependence occurred in less than 1% of people treated for pain. Unfortunately, this has escalated to the point where opioid use and related harms have been considered a crisis, with opioid overdose becoming the leading cause of death in Americans under 50 [21]. Less dramatic, but still significant and worrying, increases in opioid-related harm have been found in the UK, Australia and Europe [22, 23].

At the same time, the hopes for improved pain relief and reduced disability have not been realised. An early publication, showing improvement in back pain, which was widely cited, studied only 38 patients, finding a moderate improvement in pain, but not in employment or ability. Pain management became 'problematic in two patients, both with a prior history of drug abuse'. The conclusion was 'opioid maintenance therapy can be a safe, salutary and more humane alternative to the options of surgery or no treatment in those patients with intractable non-malignant pain and no history of drug abuse' [24]. In 2004, a systematic review found moderate efficacy, but poor tolerability, for opioids, with only 44% of patients continuing with opioids for between 7 and 24 months. The main problems were constipation, nausea and somnolence, with insufficient data to define the risk of addiction [25]. A large Danish cross-sectional study showed worse pain and poorer quality of life in those prescribed with opioids for chronic pain [26].

More recent studies have found that opioids are not superior to non-opioid analgesic drugs even for acute pain, due to a limb injury [27]. In an episode of back pain, their use may increase disability and reduce the likelihood of recovery [28, 29] while not achieving the aim of reducing pain when compared to non-opioids [30].

While the focus has been on opioids, there has also been increasing prescription of benzodiazepines, gabapentinoids, antidepressants and quetiapine, which are synergistic in causing sedation and adverse events with the opioids [31].

87.8 Neurobiology of Dependence and Pain

Opioids have been used for medicinal purposes and for their psychotropic properties since ancient times, with documentation of the use of opium on a Sumerian tablet before 2000 BC [32]. The synthesis of diamorphine in the nineteenth century, by Bayer, was advertised as a breakthrough in maintaining the beneficial analgesic effects of opiates while overcoming the drawback of addiction [33]. Unfortunately, subsequent efforts to synthesise the ideal analgesic, free of undesired side effects or risks, have been similarly ill fated.

The opioid receptors have been classified into three subtypes: μ, κ and δ (mu, kappa and delta), which are G protein-coupled receptors with their endogenous ligands being the endorphins and enkephalins. Activation of the receptor presynaptically inhibits Ca^{2+} channels and postsynaptically hyperpolarises K^{+} channels. Opioid receptors are widespread, throughout the nervous system, with their activation in the spinal cord, periaqueductal gray matter and raphe magnus being most important for analgesic effect. There is inhibition of GABAergic activity in the ventral tegmental area, which was thought to be associated with reward, due to dopaminergic receptors. More recent evidence

points to the rostromedial tegmental nucleus as well as input from the nucleus accumbens. Effects in the hippocampus may be associated with memory of drug effects. Norepinephrine in the locus coeruleus and CCK and NK1 in brainstem mechanisms may also be associated with unwanted or adverse effects. How the endogenous ligands act within the nervous system to modulate many behavioural and physiological phenomena, such as attraction, bonding, learning, sleep, immunity and hormone production, is still incompletely understood. The complexity of these systems and their importance in our experience perhaps make the prospect of discovering an agent that acts as an analgesic, while not having other psychological and behavioural effects, unlikely [34].

Research has focused on differentiation of the analgesic effect of the opioids, which is thought to be mediated through the G protein complex (GαI/O unit) on the cell membrane, while side effects may be caused by activity on β-arrestin2, an intracellular moderator of G protein activity.

β-arrestin2 leads to endocytosis of opioid and also dopamine and cannabinoid receptors. The discovery that β-arrestin2 knock-out mice had preserved the analgesic efficacy of opioids, with less side effects and development of tolerance, has led to the synthesis of ligands with no activity at β-arrestin2, but these are at an early stage of development. The complexity of intracellular actions of the arrestins may lead to other effects on immunity, apoptosis and autonomic and hormonal activity [35].

It has been hoped that drugs, such as tramadol (with μ-opioid, noradrenaline and serotonin reuptake activity) and tapentadol (with weak μ-opioid and noradrenaline reuptake activity), might be less liable to lead to dependence, but the literature does not seem to support this hope [36, 37] (Fig. 87.4 and Table 87.2).

The majority of research has focused on the problem of addiction to opioids, but there is increasing epidemiological evidence for dependence on other classes of drugs, substances and behaviours in people with chronic pain. There is overlap in the brain areas involved in pain and addiction, with aversion, craving, reward, conditioning and withdrawal common to both conditions [38]. Many people with chronic pain will meet the DSM-5 criteria for substance use disorder.

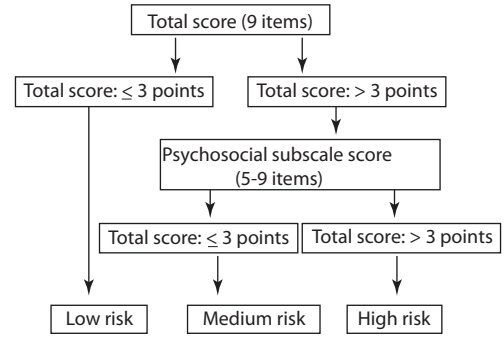

Fig. 87.4 The STarT Back Screening Tool scoring system

Table 87.2 DSM-5 criteria for substance use disorder – Mild 2–3, Moderate 4–5, Severe 6 and Greater

1.	Taking the substance in larger amounts or for longer than you're meant to.
2.	Wanting to cut down or stop using the substance but not managing to.
3.	Spending a lot of time getting, using or recovering from use of the substance.
4.	Cravings and urges to use the substance.
5.	Not managing to do what you should at work, home or school because of substance use.
6.	Continuing to use, even when it causes problems in relationships.
7.	Giving up important social, occupational or recreational activities because of substance use.
8.	Using substances again and again, even when it puts you in danger.
9.	Continuing to use, even when you know you have a physical or psychological problem that could have been caused or made worse by the substance.
10.	Needing more of the substance to get the effect you want (tolerance).
11.	Development of withdrawal symptoms, which can be relieved by taking more of the substance disorder.

87.9 Strategies to Reduce Opioid Dependence and Harm in Chronic Pain

The history of the evolution of the opioid prescribing crisis and the measures taken to attempt to counter it are well covered in the literature [21].

87.9.1 Reducing Supply

The Center for Disease Control (CDC) in the USA drew up guidelines intended to reduce over-prescription [39]. These have been taken as a model for moderating opioid use in other countries.

There are 12 main recommendations of the CDC guidelines.

The aims of the guidelines are to improve the assessment and evidence-based treatment of chronic pain and encourage clinicians to evaluate the effectiveness, adverse effects and risks: in other words, good medical care.

Since their introduction in 2016, there has been a fall in opioid prescription in the USA [40], but there has been controversy that patients have been forced to taper their opioids, that they have been denied the right to pain relief and that doctors who have been identified as high prescribers have been targeted by regulatory authorities. A letter to Pain Medicine in 2019, with 104 signatories, called for a moderation of forced opioid tapering, especially where psychosocial support was not available [41]. Some clinicians have refused to prescribe opioids and pharmacies have refused to issue prescriptions. Perhaps as an unintended result, there has been an increase in the consumption of illicit heroin and fentanyl as well as of diverted drugs [42] (Table 87.3).

87.9.2 Monitoring Opioid Use

Prescription monitoring schemes have aimed to detect variation in prescribing and prevent multiple prescribers to the same patient [43]. This has been linked to a reduction in overdose mortality in Tasmania, but there is still concern that this approach will lead to a reduction in supply and an increase in illicit drug use. Urine drug testing to monitor compliance with treatment, limiting diversion and detecting illicit drug use, is still rarely carried out [44], due to lack of clinician education, expense and perceived or actual patient resistance to testing.

87.9.3 Reducing Risk

Providing naloxone and education to patients on high-dose opioids has been found to prevent overdose deaths, but there is limited prescribing due to lack of knowledge and expense [45]. There have

Table 87.3 CDC guideline for prescribing opioids for chronic pain — United States, 2016 | MMWR

Determining when to initiate or continue opioids for chronic pain	
1.	Nonpharmacologic therapy and nonopioid pharmacologic therapy are preferred for chronic pain. Clinicians should consider opioid therapy only if expected benefits for both pain and function are anticipated to outweigh risks to the patient. If opioids are used, they should be combined with nonpharmacologic therapy and nonopioid pharmacologic therapy, as appropriate.
2.	Before starting opioid therapy for chronic pain, clinicians should establish treatment goals with all patients, including realistic goals for pain and function, and should consider how therapy will be discontinued if benefits do not outweigh risks. Clinicians should continue opioid therapy only if there is clinically meaningful improvement in pain and function that outweighs risks to patient safety.
3.	Before starting and periodically during opioid therapy, clinicians should discuss with patients known risks and realistic benefits of opioid therapy and patient and clinician responsibilities for managing therapy.
Opioid selection, dosage, duration, follow-up and discontinuation	
4.	When starting opioid therapy for chronic pain, clinicians should prescribe immediate-release opioids instead of extended-release/long-acting (ER/LA) opioids.
5.	When opioids are started, clinicians should prescribe the lowest effective dosage. Clinicians should use caution when prescribing opioids at any dosage, should carefully reassess evidence of individual benefits and risks when increasing dosage to =50 morphine milligram equivalents (MME)/day and should avoid increasing dosage to =90 MME/day or carefully justify a decision to titrate dosage to =90 MME/day.
6.	Long-term opioid use often begins with treatment of acute pain. When opioids are used for acute pain, clinicians should prescribe the lowest effective dose of immediate-release opioids and should prescribe no greater quantity than needed for the expected duration of pain severe enough to require opioids. Three days or less will often be sufficient; more than 7 days will rarely be needed.

Table 87.4 (continued)

7.	Clinicians should evaluate benefits and harms with patients within 1–4 weeks of starting opioid therapy for chronic pain or of dose escalation. Clinicians should evaluate benefits and harms of continued therapy with patients every 3 months or more frequently. If benefits do not outweigh harms of continued opioid therapy, clinicians should optimise other therapies and work with patients to taper opioids to lower dosages or to taper and discontinue opioids.
Assessing risk and addressing harms of opioid use	
8.	Before starting and periodically during continuation of opioid therapy, clinicians should evaluate risk factors for opioid-related harms. Clinicians should incorporate into the management plan strategies to mitigate risk, including considering offering naloxone when factors that increase risk for opioid overdose, such as history of overdose, history of substance use disorder, higher opioid dosages (=50 MME/day) or concurrent benzodiazepine use, are present.
9.	Clinicians should review the patient's history of controlled substance prescriptions using state prescription drug monitoring programme (PDMP) data to determine whether the patient is receiving opioid dosages or dangerous combinations that put him or her at high risk for overdose. Clinicians should review PDMP data when starting opioid therapy for chronic pain and periodically during opioid therapy for chronic pain, ranging from every prescription to every 3 months.
10.	When prescribing opioids for chronic pain, clinicians should use urine drug testing before starting opioid therapy and consider urine drug testing at least annually to assess for prescribed medications as well as other controlled prescription drugs and illicit drugs.
11.	Clinicians should avoid prescribing opioid pain medication and benzodiazepines concurrently whenever possible.
12.	Clinicians should offer or arrange evidence-based treatment (usually medication-assisted treatment with buprenorphine or methadone in combination with behavioural therapies) for patients with opioid use disorder.

also been concerns that naloxone prescribing may lead to more risk. Opioid substitution with buprenorphine/naloxone has been found to prevent relapse and reduce the risk of opioid-induced respiratory depression, but in common with methadone opioid substitution, patients with chronic pain are reluctant to attend addiction services, and there is a lack of funded provision in any case, with less than 10% of patients with addiction being able to access an addiction service [21].

87.9.4 Substituting Other Medications or Therapies

It had been hoped that the introduction of access to medical cannabinoids would reduce opioid use and harms, but despite the legalisation of medicinal prescription in 2001 and recreational use in 2017 in Canada, there continues to be a high level of opioid prescription and harms [22]. Surgeries and interventions for back pain do not have convincing evidence of improving pain management or reducing medication use [7].

87.9.5 Opioid Reduction Programmes

There has been success with helping patients to reduce their opioids using motivational interviewing, psychological therapies and mindfulness [46]. Patients attending multidisciplinary pain management services may be better able to manage their pain and to reduce medication, but there is very limited access to specialised services; more than 90% of patients with chronic pain are seen in primary care.

87.9.6 Education

Many studies have found that there is very little undergraduate teaching on chronic pain [47]. The hope would be that improving knowledge would lead to better care; however increasing evidence, guidelines and resources seem to have made very little difference to the practice of prescribing medication, rather than good advice to patients. It is possible that engaging public health advice

could have more effectiveness than trying to educate healthcare professionals [7].

87.10 Relevance

Chronic pain is a common condition, affecting 20% of the population and chronic back pain is the leading cause of disability worldwide.

Patients with chronic pain may become dependent on medications, primarily opioids, but also other medications with psychotropic effects.

Helping patients to understand their pain better, to utilise pain management techniques and to reduce their medication can improve their quality of life and reduce the pain they experience.

87.11 Conclusion

The co-occurrence of chronic pain and dependence seems to have some foundations in neurophysiological mechanisms but is also strongly influenced by societal and cultural factors. The attempts to limit prescribing have led to antagonism between pro- and anti-opioid camps, with seemingly little understanding of the scientific evidence. There is a risk of a return to the days of opioiphobia, when adequate pain relief was denied, even to patients with cancer pain. Nevertheless, the improved understanding of chronic pain mechanisms and treatment, particularly non-pharmacological treatments with a sound evidence base, must hold out some hope for the future.

Societal factors have led to an increased recognition of chronic pain and its treatment using the analgesic ladder approach, which was intended for the relief of cancer pain.

There is an overlap of brain regions involved in chronic pain and addiction. People with chronic pain may resent being stigmatised as addicts and there is very limited access to addiction services.

Improved healthcare and public understanding of the non-pharmacological management of chronic pain and the importance of a mind-body approach, rather than a biomedical focus, may lead to a long-term change, but over the last 20 years, the trend has been in the opposite direction.

Key Points

– Opioids do not have good evidence for benefit for chronic or persistent non-malignant pain. Rather, they can increase disability and reduce the chance of recovery.

COVID-19 and Substance Use Disorders: Syndemic Responses to a Global Pandemic

88

Contents

Abstract

As this chapter is being written, the COVID-19 pandemic is having enormous impact upon the world. This is not only from direct mortality and morbidity due to the infection itself but also from its impact upon existing health services capacity which has been reoriented to cope. Worldwide infection control measures are causing socioeconomic upheaval. Deep emotional trauma and prolonged anxiety over facing the unseen and unknown are predicted to have lasting effects on individuals and communities. This includes an increase in drug and alcohol use, mental health conditions such as posttraumatic stress disorder, depression, somatisation and anxiety, lowered perceived health and reduced resilience to adversity.

Alongside this however are also huge advancements in medical science and unprecedented access to information and methods of communication through an ever-expanding digital infrastructure. Furthermore, there has been an increased understanding of the interrelatedness of various aspects of life, the so-

called determinants of health, and an explosion of multidisciplinary research approaches.

This chapter proffers to the reader a framework to understand the complexities of the COVID-19 pandemic in relation to the field of addiction medicine. The proposed syndemic response requires us to see addictions and substance use disorders as existing within multiple synergistic systems of social, economic, political and cultural contexts. It opens up opportunities for more effective and responsive multidisciplinary research, interventions and programmatic evaluations. Indeed, it is a good fit for current calls for research and programmes that enable society to prepare for the psychosocial and physiological challenges that lie ahead.

88.1 Introduction

Few would argue that the COVID-19 pandemic is likely to be the worst public health emergency for a generation. COVID-19 has a high mortality rate (3–30 times that of seasonal influenza) and a high transmission rate (10 times more contagious than SARS). There is therefore a very real possibility of millions dying if the pandemic is not successfully contained [12]. The COVID-19 pandemic is also an economic crisis. The measures required to contain the spread of this disease, such as social distancing, lock-down measures and shielding, all involve a sharp reduction in economic activity. The direct impact of this unprecedented cessation of productivity is a predicted global recession, mass unemployment and debt crises [49].

Health and social services, already under strain from a decade or more of austerity following the last global financial crisis, have been overwhelmed in many countries. A redistribution of resources to manage the pandemic has resulted in the cessation of many services including those for the assessment and treatment or management of addictions [24]. Critically, in poorer, developing countries, or those without adequate investment in a social safety net, the COVID-19 pandemic will be a humanitarian crisis. The World Bank estimates that 49 million people will be pushed into extreme poverty, and the UN food agency has warned of multiple concurrent famines, with an additional 130 million pushed to the brink of starvation by the end of 2020 [67]. Basic social services such as education, health and policing will decline, with consequent increases in conflict, violence and crime.

The world is responding to the pandemic with relief measures to increase health services capacity, support those affected by public health measures and align incentives to comply with social distancing [23]. The duration of this crisis and containment phase is as yet unknown. It will however be followed by many countries undertaking recovery measures to transition out of significant socioeconomic upheaval.

What are the implications of these unprecedented events for people who use drugs and alcohol and people in need of addiction services? As with past global events resulting in socioeconomic upheaval, what are the opportunities and innovations that become possible? How do we understand, adapt, plan, design, implement and evaluate complex services and policies in the rapidly changing landscape the COVID-19 pandemic has brought to us? These are complex questions requiring us to factor in the pathogenic social contexts that people who use drugs and alcohol often experience which include socioeconomic disadvantages with low resilience and increased stigma, discrimination, homelessness and other inequalities in the upstream determinants of health [5, 6, 25, 58].

88.2 Syndemic Theory and Substance Use Disorders

The terms “syndemic”, a portmanteau of “synergy” and “epidemic”, “pandemic” and “endemic” have been used to explain the synergistic interaction of two or more conditions and

the social contexts in which these conditions develop [66] – synergistic in the sense that two or more agents or factors interact to produce a combined effect which is larger than the sum of their separate effects. A syndemics framework has been used most frequently in understanding human immunodeficiency virus (HIV) transmission, one of the leading causes of morbidity and mortality globally as a result of a communicable disease [7, 22, 54, 63]. Closely related with HIV transmission is injecting drug use, and so, unsurprisingly, a number of syndemics which include substance misuse disorder have been described in the literature (Table 88.1).

A key point about syndemics, and its relevance to populations suffering from addiction or substance misuse disorder, is that they include both disease and social epidemics. With reference to Table 88.1, we see that violence, unresolved family conflict, internalised oppression (referred to as homonegativity when in relation to the lesbian, gay, bisexual and transgender (LGBT) community), loss, trauma and homelessness are as much part of a defined syndemic as HIV, substance misuse disorder, and mental and physical ill health [43, 64, 66]. Epidemics within a syndemic framework is both psychosociological (social, structural and behavioural) and physiological [54, 66].

Ultimately, syndemics describe a heightened vulnerability to morbidity and mortality due to a variety of synergistically correlated systems. Syndemic theory is particularly useful at this time as we grapple with the challenges of the COVID-19 pandemic. For example, does the so-called "opioid epidemic" seen in Australia, North America and Scotland constitute an additional syndemic alongside the COVID-19 pandemic? Certainly, there are a number of ways in which this combination fits the syndemic definition. People with opioid dependence may have increased vulnerability to COVID-19 exposure due to the need to source their drug of choice or attend a pharmacy daily to access substitute treatment. They are vulnerable to disruptions in the drug markets which can result in experimentation with unfamiliar or more highly potent drugs. Social isolation, a necessary protective mechanism against COVID-19, increases the risk of a person who injects drugs as there is no one to help if the person experiences an overdose. The impact of COVID-19 in terms of the loss of social

Table 88.1 Examples of syndemics involving substance use

Components of syndemic	Acronym	Country	Reference
Substance abuse including injecting drug use, violence including childhood sexual abuse, intimate partner violence, non-partner sexual assault and trafficking and HIV/AIDS. Special emphasis is placed on the challenges that sufferers have to negotiate condom use or to avoid needle sharing	SAVA	USA, Malaysia, Kazakhstan, Sub-Saharan Africa	[26, 32, 39, 64]
Substance use which often co-occurs with mental illnesses such as depression, schizophrenia, manic depressive disorder mental illness, and overt familial conflicts which are acute or chronic all of which impact upon HIV outcomes	SUMIC	USA	[60]
Substance use during condomless intercourse, adolescent sexual abuse, violence, internalised homonegativity, and depression	SAVID	Tanzania	[1]
Physical health problems, abuse, mental illness, loss, instability, and substance use	PHAMILIS	USA	[42, 43]
Syndemic of lifetime mental illness, substance use disorders, and trauma and adverse perinatal outcomes	–	USA	[45]
Depression, alcohol and violence	DAV	India	[19]
Depression, substance use, violence, sexual stigma and homelessness, unprotected anal intercourse and HIV infection	–	151 countries	[61]

SAVA substance abuse, violence and HIV/AIDS, *SUMIC* substance use, mental illness and familial conflict non-negotiation, *PHAMILIS* physical health problems, abuse, mental illness, loss, instability and substance use, *DAV* depression, alcohol and violence

networks, heightened stress from news stories, and bereavement from the loss of loved ones may result in increased drug consumption. Overall, there is a heightened risk of drug-related deaths as a consequence of the pandemic [3].

As mentioned earlier, there are a number of syndemics involving both substance use and HIV. COVID-19 here would add a further burden of disease and social disadvantage [63] exacerbating the challenges people living with HIV face which often include social and economic inequalities, stigma and homelessness [2, 11, 21]. A further consideration is the syndemic we are observing between communicable (e.g., COVID-19) and non-communicable diseases (NCDs). One strategy of many countries to protect from COVID-19-related mortality was to advise those with preexisting conditions to remain shielded or cocooned at home. Generally, this has meant remaining indoors in their own home for up to 3 months, with essential needs such as food or medication delivered to them. These preexisting conditions are primarily NCDs such as diabetes, chronic obstructive pulmonary disease (COPD) and cardiovascular conditions [47]. Unfortunately, as Volkow [70] identifies, people with addictions are over-represented in the numbers with NCDs. For example, long-term smokers and people who smoke crack cocaine or heroin have higher rates of both pulmonary and cardiovascular disease, both of which increase the mortality rate from coronavirus-related severe respiratory syndrome.

88.3 Syndemics and Complex Systems Thinking

A fundamental problem with a theory of disease, which emphasises social contexts as much as it does physiological pathology, is that it does not easily lend itself to compartmentalised approaches. Complex systems thinking is an approach which supports the understanding of syndemics by examining its elements (the physiological and contextual constituents), the interconnections between them (policies, legislation, social networks and norms and individual-level risk factors) and the true purpose or function of the examined system. To clarify this last point, one would hope that systems are not intentionally designed to perpetuate a syndemic. Yet, a complex systems analysis can uncover the dynamic of a social context and reveal that in fulfilling one function, for example, the lockdown strategy to minimise public exposure to COVID-19, the unintended consequence could be the creation of a system that may perpetuate or contribute to a syndemic (for example by increasing incidences of domestic abuse and violence) [53].

Systems approaches use tools and frameworks to develop a shared understanding of the interconnected and interdependent components of a problem or situation [17]. From this shared understanding, causal relationships and leverage points within them can be identified. Examples of this are provided in Fig. 88.1 through causal loop diagram. With systems-wide leadership and cross-sectoral cooperation, coordinated action can then be carried out, targeting these leverage points to manage the problem.

A complex system has several defining characteristics including emergence, feedback and adaptation. *Emergence* describes properties or phenomena that develop from a particular combination of systems elements that cannot be predicted simply by adding all these elements together [44]. *Feedback* is a situation whereby an intervention on an element within a system reinforces or balances a (usually) desired change within that system [44]. *Adaptation* refers to behavioural changes that come about as a result of an intervention [44]. These terms are explored in more detail in a later section.

88.4 Empirical Methods to Study Syndemics

A critique of the application of syndemic theory is that insufficient attention is paid to the actual mechanisms of interaction between epidemics to form a syndemic. The issue here is that some so-called social epidemics are simply a constellation of risk factors which are added up to create a composite variable which is then

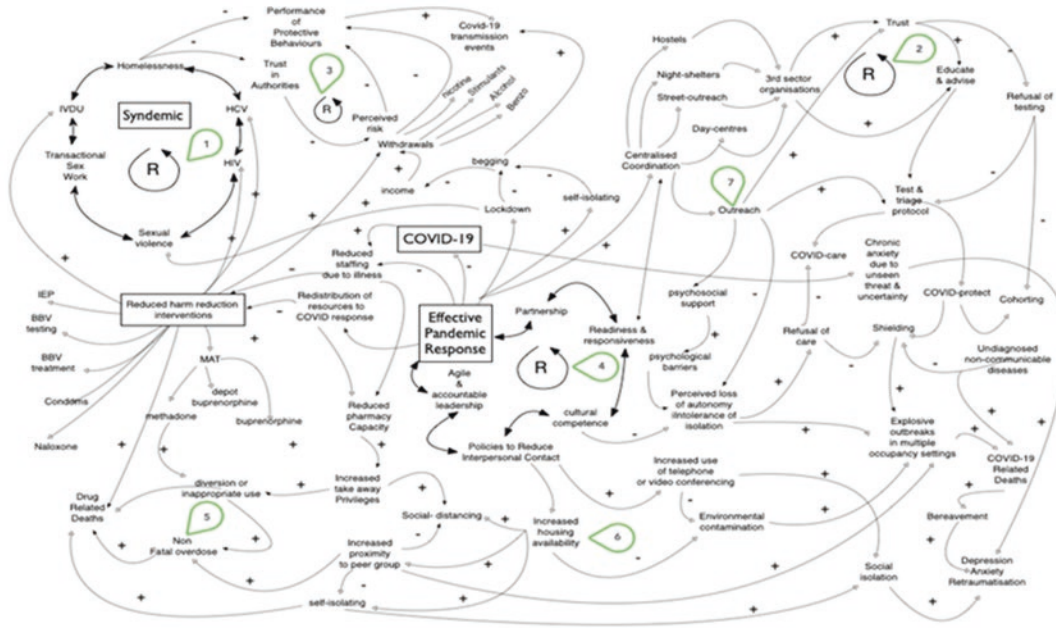

Fig. 88.1 Causal loop diagram identifying potential issues in managing the acute phase of the pandemic during a syndemic (In the diagram, the (-) symbol denotes a negative or reducing effect one variable has on the other, while (+) indicates the opposite. 'R' within a loop indicates a reinforcing series of variables.)

entered into an equation to identify a statistically significant effect [69]. Unfortunately, such practices ultimately undermine the effectiveness of the syndemic theory in not only understanding the impact of pathogenic social contexts on the mortality and morbidity of vulnerable groups but also in designing and accurately evaluating complex interventions. Table 88.2 illustrates three proposed mechanisms of interaction between epidemics to create a syndemic and suggested empirical methods to investigate them.

88.5 Applying Syndemic Theory and Complex Systems Thinking

We use a causal loop diagram to visualise an application of syndemic theory through complex systems thinking. Causal loop diagrams are a visual aid to show how different variables within a system are interrelated. There are other methods of visualising complexity which include graph visualisation, network visualisation, and node–link diagrams [56, 74]. The challenge is to describe complexity in a way that allows us to grapple with the issues it raises while not simultaneously oversimplifying and forgetting the bigger picture.

88.5.1 What Happens When a Syndemic Collides with a Pandemic? The Acute Phase

Figure 88.1 describes some of the elements involved in efforts to control the syndemic of homelessness, violence, and blood-borne viruses and their interaction with interventions to manage the COVID-19 pandemic in this vulnerable population. In recognition of the particular difficulties the homeless population would have in following public health advice during the pandemic, the National Health Service (NHS) in the UK developed specific and detailed guidance [48]. This guidance required local authorities to

Table 88.2 How do epidemics interact to form a syndemic?

Types of interaction	Description	Proposed research methods
Mutually causal epidemics 	This is the classic description of the syndemic, first described by Singer [64], i.e., the SAVA (substance abuse, violence, and AIDS) syndemic. Essentially epidemics A & B, B & C, and A & C are mutually causal	*Agent-based modelling.* Theory-led assumptions as to how a syndemic forms from different epidemics are explicitly detailed. The theorized modelled syndemic may be based on anthropological data, with emergent descriptions, compares against epidemiological data. Agent-based modelling can be used to simulate population-wide effects of complex interventions, for example, how stigma and trust in authorities may interfere with uptake of public health advice to limit COVID-19 spread. Examples include work by Zhang et al. [75] in investigating the obesity epidemic *System dynamics* is a mathematical modelling technique to frame, share understanding and unpick complex interactions [29]. Causal loop diagrams illustrated in Fig. 88.1 can be converted into stock and flow diagrams or can be used as they are to perform system dynamics via various computer programmes (Binder et al., [10]
Synergistically interacting epidemics 	In this syndemic, both A & B can cause C. When both co-occur, they have a synergistic effect which results in a much larger epidemic of C. This syndemic pattern is described by Singer & Clair [65]. Examples include the synergistic effects of alcohol abuse and HIV on the morbidity and mortality for patients with HCV coinfection [55]	
Serially causal epidemics 	This proposed pathway to a syndemic runs parallel with theories of accumulated risk exemplified by life course epidemiology [55]. Most topical in many countries currently is the association of adverse childhood experiences [8] as a life course determinant of adult health [27]	*Social network analysis* In the social network perspective, individual risk factors as well as the interconnections between key risk factors are important across the lifetime to explain how epidemics become a syndemic. In this model, low-prevalence health risks can become critical if they are strongly and closely connected to other risks. These high-density nodes become good targets for intervention. Examples of this include work by Tomori et al., [68] and McNally et al., [46] *Structural equation modelling* Hypothesised associations between several different variables are tested statistically. Examples include work by Khan et al. [35] to understand the impact of poverty and unemployment on alcohol abuse

Adapted from Tsai [69]

coordinate their resources with health, third sector organisations, and addiction services and included the following:

- Arranging appropriate accommodation, which at a minimum needed to have en-suite washroom facilities to minimise unnecessary interaction
- Identifying individuals needing to be shielded due to comorbid health conditions which increase their risk of poor outcomes from a COVID-19 infection
- Providing the conditions to support the shielding process for this identified group, to keep them separate from their peers and community
- Case finding through testing of symptomatic individuals and keeping them isolated for the duration of their illness (2 weeks) or until a negative test is obtained

The diagram is not intended to be a comprehensive illustration of every contingency but more to illustrate the implications of a syndemics perspective. The authors have some experience working through some of these pathways in the homeless and substance-using populations as the COVID-19 pandemic has unfolded [31]. The first reinforcing loop (1) is a visual representation of the synergistic effect of intravenous drug use, homelessness and violence upon HIV and hepatitis C (HCV) transmission. Opiate substitute therapy (OST), injecting equipment provision (IEP), condom supply, and HCV and HIV testing and treatment are important individual services. Collectively, as a complex public health intervention, these services have a greater impact than they do individually because of their impact on several elements of the syndemic. Furthermore, interrupting the provision of harm reduction services during the pandemic will potentially increase syndemic effects and contribute to drug-related deaths. In recognition of this, the Scottish government has specifically identified harm reduction and addictions services as essential through the pandemic [62].

Reinforcing loops (2) and (3) focus on the importance of trust as a driver for the success of public health interventions. Indeed, this has been highlighted as a key component in the acceptance of and compliance with public health advice [14, 15, 28, 52, 71]. Marginalised groups such as people who are homeless or people who use drugs have had a tendency to distrust institutions with authoritative powers, for example health or social services [50]. This mistrust is not the preserve of marginalised groups. The ability to retain the trust of the general public is increasingly seen as invaluable by many commercial, third sector and statutory institutions and organisations [30, 38].

There are a number of explanations for this which include media and government responses to actual and perceived failures within healthcare services [51], frustrations with healthcare rationing and unmet public expectations [20], and a cultural shift towards challenging the authority of experts, particularly if they are perceived to be detached from the realities of everyday life [72]. Indeed, and in line with Wilson et al., [73], syndemic theory can be useful here to understand the link between trust, structural violence (the suffering that comes from being stigmatised or oppressed due to socioeconomic status, homelessness or some other social factor), trauma and the motivation that individuals have to adopt health protective behaviours such as social distancing and self- isolating.

Carver et al. [18] unpick the service elements most valuable to the homeless population when seeking help for substance use disorders and identify the centrality of non-judgemental, compassionate and supportive relationships. Many frontline workers in the homeless sector have built these trusting supportive relationships with their clients over many years [9, 18, 40, 41]. Efforts to successfully remove barriers to homeless individuals complying with public health interventions to limit the spread of COVID-19 such as arranging suitable housing and welfare, nutritional, health and addiction support are contingent on building upon these invaluable, hard-won, human connections.

The restoration of public trust in healthcare requires an understanding of what is at the core of this concept [33], how it is lost and what strategies may return it [16]. Trust, relationships, social capital, reciprocity and similar concepts are difficult to measure or observe, yet are pivotal to the efficacy of public health interventions [73]. The application of syndemic theory necessitates that we understand psychosocial evidence in an equivalent way as physiological and biomedical evidence of the disease and offers a framework and the tools to do so.

It is worth at this point identifying examples of emergence, feedback and adaptation defined earlier in this chapter. Referring to (5) and (6) in Fig. 88.1, a transient rise in non-fatal drug overdose (NFO) rates among people who have a long history of homelessness may be an *emergent* property following interventions to enable them to self-isolate and practice social distancing. These interventions include rapid access to housing and the provision of opiate substitute therapy where required.

While protective against COVID-19 transmission, there are some issues which may increase

NFO rates at least in the early stages. This includes concentrating a large number of individuals with substance use issues in close proximity to each other, increasing their exposure to negative peer influences. During the initial phase of opiate substitute therapy, prescribers often do not provide take-home doses until the patient has a degree of social stability. In the context of the COVID-19 pandemic, this may not be possible due to reduced pharmacy capacity to supervise the daily consumption of medication or due to a need to shield the patient from unnecessary social contact. Individuals who have not been used to take-home doses may not take their medication as prescribed or be victimised by others because of their possession of valuable medication. In other words, in the short term at least, interventions widely seen as positive and supportive may increase substance-related harms.

The importance of *adaptation* is illustrated in (4). Bearing in mind that most countries have not the experience of managing a pandemic of this nature before, a region's COVID-19 response is more likely to be effective if authorities are able to coordinate their efforts rapidly and flexibly. To use the analogy of a plant growing around obstructions to reach the sunshine and thrive, agile and accountable governance and management structures, strong partnership working and culturally informed practices can contribute to the implementation of an effective COVID-19 containment strategy.

An example of *feedback* is observed here at (7). Marginalised groups such as people who are homeless or who use substance have often been through complex trauma. Fundamental to trauma-informed interventions are principles such as providing choice, collaboration and opportunities for empowerment, all of which are essentially about respecting the autonomy of the individual [4, 34]. While outreach interventions often closely fit with trauma-informed principles, public health messages which appear restrictive of civil liberties, freedom of movement or contingent on the tolerance of social isolation are likely to challenge this sense of autonomy. Getting the balance right here is essential to avoid situations of treatment refusal and to preserve the efficacy of interventions to reduce COVID-19 transmission events.

88.6 Multilevel Analysis

Based on theoretical models such as the risk environment framework [57, 58], the socioecological model [13] and the eco-social model [37], multilevel analysis looks at data nested within hierarchies. An individual is part of an interpersonal network within a community which accesses a health system which in turn is influenced by the political economy of the country. Failing to recognise these hierarchies and not accounting for them in mathematical modelling produce incorrect inferences. An example is how large-scale social forces such as economic upheaval or war can impact upon the individual's choices and risks leading to increased exposure to HIV (Tim [59]). Critically Bradley et al. [12] point out that the complexity involved in researching priority areas around COVID-19 necessitates the use of multidimensional and multilevel perspectives. Table 88.3 goes through some of the issues that will need to be considered both during the acute and recovery phases of the pandemic.

The micro-level here refers to the smallest level of interaction. This could be at the level of interpersonal relationships or communication and could also include the internalisation of perceived public opinion to form their self-identity. This term also indicates individual characteristics, capacities or abilities which influences behaviour.

The meso-level refers to organisational-level behaviour. This can range from individuals developing a sense of solidarity with each other and forming a community group, organisational behaviour in the face of a changing environment or social norms with a group.

The macro-level refers to large-scale patterns or influences, for example the impact of laws, the economy or widespread public opinion.

Table 88.3 Summary of problems and interventions in the acute and post-COVID-19 phases

Level of analysis	Acute phase(s) of uncertain duration Public health interventions and supportive relief measures	COVID-19 recovery phase Transitioning out of socioeconomic upheaval
Micro Individual-level interactions personal decisions and agency Individual values, strengths, capabilities, life experiences	*Problems* Distrust of authority Re-traumatisation Fear of isolation Alternate rationalities influenced by substance use Stigma	*Problems* Coping with disaster Loss and bereavement Trauma Chronic fear and anxiety Helplessness Increased substance use
	Opportunities Shared decision-making Co-producing services Build or attach to peer and frontline worker relationships Psychologically informed environments and interventions	*Opportunities* Maintaining capacity to provide mental health care Removing barriers to treatment Building upon collaboration across sectors, disciplines and service-users
Meso Organisational service delivery Third sector Community groups Community engagement Community level norms and practices	*Problems* Deprioritising of addictions services Re-deployment Staff illness Unresponsive management structures	*Problems* Re-orienting services towards future pandemic preparedness Catch up with urgent care delayed by the current pandemic Increased demand on services due to trauma and chronic anxiety and stress Unrecognised value of addiction and mental health services
	Opportunities Sharing experience and knowledge Digital platforms Advocacy Build upon networks, for example public health	*Opportunities* Developing novel technological solutions Targeting digital inequality Developing peer support, co-production and collaboration with service-users The definition of essential workers and their importance in society have changed for the better Collecting data and research to show the value of psychological and psychosocial factors in physical health responses
Macro Policy level (macro-economic, public health, social, legal) Public discourses Media	*Problems* Economic or public health crisis? Tensions between the needs of economic security and public health Relief measures have had a direct effect on the public purse through increased spending, for example, increased expenditure on health care, while at the same time there is a reduction in tax income due to reduced economic productivity	*Problems* Avoiding collapse through relief measures Austerity Reduced spending on health and social services Benefits cuts Shrinking of the state

(continued)

Table 88.3 (continued)

Level of analysis	Acute phase(s) of uncertain duration Public health interventions and supportive relief measures	COVID-19 recovery phase Transitioning out of socioeconomic upheaval
	Opportunities 1. Recognition of the importance of the social net and publicly well resourced publicly funded healthcare 2. Recognition of the importance of civil liberties may lead to increased public participation 3. A number of long-debated initiatives such as universal basic income and housing first may become relevant again 4. Improved environmental health and reduction in the carbon footprint	*Opportunities* 1. Critical times require well-designed government action and effective public service delivery 2. A monetary and fiscal policy, which avoids desperate measures, ensuring continuity of public services provision for vulnerable people, contributes to macroeconomic stability

88.7 Conclusions

Syndemic theory differs from conventional health models by incorporating the upstream social determinants of health into explanations of disease clustering from the outset. This means that complex population-based interventions can be designed which address macro-level social elements, for example societal and institutional stigma. Complex public health interventions offer a number of benefits, not least, the avoidance of duplication through multiple independent initiatives or competing smaller projects [69].

There is however the issue of local areas often having different priorities, resources and demographics. Awaiting consensus across several administrative regions on one comprehensive intervention may result in an unresponsive local health service with consequent risks of increased mortality and morbidity. Similarly, different communities may have different vulnerabilities. Worldwide, large communities of displaced people and international migrant workers may live in conditions that increase their vulnerability to COVID-19. They are also at risk of income loss, healthcare insecurity, postponement of decisions on their legal status and an inability to protect themselves or their families from violence [36]. Population-level initiatives to reduce viral transmission must address these needs in order to be successful.

Single health issue interventions or quality improvement activities by services have an important role in meeting the needs of individuals suffering from syndemic conditions. Conceptualising these interventions within a complex systems approach allows us to understand its contribution to the functioning of the overall system. For example, removing barriers to medication-assisted therapy during the pandemic has the obvious outcome of stabilising drug use and removing the suffering of withdrawals. It may also rebuild trust between people who use drugs and authorities, and through this, improve compliance with social distancing.

The provision of good-quality housing to enable homeless individuals to self-isolate during the pandemic will reduce their immediate risk of COVID-19 infection. It may also signal to these individuals that they are cared for by society. Supported and stable housing may provide opportunities for people who use drugs to remove themselves from destructive social networks and experience sobriety for the first time. This in turn could have benefits or disadvantages such as a deterioration in mental health due to the recollection of past trauma. Using network science, agent-based models or other syndemic and systems analytical tools allow us to develop, design and better evaluate interventions [69]. We are

able to look at individual strands, while also keeping an eye on the overall complex tapestry.

Syndemic and complex systems approaches support a recent position paper by Holmes et al. [28] regarding mental health science research priorities during and following the COVID-19 pandemic. The paper recommends a research strategy that is global, collaborative, multidisciplinary, cross-sectoral and incorporating people with lived experience which addresses the psychological, social and neuroscientific underpinnings of the mental health impacts of the pandemic. The essential role that the social sciences, humanities and technology have in terms of understanding the uptake and acceptance of evidence and public health measures and in reducing fear and stigma has been highlighted and should be capitalised upon to develop future comprehensive and complex interventions.

89

Psychiatric Comorbidities and Complications of Alcohol, Other Drugs: An Introduction, and International Perspectives: An Introduction and International Perspectives: An Introduction

Kathleen T. Brady and Giuseppe Carrà

The co-occurrence of substance use disorders (SUDs) with other psychiatric disorders has been an area of increasing focus over the past 30 years. This intense focus has increased the knowledge base with regard to the prevalence of co-occurring disorders, the neurobiological interface between substance use and other psychiatric disorders, and pharmacologic and psychotherapeutic treatment options. In addition, a critical focus on workforce training and designing systems of care that can optimally address the treatment needs of individuals with co-occurring disorders is needed. In these efforts, sharing knowledge across cultural and national boundaries is essential.

An international perspective on co-occurring disorders is particularly important for a number of reasons. Just as there are cultural influences in definitions, recognition, diagnosis, and treatment approaches to substance use disorders, there are important cultural influences in other psychiatric disorders and in the approaches to comorbidity. As articulated in the overview, while different countries experience varying levels of recognition of the importance of the co-occurrence of substance use and substance use disorders in mental health-care systems, the concept of "dual diagnosis" is becoming increasingly well accepted, and recognition of the importance of co-occurring disorders is rapidly expanding around the globe. In this context, the importance of recognizing that "ethnic, racial and cultural groups manifest their medical illnesses, including psychiatric illnesses, within the context of their culture, tradition, beliefs and heritage" is acknowledged as a critical issue.

The chapters that follow are written by clinicians and scientists from a wide range of countries in an attempt to give the reader a broad and international perspective on co-occurring disorders. The chapter on psychotic disorders by Dr. Carretta and colleagues provides an excellent overview of the epidemiology of co-occurring psychotic disorders and SUDs as well as a scholarly discussion of potential etiologic connections (Chap. 94). The area of cannabis and psychotic disorders is particularly well covered as this has been a topic of intense investigation and discussion at an international level for the past 25 years. Drs. Nunes and colleagues have written a comprehensive chapter covering the topic of

co-occurring mood and substance use disorders. In particular, their discussion of the approach to differential diagnosis and treatment of individuals with these comorbidities is detailed and useful across global boundaries. Their discussion of mood disorders in opioid dependence is particularly timely and valuable in light of the opioid overdose epidemic in the United States over the last decade.

Dr. Bartoli and colleagues have extensively reviewed epidemiological and clinical issues with regard to the comorbidity between anxiety and alcohol or SUDs whose etiologic links and temporal relationships are still unclear and, probably, heterogeneous and multifactorial. Alcohol and substances may be misused to self-medicate anxiety, avoidant, and phobic symptoms, but also anxiety disorders may be consequences of alcohol and/or substance misuse. Dr. Levin and colleagues have also provided a scholarly and comprehensive chapter addressing the issue of co-occurring ADHD and SUDs, including a discussion of the updated DSM-V criteria for both ADHD and SUDs. This comorbidity is an issue of particular concern in the United States where the diagnosis of ADHD has increased dramatically in prevalence over the past 30 years. In this regard, other nations and health-care systems may be able to learn from experiences of the United States concerning potential problems stemming from both under- and overdiagnoses of ADHD. The chapter on substance-induced disorders by Baldacchino and Sharma provides an excellent overview of general concepts in the dual diagnosis and comorbidity literature from an international perspective before an in-depth and comprehensive discussion of specific substance-induced psychiatric syndromes (Chap. 90). The chapter by Brady and colleagues (Chap. 93) tackles the very common and problematic area of trauma and addictions. Considering the level of conflict and trauma across the globe today, this is an area of international importance, and new pharmacotherapeutic and psychotherapeutic treatments under development are discussed.

The chapter by Fraser and colleagues (Chap. 96) explores the complex interface between addictive disorders and personality disorders, highlighting their interactions, and how this might inform treatment choices, specifically the need for comprehensive approaches for the patients who tend to be stigmatized and marginalized.

In sum, this section provides a thorough and comprehensive review of the co-occurrence of psychiatric and SUDs from multiple perspectives. We have much to learn from sharing evidence and observations across cultural, geographic, and political boundaries in order to develop the most sophisticated understanding of this complex patient population. This improved understanding is essential to expanding treatment options and improving treatment outcomes worldwide.

Substance-Induced Mental Disorders

Contents

Abstract

Comorbidity is a condition that describes the presence of two or more diagnosable conditions, either happening at the same time or having a close temporal relationship, in the same individual. This is usually more focused on the presence of psychological/psychiatric problems and associated polydrug use and misuse. This chapter will try to identify and clarify the nature and relationship of the different avenues of clinical presentations presenting as substance-induced mental disorders.

They include the following:

- Substance use and withdrawal from substances may lead to psychiatric syndromes or symptoms.
- Intoxication and dependence may produce psychological symptoms.
- Substance use exacerbating or altering the course of preexisting mental disorder.
- A primary mental disorder precipitated by a substance use disorder, which may lead to psychiatric syndromes.

Keywords

Comorbidity · Dual diagnosis · Mental health

Although there are several different classification schemes for psychoactive drugs (pharmacological, legal, medical), the most common organization is based on their effect on behavior and cognition. According to this scheme, psychoactive drugs can be classified into three broad categories: (1) sedatives, (2) stimulants, and (3) hallucinogens. Substance-induced mental disorders will be described on the basis of this classification in this chapter.

90.1 Introduction

Four categories of dual diagnosis involving substance misuse have been suggested by Krausz [31]:

- A primary diagnosis of a mental disorder, with a subsequent (dual) diagnosis of substance misuse that adversely affects mental health
- A primary diagnosis of drug dependence with psychiatric complications leading to mental disorder
- Concurrent diagnosis of substance misuse and mental disorders
- A dual diagnosis of substance misuse and mood disorder, both resulting from an underlying traumatic experience, for example, post-traumatic stress disorder.

Central to these explanations is the distinction between "primary" and "secondary" in terms of cause and effect. However, the distinction has also been made in terms of temporal appearance or age at lifetime onset [17]. While such a distinction has face validity in suggesting that the first temporal disorder is independent of subsequent disorders, it does not clarify whether the secondary disorder is independent of the first or how the disorders may be interrelated [47].

However, it is widely recognized that certain mental disorders have characteristic ages of onset and can thus be distinguished temporally as primary or secondary. For example, attention deficit disorder (ADD) and conduct disorder begin in childhood; alcohol and drug abuse in early to mid-adolescence; and anxiety, mood, and psychotic disorders in late adolescence and adulthood.

The operational use of concepts of substance use and misuse relies heavily on the etiology, clinical practice, particular cultures, and ideology [58] as well as the purpose(s) behind their use. Berridge points out that "definitions of alcoholism and drug addiction are historically constructed, are the products of particular historic sets of circumstances and interrelationships [7, 49]. Disease concepts, for example, may have been common in the 1890s and 1950s, but the components of the theoretical basis were very different in those decades" [6].

Many terms have been used over the past century or more to describe or define problems related to the use of alcohol, drugs, and other substances.

Some of these terms are, to say the least, very ambiguous and fluid. It is important to appreciate the latter point since these terms are in turn employed in some of the descriptions or definitions of dual diagnosis, comorbidity, etc. The definition of addiction dependence, etc., is key to intervention with substance abusers as it classifies abusive drug/drinking behaviors and impacts on the type(s) of treatment that is given.

90.2 Dimensions of Substance-Induced Mental Disorders

The difficulty of making a diagnosis of a substance-induced mental disorder is because of the different points of view from mental health and addiction services that tend to confuse the situation. Furthermore, Abdulrahim [1] suggests that the nature and relationship of comorbidity is complex and is so for the following reasons:

- Substance use and withdrawal from substances may lead to psychiatric syndromes or symptoms.
- Intoxication and dependence may produce psychological symptoms.
- Substance use may exacerbate or alter the course of preexisting mental disorder.

- A primary mental disorder may precipitate a substance use disorder (SUD), which may lead to psychiatric syndromes.

90.2.1 Examples

90.2.1.1 Cannabis-Induced Mental Disorders

An issue which has caused considerable debate in this area is the precise mechanism of the link between cannabis and psychosis. Specifically, cannabis use may alter the onset, course, and clinical expression of the psychotic episode.

There are several theories including:

A. Cannabis use occurs as a means of self-medicating for the effects of a prodromal or florid psychosis episode/illness [28].
B. Latent form of schizophrenia. Cannabis use interacts synergistically with a predisposition to psychosis to result in the emergence of psychotic symptoms earlier. It assumes that cannabis is just one of many confounding factors, including a genetic predisposition, which precipitates psychosis. According to this theory, the psychosis will not necessarily reduce or cease with a withdrawal from cannabis use and will not present with a distinctive psychopathology [24, 37].
C. Cannabis worsens or ameliorates an established psychosis [11].
D. Cannabis use directly causes toxic effect resulting in specific psychosis. Psychosis would not occur in the absence of cannabis use, and the fact that cannabis is the cause of the psychosis can be inferred from the symptoms or psychopathology of the psychosis [20].
E. Coincidental presentation of two prevalent disorders which peak in a young age group. Understanding how clusters of disorders through either concurrent or sequential links may promote a specific type of psychopathology [12].

Another possibility is that cannabis and associated psychosis are not different from psychotic symptoms in the presence of other substances such as amphetamine, cocaine, and alcohol use. For example, Jordaan et al. [26] conclude that since patients with alcohol-induced psychotic disorder have fewer negative and disorganized symptoms, better insight and judgment, and less functional impairment than patients with schizophrenia, this alcohol-induced psychotic disorder is a distinct entity. This resonates with the conclusions that alcoholic hallucinosis was not a variant of schizophrenia but a distinct condition [21].

90.2.1.2 MDMA-Induced Neurotoxic Damage and Mental Disorders

That substance use could cause mental disorders or at least can intensify such problems is supported by both psychological and neurobiological data. For example, it is known that the effect mechanism of MDMA significantly concerns the serotonin system [5, 27, 30, 42] and chronic MDMA use is supposed to have a neurotoxic effect on the serotonin system [34]. Since the use of MDMA is linked to decreased sensitivity of serotonin receptors, it is a well-supported assumption that this bodily change could have a significant role in the often experienced symptoms of depression of MDMA users. This view seems to be strong, although it has been often stated that emotional instability might precede substance use, and it may have a role in the development of substance use; thus, a circular causality might be assumed.

90.2.1.3 Chronic Opioid Use and Neuropsychological/Cognitive Impairment

Given the current emphasis on patients suffering from co-occurring substance use disorders (SUD) and mental disorders, one may forget that dual diagnosis can also include patients displaying both SUD and cognitive impairment. For example, chronic exposure to opioids has been reported to be associated with a number of neuropsychological impairments both during active use and after a period of abstinence. A wealth of studies have examined the acute, subacute, and chronic

effects of opioids on neuropsychological performance using a broad variety of measures sensitive to component aspects of attention, memory, learning, and executive functioning [14, 18].

However, for methodological reasons, defining the nature and extent of opioid-related impairments remains elusive. For instance, research on memory functions has resulted in a number of studies showing impairments in word/pattern recognition, learning and recall of words/figures, paired associate learning, and retrieval [15, 19, 41, 44]. However, other studies failed to replicate these findings of memory deficits in chronic, opioid-dependent individuals [13, 39]. In addition to memory function, studies on attention also suggest inconsistent findings. Studies have shown either no impairments in attention [13, 53] or a significant reduction in attention span [48, 54] in chronic, opioid-dependent individuals.

Neuropsychological studies of chronic opioid users have identified similarly inconsistent deficits in executive function measures. These have included impairments in cognitive flexibility [43], strategic planning [19], decision making [9, 61], and risk taking [44, 62]. However, other studies found no clear deficits when comparing the performance of healthy controls with that of opioid-abstinent, polysubstance users, head injury patients, or patients with chronic pain [22, 46].

A meta-analysis by Baldacchino et al. [4] suggests that chronic opioid exposure is associated with deficits across a range of different neuropsychological domains. However, the only domains where meta-analysis suggests robust impairment were those of verbal working memory, risk taking, and cognitive flexibility (verbal fluency).

90.2.2 Presentations

Although there are several different classification schemes for psychoactive drugs (pharmacological, legal, medical), the most common organization is based on their effect on behavior and cognition. According to this scheme, psychoactive drugs can be classified into three broad categories: (1) sedatives, (2) stimulants, and (3) hallucinogens. Substance-induced mental disorders will be described on the basis of this classification (Table 90.1).

Table 90.1 Substance-induced mental disorders

Sedatives		Stimulants	Hallucinogens
Acute effects	Relaxation, sedation, disinhibition and impaired judgment, slurred speech, ataxia, nystagmus, auditory hallucinations with delusions, labile mood, stupor, and coma. Impairment of motor coordination and cognition	Increased alertness, energy, and confidence; reduced hunger and sleep; euphoria, anxiety, and paranoia	Relaxation, sedation, disorientation, euphoria, and increased sensory awareness with hallucinations and delusions. Sometimes dysphoria, an overwhelming sense of fear often leading to panic attacks. Synesthesia
Withdrawal effects	Anxiety, agitation, disorientation, hallucinations (tactile, visual, auditory), and insomnia	Fatigue, anxiety, and depression (“crash”)	Emotional and behavioral disturbance, anxiety, depression, insomnia, and loss of appetite
Chronic effects	Depressive and anxiety symptoms including guilt and hopelessness confusion, ataxia, ophthalmoplegia, nystagmus, anterograde memory loss, and confabulation. Others include deficits in abstract thinking, perceptual motor skills, and visuospatial and verbal learning	Depressive and psychotic symptoms. Cognitive impairments	Cognitive impairment and possible long term, anxiety, depressive, and psychotic symptoms. Suicidal ideations. Cognitive impairments

90.2.3 Sedative-Induced Mental Disorders

Sedatives depress or inhibit brain activity and produce drowsiness, sedation, or sleep, relieve anxiety, and lower inhibition. Although the depressant compounds do not share a common neural mechanism of action, most of them either decrease the metabolic activity in the brain or increase the transmission of the principal inhibitory neurotransmitter of the brain, gamma-aminobutyric acid (GABA). Common depressants include barbiturates, benzodiazepines, opioids, and alcohol [16].

There are several mental disorders presenting as a direct consequence to excessive consumption of alcohol. The conditions presented with benzodiazepine and other sedatives tend to have the same quality but not necessarily severity of the psychopathology arising.

90.2.3.1 Alcohol-Induced Amnesia (Blackout)

Loss of memory is related to periods when intoxicated with alcohol. Anterograde memory loss tends to be a result of lack of recall rather than registration [25]. Two types have been identified:

(a) "En bloc" – discrete start and finish points with complete loss of memory for interim events
(b) Fragmentary – partial amnesia with islands of recollection still intact

90.2.3.2 Alcohol-Induced Psychosis/ Hallucinosis

This mental disorder presents with a sudden onset of auditory hallucinations and delusions in the presence of clear "sensorium" in individuals with a history of alcohol abuse. Auditory hallucinations are usually derogatory in nature or portray negative connotations [26]. These symptoms usually improve quickly (usually within a week) although they can become chronic due to ongoing alcohol misuse where they tend to persist. Patients with alcohol-induced psychosis can present with later onset of psychosis, lower educational level, more anxiety and depressive symptoms, fewer negative and disorganized symptoms, and less functional impairment than patients with schizophrenia [26].

90.2.3.3 Alcohol Withdrawal Syndrome (AWS)

This arises in alcohol-dependent patients, usually within 24–48 h of stopping alcohol consumption [35]. AWS can occur unexpectedly in an alcohol-dependent patient following hospital admission and intentionally in those seeking abstinence. Alcohol withdrawal is common and usually mild but can also lead to withdrawal seizures and delirium tremens, both of which may be fatal [35]. The definition of alcohol withdrawal encapsulates the key clinical findings of AWS including anxiety, agitation, tremor, delirium, disorientation, hallucinations (tactile, visual, auditory), and insomnia.

90.2.3.4 Delirium Tremens

This is characterized by an acute confusional state with fluctuating levels of cognition and consciousness over the day following alcohol withdrawal in a patient with alcohol dependence. It usually occurs 2–4 days after last alcohol consumption unlike simple alcohol withdrawals which occur within a few hours of stopping alcohol. Autonomic symptoms including sweating, nausea, palpitations and tremor, hypertension, and tachycardia are invariably present. It occurs in about 5% of withdrawal episodes in admitted patients [33]. Important clinical features include visual hallucinations and severe tremors. Other symptoms include fear, paranoid delusions, and psychomotor agitation.

90.2.3.5 Wernicke's Encephalopathy and Korsakoff Psychosis

Chronic alcohol consumption can result in thiamine deficiency via inadequate dietary intake, malabsorption of thiamine from the gastrointestinal tract, and impaired utilization of thiamine in the cells. Thiamine is an essential cofactor for several enzymes involved in brain cell metabolism that are required for the production of precursors for several important cell components as

well as for the generation of the energy-supplying molecule ATP. Accordingly, thiamine deficiency can cause a number of processes that are toxic to brain cells [32].

Wernicke's encephalopathy is a relatively common and potentially dangerous neuropsychiatric condition caused by thiamine (vitamin B1) deficiency [8]. If not treated, it can result in a chronic form of the disease known as Korsakoff psychosis. As a result of the close relationship between Wernicke's encephalopathy and Korsakoff psychosis, reference is often made to the Wernicke-Korsakoff syndrome [57].

The symptoms of Wernicke's encephalopathy include mental confusion, oculomotor disturbances, and gait ataxia (an impaired ability to coordinate movements, particularly of the lower extremities). Patients will also manifest deficits in memory function, abstract problem solving, perceptual motor skills, visuospatial function, verbal learning, and motor function.

Korsakoff syndrome consists of memory impairments (preserved primary memory, impaired recent memory, and extensive retrograde amnesia) occurring in clear sensorium. Other psychopathology includes poor insight into the memory deficit with resulting confabulation, absence of impairment or loss of consciousness, and absence of global cognitive impairment [29].

90.2.4 Stimulant-Induced Mental Disorders

Stimulants produce behavioral arousal. As with the sedatives, there are a variety of substances, each with a different neural mechanism of action. These drugs act by increasing the activity of three neurotransmitters in the brain: serotonin, dopamine, and norepinephrine [56]. Examples of stimulants are cocaine, caffeine, and nicotine. Other examples of stimulants are amphetamines and amphetamine-like substances such as methamphetamine. Smoking, sniffing, ingesting, inhaling, and injecting are the most common methods through which these drugs are used.

Stimulant-induced mental disorder presents in the acute stage with euphoria and in vulnerable groups with severe anxiety, paranoia, and manic-type (increased energy, mental alertness, increased sexuality, and extended periods of wakefulness) psychopathology [23, 36]. This is associated with improved attention and suppressed appetite [55]. It can also cause perceptual disturbances especially "formication." This is described as a sensation that resembles that of insects crawling (tactile hallucination) on (or under) the skin. It is one specific form of a set of sensations known as paresthesia, which also include the more common prickling, tingling sensation of "pins and needles." As the effects of the drugs subside, the user feels dysphoric, tired, irritable, and mildly depressed, which may lead to subsequent drug use to regain the previous experience [51, 52].

Chronic use of excessive amounts of stimulants can intensify symptoms or precipitate a psychotic episode similar to schizophrenia in vulnerable individuals [59, 63].

90.2.5 Hallucinogen-Induced Mental Disorders

Hallucinogens and psychedelics do not share a common mechanism of action, but all induce hallucinations. These drugs can be either natural such as mescaline, which is derived from the peyote cactus, or synthetic such as lysergic acid diethylamide (LSD), but they are typically classified pharmacologically according to the affected neurotransmitter system. Cholinergic psychedelics (drugs altering acetylcholine transmission) include physostigmine, scopolamine, and atropine. Drugs that alter norepinephrine transmission include mescaline and ecstasy. Drugs that alter serotonin transmission include LSD and psilocin. Other drugs in this category include the psychedelic anesthetics phencyclidine (PCP) and ketamine [40, 50, 60].

Cannabinoids, psychoactive substances derived from the hemp plant *Cannabis sativa*, are often classified as hallucinogens. There are two types of acute effects on mental function – euphoric and calming. Besides the dramatic impact on emotional functions, acute cannabis

intoxication can induce cognitive impairments, sometimes persisting for weeks or months following abstinence. This usually presents as a fragmentation of thought process, major disruption of temporal understanding, distortion of perceptual stimuli, and poor attention and concentration. "Cannabis psychosis" may not be qualitatively any different from other forms of psychosis [3]. Some specific psychopathologies stated include confusion, disorientation, amnesia, depersonalization, delusions, hallucinations, paranoia, ideation, psychomotor agitation, labile affect, and hostility [2].

Chronic exposure to cannabis leads to a cannabis withdrawal syndrome [10] characterized by the frequently reported symptoms of emotional and behavioral disturbance which includes depression, anxiety and irritability, nausea, abdominal discomfort, decreased appetite, weight loss, physical discomfort, and insomnia with strange dreams [10]. A chronic buildup of cannabinoids produces both short-term and long-term cognitive impairments. There is insufficient knowledge to determine the level of risk associated with cannabis use in relation to long-term psychotic symptom [38].

90.3 Conclusion

Substance-induced mental disorders are important conditions that need to be contextualized within the substance use history but also need to be well managed to prevent further deterioration. Substance-induced mental disorders also need to be understood within the context of the overall lack of defined and strict operational definitions used in the field of comorbidity or dual diagnosis.

Abstract

Mood disorders, which include depressive and bipolar disorders, are among the most common disorders observed to co-occur with substance use disorders. These disorders have been associated with a worse prognosis among substance use disorder patients, and vice versa. Furthermore, treatment of co-occurring mood disorders has been shown to improve treatment outcome among substance-dependent patients with improvement in both mood and substance use. At the same time,

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment*, https://doi.org/10.1007/978-3-030-36391-8_91

mood symptoms among patients with substance use disorders frequently remit when patients reduce substance use or achieve abstinence without specific mood disorder treatment. Thus, it is important for clinicians working with substance-abusing patients to be able to recognize mood disorders in the clinical history, distinguish mood disorders that require specific treatment, recommend appropriate treatment options, and monitor clinical course. This chapter reviews the evidence on the diagnosis and treatment of co-occurring substance and mood disorders, with emphasis on depressive disorders.

Keywords

Attention Deficit Hyperactivity Disorder - Bipolar Disorder - Mood Disorder - Social Anxiety Disorder · Major Depressive Disorder · Substance Use Disorders

Highlights

1. Substance use disorders have a high prevalence of comorbid mood disorders, and vice versa.
2. There is substantial overlap in the symptoms of substance use disorders and mood disorders.
3. An understanding of both mood and substance use disorders is essential for the assessment and treatment of either.
4. Differentiation of symptoms arising from a mood vs. substance use disorder can be differentiated through careful history taking or use of a clinical research tool.
5. A substance use disorder should always be treated when diagnosed, and this may resolve mood symptoms.
6. In cases with significant mood symptoms, or symptoms that do not resolve with substance abstinence, targeted mood disorder treatment may be warranted.

91.1 Introduction

The co-occurrence of mood and substance use disorders has been a source of considerable controversy, sparked by the complexity of potential relationships and overlap between mood syndromes and substance-related disorders. For example, in patients with alcohol use disorder, do depressive symptoms represent side effects of chronic alcohol exposure that will resolve if the patient achieves abstinence? Or do they represent an independent mood disorder that requires specific treatment, either with behavioral therapy, medication, or a combination of the two? In any given patient, either of these explanations may be correct. Effective management of co-occurring mood symptoms in substance-abusing patients requires a nuanced awareness of the differential diagnosis of the mood symptoms and the expected effects of abused substances. This chapter will attempt to provide a guideline for clinicians to the differential diagnosis and therapeutics of mood syndromes among substance-dependent patients, based on the current evidence.

The co-occurrence of bipolar disorders and substance use disorders is covered in detail in a separate chapter of this text. However, because it is very important to consider bipolar disorders in the differential diagnosis when conducting a diagnostic evaluation and planning treatment, this chapter provides an overview of the diagnosis of bipolar disorders.

91.2 Prevalence and Co-occurrence

91.2.1 DSM-IV and DSM-5

As much of the existing literature on co-occurring mood and substance use disorders was conducted with DSM-IV mood disorder, "substance abuse," or "substance dependence" diagnostic criteria, the empirical evidence cited in this chapter derives from investigations that use both DSM-5 and DSM-IV [2] or earlier criteria sets. The criteria for depressive disorders (major depression, persistent depressive disorder (previously known as dysthymia)) and bipolar disorders (bipolar I, bipolar II, cyclothymia) have changed little between DSM-IV and DSM-5. DSM-5 added a new category of disruptive mood dysregulation disorder (DMDD) to the group of depressive disorders to distinguish children with predominantly irritable mood, but without other features of

bipolar disorder, from children in the bipolar spectrum. The substance-induced diagnoses (substance-induced depressive disorder, substance-induced bipolar disorder) are similar conceptually in DSM-5 and DSM-IV with some subtle differences reviewed below.

A thorough review of the diagnostic criteria for depressive and bipolar disorders is beyond the scope of this chapter. Readers who are not familiar with these diagnostic criteria should review the DSM-5 [3], which provides detailed descriptions.

The substance use disorders were changed in DSM-5, in that substance dependence (DSM-IV) and substance abuse (DSM-IV) have been combined into one category, named substance use disorder (DSM-5). This was done because the weight of the evidence indicated the criteria for DSM-IV substance abuse, which involved hazardous use (e.g., driving while intoxicated), social or interpersonal problems related to use, or failure to perform in major role responsibilities, were intermixed across the severity spectrum with substance dependence criteria, representing part of a chronic pattern of substance use with loss of control, tolerance, dependence, and adverse consequences [33]. Another difference between DSM-IV and DSM-5 is the addition of "craving" as a criterion for substance use disorder in DSM-5.

In terms of the evidence on the co-occurrence of mood and substance use disorders, these changes should make little difference, as substance dependence (DSM-IV) and substance use disorder (DSM-5) are conceptually similar, representing a chronic pattern of substance use with loss of control, tolerance, physical dependence, and actual or threatened adverse consequences.

Thus, the DSM-5 criteria for mood and substance use disorders are similar enough to DSM-IV (and prior) criteria that the evidence on co-occurrence based on earlier criteria can be expected to generalize to the DSM-5 framework.

91.2.2 Depressive Disorders

91.2.2.1 Major Depressive Disorder

Major depressive disorder represents an episode, lasting 2 weeks or more, of relatively severe depression, characterized by a persistent state, "most of the day, nearly every day", of either depressed mood or markedly diminished interest or pleasure in usual activities, or both, along with at least three or four associated symptoms, again occurring nearly every day (anorexia and weight loss, insomnia or hypersomnia, psychomotor agitation or retardation, fatigue or low energy, feelings of worthlessness or guilt, trouble concentrating or making decisions, recurrent thoughts of death or suicide) [3]. Major depression may occur as a single episode, but a chronic course is not uncommon, in which there are recurrent major depressive episodes, followed by partial remissions during which some of the depressive symptoms persist.

91.2.2.2 Persistent Depressive Disorder

Persistent depressive disorder (DSM-5), called *dysthymia* in DSM-IV, represents a chronic syndrome of depressed mood "more days than not… for at least 2 years" [3], along with at least two of the following associated symptoms – either low appetite or overeating, insomnia or hypersomnia, fatigue or low energy, low self-esteem, poor concentration or difficulty making decisions, and feelings of hopelessness. Persistent depressive disorder may be specified "with persistent major depression" or "with intermittent major depressive episodes" to indicate the confluence of major depressive episodes with the chronic low-grade symptoms.

91.2.2.3 Prevalence and Co-occurrence of Depressive Disorders with Substance Use Disorders

Like substance use disorders, depressive disorders are among the most commonly occurring mental disorders. Community surveys indicate 10% or more of individuals have experienced a depressive disorder during their lifetime [30, 34]. Depressive disorders are responsible for substantial suffering, functional impairment, lost productivity [21], and suicide risk. Large community surveys, such as the Epidemiological Catchment Area study (ECA) [63], the National Comorbidity Survey (NCS) [39–41], and the National Epidemiologic Survey on Alcoholism and Related Conditions (NESARC) [24, 25, 30], consistently

show that the presence of a depressive disorder significantly increases the risk of alcohol or drug dependence (or vice versa) and a 2014 meta-analysis found that depression increases the risk by a factor of 2.4 for alcohol use disorder and 3.8 for illicit drug use and major depression [44]. Treatment-seeking samples tend to display even greater comorbidity due to the relatively greater severity of illness of treatment seekers. Across numerous studies of such samples, the prevalence of major depression has ranged from 15% to 50%, making it one of the most common co-occurring psychiatric disorder encountered among drug- or alcohol-dependent patients in treatment [29].

91.2.2.4 Prognostic Effects of Depressive Disorders on Substance Use Disorders

Many (although not all; [19, 46]) longitudinal studies have found that the presence of depression in patients with substance use disorders is associated with worse treatment outcome and prognosis. These findings suggest the importance of identifying and treating depression among substance-dependent patients, since the implication is that treatment of the depression has the potential to improve prognosis. Importantly, the findings of the adverse prognosis of depression are most consistent among studies where a depressive disorder (mainly major depression) is diagnosed by clinical history and structured diagnostic assessment. Findings on the association between depression and prognosis of substance use are less consistent when depression is measured only with cross-sectional scales [29]. For example, one study that followed alcohol-dependent patients for a year after an index hospitalization found that a diagnosis of major depression was associated with poor drinking outcome over the coming year, while the Hamilton Depression Rating Scale score at baseline was not [26].

91.2.3 Bipolar Disorders

Bipolar disorders are rarer in the general population but are more strongly associated with co-occurring substance use disorders. Large community surveys yield estimates of the lifetime prevalence of bipolar I disorder ranging from 1% to 3%, another 1% for bipolar II disorder, and 2% or more having subthreshold disorders in the bipolar spectrum [24, 50]. Although bipolar disorders are characterized by the presence of manic or hypomanic episodes during the lifetime, these episodes alternate with episodes of major depression or chronic depression, and the depressed periods typically predominate, particularly later in the course of the illness. Thus, bipolar disorder patients are most likely to present clinically as depressed. When evaluating a depressed, substance-using patient, it is therefore very important to search the history for evidence of past manic or hypomanic episodes, because the treatment of bipolar disorders differs significantly from the treatment of depressive disorders. The cornerstone of the treatment of bipolar disorder is mood stabilizer medications – lithium, anticonvulsants, or neuroleptics. Treating bipolar depression with antidepressant medications alone can be ineffective and may cause worsening of mood instability.

91.2.3.1 Bipolar I Disorder

Bipolar I disorder is characterized by the presence of one or more manic episodes over the course of one's lifetime. Manic episodes are characterized by a week or more of persistently elevated, expansive, or irritable mood, accompanied by at least three associated symptoms, including grandiose thinking, decreased need for sleep, increased talkativeness, racing thoughts, distractibility, increased activity level, and risky behavior that the person would not usually engage in. The syndrome is severe and causes marked impairment in functioning. Mania may become psychotic with paranoid or grandiose delusions (e.g., a patient becomes convinced that he/she is a messiah or on a special mission from God). Typically, the course of bipolar I includes episodes of major depression, may also include hypomanic episodes, and typically runs a course that is predominated by depressive symptoms.

91.2.3.2 Bipolar II Disorder

Bipolar II disorder is characterized by one or more hypomanic (as opposed to manic) episodes,

along with one or more episodes of major depression over the lifetime. A hypomanic episode resembles a manic episode, except that hypomania may be shorter, and is less severe. There must be a change in functioning to meet criteria for hypomania, but hypomania does not cause marked impairment or psychosis. Again, bipolar II frequently runs a predominantly depressive course.

91.2.3.3 Co-occurrence of Bipolar and Substance Use Disorders and Prognostic Effects

Large-scale community surveys indicate that the presence of a bipolar disorder increases the odds of having an alcohol use disorder by a factor of five or more and a drug use disorder by a factor of eight or more [6, 24, 30, 39, 40, 63]. In outpatients seeking treatment for substance use disorders, bipolar disorder is less commonly encountered than depressive disorders because bipolar is less frequent in the general population. However, patients with co-occurring bipolar and substance use disorders are particularly likely to be encountered in inpatient settings dealing with more severely ill dually diagnosed patients.

The co-occurrence of bipolar and substance use disorders is associated with worse outcome for both disorders. Patients with bipolar disorders can be very difficult to manage until the disorder is recognized and successfully treated with mood stabilizers. Conversely, finding the right mood stabilizer regimen for a given patient can be dramatically effective. This, again, suggests the importance, when evaluating substance-dependent patients, of taking a careful history for past episodes of mania or hypomania.

91.2.4 Co-occurring Depression and Substance Use as a Signal for Other Disorders

An analysis of the NESARC data on co-occurrence of mood and substance use disorders yielded an interesting finding [32]. When the association between major depression and substance use disorders is analyzed in such a way as to control for the presence of other disorders (bipolar disorder, anxiety disorders, etc.), the odds ratio of association between depression and substance use disorders is substantially reduced. This suggests that the apparent association between depression and substance use disorders may be explained, at least in part by the presence of the other co-occurring disorders, including anxiety disorders, since anxiety is a commonly occurring symptom among those with depression. In contrast, the association between bipolar disorder and substance use disorders remained significant after controlling for the other disorders. Substance use disorders have high rates of co-occurrence with anxiety disorders, such as panic disorder, social anxiety disorder, and post-traumatic stress disorder (PTSD); attention deficit hyperactivity disorder (ADHD); and personality disorders, including antisocial personality and borderline personality. Each of these disorders, in turn, has high co-occurrence with depressive disorders or symptoms or has symptoms that resemble depression. Thus, in substance-dependent patients, depressive symptoms may be a signal that other disorders are also present. It is therefore important to take a careful history looking not only for bipolar disorder but also for anxiety disorders, ADHD, or personality disorders. These disorders have distinct behavioral and pharmacological treatment indications and instituting appropriate treatment will be important to securing the best clinical outcome.

91.3 Diagnosis of Co-occurring Mood Disorders with Substance Use Disorders

In approaching the differential diagnosis of a patient with a substance use disorder and mood symptoms, it is important to recognize the multiple potential relationships between mood symptoms and a substance use disorder. There may be an independent mood disorder (e.g., major depressive disorder or bipolar disorder), or the depressive symptoms may be a manifestation of another co-occurring disorder such as PTSD or ADHD. Mood and substance use disorders may both be caused by common genetic or environmental risk factors. Stress is the most obvious

example of this, as stress is a causal risk factor for both mood disorders and substance use disorders.

Substance use may also cause mood symptoms, either as part of substance intoxication or withdrawal or from the toxic effects of chronic exposure to substances. Individuals with substance use disorders also often experience negative consequences and losses (e.g., medical problems, loss of employment or family), which may trigger depressive symptoms.

Substance-related or substance-induced mood symptoms will generally resolve if the patient is able to achieve abstinence. Hence, it is generally appropriate to initiate treatment for a substance use disorder, while sorting out the co-occurring mood disorder. If the patient's substance use is substantially reduced or resolved, the mood symptoms may resolve with it. A number of studies across alcohol- and drug-dependent samples have shown that initiation of treatment for substance use disorders and achievement of abstinence are associated with marked improvement in mood symptoms [7, 8, 45, 72, 75, 79].

It is also important to bear in mind that resolution of a depressive syndrome with treatment of the substance use disorder alone is not pathognomonic of a substance-induced depression. Depressive disorders, particularly in the mild to moderate range of severity, respond well to psychotherapy, such as cognitive behavioral therapy (CBT) or interpersonal therapy (IPT). Treatment for substance use disorders generally includes nonspecific psychotherapeutic elements, such as development of a supportive clinician-patient relationship and treatment alliance, which are likely to be helpful with treating depression. Further, many treatments for substance use disorders include components on coping with stress and with dysphoric moods that overlap with cognitive behavioral techniques for treating mood and anxiety disorders. Furthermore, reductions in substance abuse and related problems in response to treatment are likely to reduce stress and improve self-efficacy, and likely to help depression. In summary, good treatment for substance use disorders may also be effective for treatment of an independent depressive disorder.

91.3.1 DSM-IV/DSM-5 Approach to Co-occurring Mood and Substance Use Disorders

Before the advent of DSM-IV, there was no clear consensus on how to diagnose co-occurring mood disorders in the setting of substance use disorders. There was recognition that some co-occurring mood disorders were independent of substance use while others were caused by substance use. However, determining the optimal way to handle the large proportion of cases, (in which the temporal relationship between the disorders was unclear or when the patient does not quickly achieve abstinence) had not been addressed. DSM-IV advanced the field by distinguishing between independent mood disorders, substance-induced mood disorders, and mood symptoms that are usual effects of substances and for providing some criteria to make the distinctions. DSM-5 has retained this system. Substance-induced mood disorder provides a category in which to place the unclear cases, in which a mood disorder syndrome exceeds the symptoms that would be expected from intoxication and withdrawal, but the syndrome has not occurred in the absence of regular substance use. It has generated meaningful research as to its prognosis and course, as reviewed below.

91.3.1.1 Independent Mood Disorder

An independent mood disorder is diagnosed if the patient meets full criteria for the mood disorder (e.g., major depression, persistent depressive disorder, bipolar I) and the symptoms can be established by history to be temporally independent of substance abuse (prior onset or emergence or persistence during periods of abstinence). DSM-IV also suggested that an independent disorder could be diagnosed if its symptoms were substantially in excess of effects expected to be caused by the substance(s) the patient was taking. DSM-5 deals with this by specifying that a substance-induced disorder is only diagnosed if the mood syndrome and symptoms are consistent with symptoms known to be caused by the substance(s). The clinical implications are similar. In the criteria sets for substance-induced mood disorders, DSM-5

suggests that a mood syndrome co-occurring with substance use may be considered an independent disorder (and thus distinguished from substance-induced disorder) if the mood syndrome had its onset before the onset of substance abuse, or persists for about 1 month or more after abstinence is achieved, or there is a clear history of independent mood disorder episodes. An example might be a current major depression syndrome that had its onset concurrent with substance abuse in the current episode, but there is a clear history of one or more major depressive episodes during past abstinent periods.

91.3.1.2 Substance-Induced Mood Disorder

A substance-induced mood disorder is diagnosed if there is a "persistent disturbance in mood," which (a) develops at or soon after substance intoxication or withdrawal and (b) the substance(s) in question is "capable of producing the symptoms," and the syndrome is not better explained by a diagnosis of an independent mood disorder. There must be significant distress or impairment. Further, with respect to distinguishing a substance-induced mood disorder from usual effects of substances, the DSM-5 criteria state that a substance-induced mood disorder should be diagnosed, instead of a diagnosis of substance intoxication or withdrawal, only if "the mood symptoms predominate and are sufficiently severe to warrant clinical attention." DSM-IV worded this slightly differently, indicating that substance-induced mood disorder should be diagnosed when the mood and related symptoms (e.g., insomnia) exceed what would be the expected effects of intoxication or withdrawal and warrant clinical attention. Again, the clinical implications are similar.

91.3.1.3 Usual Effects of Substances

Mood symptoms, such as depressed mood, insomnia, and weight loss, can also be due to substance intoxication or withdrawal. DSM-IV and DSM-5 contain detailed criteria sets for the intoxication and withdrawal syndromes of alcohol, nicotine, and each of the other commonly abused drugs. Clinicians should be mindful of these lists of symptoms when evaluating patients with co-occurring mood symptoms and substance use. These symptoms have various time frames, but generally, symptoms of intoxication last only for the few hours during and after substance ingestion while blood levels are peaking and before they substantially decrease. Symptoms of withdrawal usually evolve and resolve over a period of a few days. Subacute withdrawal syndromes (also called protracted withdrawal), sometimes lasting a few weeks, have been described, particularly for alcohol and opioid dependence. Depressed mood and related symptoms (e.g., anxiety, fatigue, hypersomnia, insomnia, difficulty concentrating, irritability) occur variously as part of the withdrawal syndromes of most of the common addictive substances.

In summary, when conducting a diagnostic evaluation on a substance-using patient, familiarity with the intoxication and withdrawal effects of the substance(s) involved is important to distinguish mood symptoms that are best explained as components of intoxication or withdrawal from symptoms that are better explained as a substance-induced disorder.

91.3.1.4 Co-occurring Bipolar and Substance Use Disorder

Episodes of frank mania are generally too persistent (week or more) and too severe to be explained as substance-induced. For example, cocaine intoxication may produce a syndrome closely resembling mania (increased activity, hyperloquaciousness, grandiosity, lack of need for sleep, and psychosis with paranoid or grandiose delusions), but this typically only lasts for the duration of the drug binge, a day at most, after which there will be a crash with the typical depressive withdrawal symptoms (fatigue, hypersomnia, depressed mood, etc.). Hence, a history of one or more episodes of frank mania in a patient presenting with co-occurring mood symptoms and substance problems is clear evidence of co-occurring independent bipolar disorder that requires appropriate mood stabilizer medication. Methamphetamine psychosis can last considerably longer, however, and can cause a more complicated differential diagnostic process.

Hypomania can be more difficult to identify both in the present and historically. Hypomania is milder, and patients may not report it because they do not remember it or did not experience it as a departure from normal functioning. Moreover, periods of elevated mood, and increased energy and activity, may be difficult to distinguish from periods of normal mood – for example, when a chronically depressed patient becomes euthymic or when a patient has an exciting life event such as a new job or another major success. Periods of hypomania can be difficult to distinguish in a patient with heavy stimulant use, given the shorter duration of hypomania and the overlap in symptoms between hypomania and cocaine or stimulant intoxication (e.g., euphoria, increased sociability). As with depressive disorders, to confirm an independent bipolar II disorder, it becomes important to seek episodes in the history in which syndromes of hypomania occurred in the absence of stimulant-like substances.

91.3.2 Course and Prognosis of DSM-IV Independent and Substance-Induced Depression

Before DSM-IV, considerable evidence existed that independent depressive disorders could be identified with distinct prognostic and treatment implications. Brown and Schuckit demonstrated that a history of major depression before the onset of alcohol problems over the patient's lifetime (primary depression) was associated with depressive symptoms that persisted despite 3–4 weeks of abstinence in a sample of individuals hospitalized with alcohol use disorder [7, 8]. Rounsaville and colleagues, using the Schedule for Affective Disorder and Schizophrenia, a structured diagnostic instrument, found major depression to be associated with worse prognosis among drug-dependent patients [13, 67, 68]. We and others found that depression with evidence of temporal independence from substance use either by history [49, 53, 54] or through observed persistence of depression symptoms during abstinence [15, 47, 69] responded to antidepressant medication.

91.3.2.1 Structured Diagnostic Assessment

With the advent of DSM-IV, the Structured Clinical Interview for DSM-IV (SCID) incorporated a module for substance-induced mood disorder and logic for diagnosing a mood syndrome as independent or substance-induced. However, the determinations were left largely up to clinical judgment with little guidance in the interview as to how to make the distinction. The Psychiatric Research Interview for Substance and Mental Disorders (PRISM) [31] was developed to operationalize the diagnosis of co-occurring substance and other mental disorders within the DSM-IV framework. For a given syndrome, such as major depression, the interviewer is asked, for each criterion symptom, to judge whether that symptom appears attributable to usual effects of substances. The substances that might cause that symptom, either as intoxication or as withdrawal effects, are listed. For example, when a depressed patient reports insomnia, the interviewer is asked to determine whether substances that might cause insomnia (stimulant intoxication or alcohol, sedative, or opioid withdrawal) could explain the insomnia. The insomnia is only scored as positive to contribute to a diagnosis of a depressive disorder if it can be determined either not related to or exceeding the expected effects of the substance use. If sufficient criteria are endorsed to allow diagnosis of a depressive syndrome, then the interviewer is asked to determine whether the depressive syndrome is temporally independent of current substance use in terms of its onset and persistence during abstinence. If the history indicates that the depressive episode started before the onset of substance use or persists during a substantial abstinent period (e.g., a month or more), then it is diagnosed as independent. Otherwise, it is diagnosed as substance-induced.

Thus, the PRISM provides an operationalized definition of substance-induced depression that is quite stringent. It requires criteria for a full depressive syndrome (e.g., for major depression) to be met, and it requires that the symptoms con-

tributing to that syndrome not be better explained as toxic or withdrawal effects.

91.3.2.2 Prognostic Effects

Subsequent research with the PRISM established good to excellent reliability of diagnoses of independent and substance-induced major depression [31]. Further, there were clear prognostic effects. In a longitudinal study, substance-dependent patients entering an inpatient treatment facility were diagnosed with the PRISM while hospitalized, then followed for 1 year after discharge. Substance-induced major depression was found to predict failure to achieve abstinence after discharge from hospital, while independent major depression was found to predict relapse to substance use after periods of abstinence [28, 71]. Both independent and substance-induced depression were associated with suicidal ideation [1]. Further, over half of cases diagnosed as substance-induced depression at baseline converted into an independent depression over the year's follow-up, based on the major depression persisting during a period of at least a month of abstinence [55]. Predictors of conversion to independent depression included a history of an independent major depression and either PTSD or borderline personality disorder [55], again suggesting the importance of identifying other disorders that commonly co-occur with both mood and substance use disorders.

Studies with other samples and diagnostic methods have similarly suggested the validity and prognostic significance of independent and substance-induced depressive disorders as conceptualized by DSM-IV/DSM-5 [64, 65, 73] and the finding that a substantial proportion of substance-induced depression will convert to an independent depressive disorder over time [62].

91.3.2.3 A Note About Terminology

The term "substance-induced depression" carries a causal implication, namely, that the substances cause the observed depression syndrome. This can cause clinicians to underestimate the potential clinical significance of a substance-induced depression, both because intoxication and withdrawal effects are also induced by substances and because, as reviewed above, some depressions diagnosed as "substance-induced" will turn out to be independent depressions if followed into a period of abstinence. Substance-induced is to some extent a holding category for depressions for which the status as independent is uncertain at the time of diagnosis. It might be useful for clinicians to think of this as "substance-induced until proven otherwise," to emphasize that continued clinical attention is warranted and that the depression may turn out to be independent or to warrant specific treatment.

In summary, these studies suggest that substance-induced depression is a valid and useful category. It represents a diagnostic entity that lies between usual toxic effects of substances and an independent mood disorder. As the DSM-IV and DSM-5 criteria suggest, substance-induced depression "warrants clinical attention" because it carries adverse prognostic effects (suicidal ideation, lower likelihood of achieving abstinence) and is likely to convert to an independent depression over time. Further, as the DSM-5 criteria suggest, a history of independent depression may be considered sufficient evidence to diagnose a current depression as independent, rather than substance-induced. Other co-occurring disorders such as PTSD should also be suspected.

91.3.3 Summary and Recommendations for Diagnostic Assessment

91.3.3.1 Screening Instruments

Instruments that assess cross-sectional mood symptoms (e.g., Beck Depression Inventory, Hamilton Depression Rating Scale, Brief Symptom Inventory, or Quick Inventory of Depressive Symptomatology – Self-Report (QIDS-SR)) are useful for screening. However, by themselves they do not indicate the presence of any specific mood disorder and have unclear prognostic or treatment implications.

91.3.3.2 Clinical History and DSM-IV/DSM-5 Criteria

A substance-dependent patient with mood symptoms should be evaluated by taking a

careful lifetime clinical history. The history should seek to establish the onset of substance use disorders over the lifetime and substantial periods of abstinence lasting a month or more. The history should then establish the onset and course of mood syndromes (major depressive episodes, persistent depressive disorder, mania, hypomania), in the context of the lifetime course of substance use and apply the DSM-5 criteria for independent or substance-induced disorders. Among other things, this means establishing that symptoms of a mood disorder are not better explained as usual effects of substances or exceed what would be expected from the usual effects of substances. A mood disorder that cannot be established to be temporally independent of substance abuse, but exceeds the expected effects of substances, is diagnosed as substance-induced. For substance-induced syndromes, we also recommend noting the full syndrome that is in evidence, for example, "substance-induced major depression" if the full criteria for major depression are met (i.e., five or more criteria are met), as some of the stronger prognostic data pertain to substance-induced depression defined in this way [1, 28, 55, 71].

91.3.3.3 Search the History for Mania or Hypomania

The presence of one or more episodes of mania and hypomania indicates a bipolar disorder, which carries prognostic and treatment implications distinct from depression. Mania and hypomania may be difficult to elicit in the history. It is often helpful to interview family members, who may recall such episodes when the patient does not.

91.3.3.4 Look for Other Co-occurring Disorders

We also recommend a thorough review of the history for other disorders that commonly co-occur with mood disorders, including PTSD, social anxiety disorder, and other anxiety disorders; ADHD; and borderline personality. The presence of mood symptoms may signal the presence of one of these disorders. Such disorders have symptom patterns that are distinct from typical substance effects – substance use does not cause phobias, social anxiety, or re-experiencing symptoms of PTSD. Some have clear childhood onset (e.g., ADHD, social anxiety disorder), well before the onset of substance problems. Moreover, they have distinct treatment indications for both behavioral therapy and medications.

91.4 Treatment of Co-occurring Mood Disorders

91.4.1 Depressive Disorders

91.4.1.1 Antidepressant Medications

A number of placebo-controlled trials have examined the effect of antidepressant medication on mood and substance use outcome among substance-dependent patients with diagnosed mood disorders. Two meta-analyses [52, 78], published 15 years ago, reached similar conclusions, namely, that antidepressant medications are useful in improving both mood outcome and substance use outcome; these findings are more clear among alcohol-dependent patients. However, several national medical guidelines suggest medications should be avoided until an individual is abstinent for an extended period and continues to experience depression [5, 84]. This recommendation is based on the evidence that many individuals' depression will spontaneously remit with abstinence. Some recent studies have also implied antidepressants might worsen alcohol use disorder, particularly among those with the 'early onset' subtype of alcohol use disorder characterized by onset before age 25 and externalizing psychopathology [14, 42, 60]. Other evidence shows that studies have been mixed, with some negative trials [16, 27, 43, 61]. These include a large trial among alcohol-dependent outpatients that showed a high placebo response rate and no medication effect on mood or substance use outcome, despite patients being diagnosed with independent major depression using the PRISM. Other more recent trials have also been positive, at least in showing a beneficial effect of antidepressant medication on mood outcome [36, 48, 66].

91.4.1.2 Placebo Response and Other Factors Associated with Response to Antidepressants

A striking finding from the antidepressant trials is the wide variation in placebo response among studies, which varies from 20% to more than 70%, and the strong relationship between placebo response and study outcome. Studies with low placebo response tended to show beneficial effects of antidepressant medication on mood and substance use outcome, while studies with high placebo response showed no benefits of medication, a pattern observed in the original meta-analysis [52] and evident in the more recent studies [16, 27, 36, 43, 48, 61, 66]. Several other study features were also found to be related to low placebo response and to benefit of medication, including (a) diagnosis of depression after abstinence has been established, particularly enforced abstinence on an inpatient unit; (b) diagnosis of a depressive disorder, as opposed to merely depressive symptoms; (c) noradrenergic or mixed-mechanism antidepressants (serotonin reuptake inhibitors have shown little evidence of efficacy); and (d) concurrent manual-guided psychosocial intervention (psychosocial interventions were associated with high placebo response and absence of benefit of medication). These are described further in Table 91.1 along with their possible mechanisms and implications for clinical practice.

The phenomenon of high placebo response is not surprising, given the evidence from the wider literature on treatment of depression, which shows cognitive behavioral and other psychosocial interventions to be effective, and where high placebo response is often observed, particularly among patients with only mild to moderate depressive symptoms. Generally, the level of severity of depression in clinical trials needs to be high (severe) before there is consistent evidence

Table 91.1 Factors associated with low placebo response and beneficial effect of antidepressant medication in placebo-controlled trials among patients with depression and substance use disorders

Factor associated with low placebo response and medication efficacy	Potential mechanism	Implications for clinical management
Abstinence established before diagnosing depression	Withdrawal effects and substance-induced depression resolve with abstinence, leaving independent depressions more likely to benefit from medication	Initiate treatment with hospitalization for severely ill patients or evidence-based psychosocial treatment (e.g., cognitive behavioral relapse prevention). Some depression will resolve. Depression that persists should be considered for antidepressant medication
Diagnosis of a depressive disorder, rather than merely depressive symptoms	Depressive symptoms are more likely to represent withdrawal effects or be substance-induced	Base diagnosis of depression on careful clinical history and application of DSM-IV/DSM-5 criteria for independent or substance-induced depression
Noradrenergic or mixed-mechanism antidepressants	Less evidence of efficacy for serotonin reuptake inhibitors (SRI) among substance-dependent patients may relate to the study samples (high placebo response) rather than lack of efficacy. However, several trials suggest SRI makes drinking worse among early onset alcoholics	SRIs may still be considered the first-line treatment based on their good safety and tolerability, but consider switching to a noradrenergic or mixed-mechanism medication (e.g., venlafaxine, duloxetine, mirtazapine, nefazodone) if non-responsive to SRI
Concurrent manual-guided behavioral intervention	Behavioral interventions for substance use disorders (e.g., cognitive behavioral relapse prevention) typically contain elements likely to help with depression (e.g., support, coping skills)	Initiate psychosocial treatment for the substance use disorder as a first step

that antidepressant medication is superior to placebo [22]. For the treatment of substance-dependent patients with depression, then, a reasonable first step is to initiate treatment for the substance use disorder. For more severely depressed or substance-dependent patients, hospitalization may be needed to induce abstinence. Or, on an outpatient basis, evidence-based behavioral treatment or medication for the addiction can be offered. If the depression fails to respond once addiction treatment is initiated, then specific antidepressant treatment should be considered.

91.4.1.3 Depression in Individuals on Medication for Opioid Use Disorder

Individuals with Opioid use disorder (OUD) and comorbid depression represent a unique population as all individuals with OUD should be started on an approved maintenance medication for opioid use disorder (methadone, buprenorphine, or injection naltrexone), which are effective treatments for reducing or eliminating opioid use and protect against the risk of overdose and death. Depressive symptoms have been shown to improve after initiating of each of these medications. Substantially improved depression after starting MOUD would preclude the need or benefit of further antidepressant medication. A recent meta-analysis [35] found evidence to support the effectiveness of tricyclic antidepressants, but not SRIs. The meta-analysis also supports the effectiveness of cognitive behavioral therapies in patients maintained on methadone. The findings suggest initiation of MOUD as a first step for patients with OUD and depressive symptoms, and reserving antidepressant treatment for patients whose depression does not improve after stabilization on MOUD.

91.4.1.4 Behavioral Treatments

As noted above, manual-guided psychosocial treatments for substance use disorders are associated with high placebo response rates in the antidepressant medication trials, suggesting these interventions have some efficacy at treating depression in this population. Some controlled trials have examined cognitive behavioral treatments for depression among substance-dependent patients, with some evidence of efficacy [9–12, 18, 37, 56]. Psychosocial and behavioral treatments have solid evidence of efficacy for treatment of mood and anxiety disorders, and their use avoids risks of drug interactions that may be of concern when prescribing antidepressant medications to substance-dependent patients. Integrated treatments that target both the mood and substance use disorders have been found to be especially helpful for both mood and substance use outcomes [4, 51]. Thus, such behavioral interventions may be considered as a first step, before medication, particularly when the severity of depression is in the mild to moderate range.

It should be noted that several automated interventions have been developed to try to standardize and increase access to evidence-based psychosocial interventions for individuals with comorbid substance use disorders and mood disorders. These programs usually include elements of CBT skills training along with motivational interviewing delivered either online or via a smartphone application. Examples of such programs with good research evidence are Breaking Free [20] and SHADE [38].

91.4.1.5 Treatment of the Substance Use Disorder

Again, it bears emphasizing that when a patient presents with combined substance use and mood disorders, treatment should begin by identifying the substance as a problem and initiating treatment for the substance use disorder. This could range from brief motivational intervention to a more formal treatment regimen. Successful treatment of the substance use disorder, with resultant reduction in substance use or abstinence, eliminates the toxic effects the substance may likely be having on the nervous system and is likely to improve or even eliminate symptoms of depression [7, 8, 45, 72, 75, 79]. That said, when a depressive disorder persists after initiation of treatment for the addiction, specific antidepressant treatment, either behavioral, medication, or a combination of the two, should be initiated.

91.4.1.6 Combined Medications for Depression and Substance Use

There have been a few studies of medications for treatment of addictions, such as disulfiram and naltrexone [57, 58], buprenorphine, or methadone [54, 75], among patients with substance and mood or anxiety disorders or symptoms. These studies suggest such medications are at least well tolerated and potentially effective at improving mood symptoms, probably because they are effective in reducing or eliminating substance use.

One innovative study examined the combination of sertraline and naltrexone for alcohol-dependent patients with depression, finding the combination superior to either medication alone or placebo [59]. Medications for treating substance use disorders are generally underutilized and should always be considered as part of treatment planning generally, as well as specific treatment planning for patients with combined mood and substance use disorders.

91.4.2 Bipolar Disorders

Thorough reviews of medication treatments of bipolar disorder can be found in published reviews elsewhere [76, 77], and treatment of bipolar disorders in the setting of substance use disorders is covered in detail in a separate chapter of this text. Briefly, lithium, anticonvulsants (e.g., valproate, carbamazepine, lamotrigine), and neuroleptics (particularly second-generation agents such as quetiapine, risperidone, and aripiprazole) are the mainstays of treatment for bipolar disorder. Among these, lithium [23] and valproate [70] have been tested in controlled trials and found effective for patients with co-occurring bipolar and substance use disorders. Despite the typical predominance of depressive symptoms and syndromes among bipolar patients, antidepressant medications are often ineffective or even counterproductive among bipolar patients. This again highlights the importance of making the differential diagnosis between bipolar and depressive disorders with the clinical history.

Behavioral treatments can also be helpful as adjuncts to medication treatment for bipolar disorder by building treatment alliance, medication adherence, and coping skills [17, 74]. Weiss and colleagues have developed a group behavioral treatment for patients with combined bipolar and substance use disorders, integrated group therapy (IGT), which has shown evidence of efficacy in a series of controlled trials [80–83]. Interestingly, among its key features, IGT encourages patients to think of their combined mood and substance problems as a single disorder ("bipolar substance abuse"). This stands in contrast to the DSM approach, reviewed above, which involves establishing separate mood and substance use disorder diagnoses. It suggests that a co-occurring mood and substance use disorder may be more than the sum of the separate diagnoses and best treated in an integrated fashion.

91.5 Conclusion

As we hope this chapter has illustrated, considerable evidence has accumulated that mood disorders can be distinguished from substance-related syndromes and effectively treated. This can be accomplished through a careful clinical history and longitudinal observation of the response of mood symptoms and substance use as treatment is implemented to make the differential diagnosis between independent versus substance-induced mood disorders versus intoxication or withdrawal effects of substances, based on DSM-IV/DSM-5 criteria. In all cases, it makes sense to initiate treatment of the substance use disorder as a first step. Substance-induced depression, and even cases that meet criteria for an independent depressive disorder, may respond to behavioral treatment for the substance use disorder. However, for cases that do not respond, specific antidepressant treatment should be considered – either medication or behavioral treatment or both. It has been shown that many cases of substance-induced depression, particularly if a full major depressive syndrome is present, will be observed to persist during abstinence over

follow-up, thus converting to independent depression. For clear-cut or severe cases of major depression, initiation of antidepressant treatment may be considered concurrent with substance abuse treatment from the outset. A careful search of the history should be conducted for episodes of mania or hypomania, indicating the presence of bipolar disorder. Bipolar disorder should generally be treated with mood-stabilizing medications concurrent with the initiation of treatment for the substance use disorder.

92 Comorbid Anxiety and Alcohol or Substance Use Disorders: An Overview

Francesco Bartoli, Daniele Carretta, and Giuseppe Carrà

Contents

Abstract

The comorbidity between anxiety and alcohol or substance use disorders represents a common and serious clinical challenge, characterized by a high worldwide prevalence. The co-occurrence of these disorders complicates treatment, management and prognosis of both disorders, but it remains often unrecognized and untreated. Mental health professionals should accurately assess and evaluate this comorbidity, although related etiological links and temporal relationships are still unclear and, probably, heterogeneous and multifactorial. Individuals may misuse alcohol and substances to self-medicate their anxiety, avoidant and phobic symptoms, and, on the other hand, anxiety disorders may be induced by alcohol and/or substance misuse. Integrated treatment appears the most promising approach, but there is paucity of evidence on pharmacological and non-pharmacological treatments addressed to both anxiety and substance use disorders. This chapter provides a comprehensive overview of main epidemiological and clinical issues, etiological/temporal

Anxiety · Alcohol · Substances · Illicit drugs
Addiction · Dual diagnosis

92.1 Introduction

Anxiety is a physiological defensive response for approaching or avoiding threatening stimuli [36]. Excessive levels of anxiety may impair performance and lead to suboptimal behavioral responses and ultimately to mental disorders [36]. Clinical evidence demonstrate that people with anxiety disorders, such as social phobia, generalized anxiety, panic, agoraphobia without history of panic, and specific phobia disorders, often misuse alcohol, prescription (e.g., benzodiazepines) and/or illicit drugs (e.g., stimulants or cannabinoids), being more vulnerable to addictive behaviors than general population. At the same time, individuals primarily treated for an alcohol or drug use disorder are more likely to suffer from a comorbid anxiety disorder, as a direct effect of substance use on anxiety symptoms. Comorbid anxiety and alcohol or substance use disorders represent a serious clinical challenge, influencing both treatment and prognosis.

All clinicians and mental health professionals who care people with anxiety and substance use disorders should have a comprehensive knowledge of main relevant clinical and epidemiological issues such as the following:

- Prevalence and correlates of substance use disorders among subjects suffering from anxiety disorders
- Etiological hypotheses and temporal relationships underlying this comorbidity
- Methods to assess and classify comorbid anxiety and alcohol/substance use disorders
- Specific clinical features, course and prognosis of people with this comorbidity
- Main evidence on prevention and treatment strategies

In this chapter, we provide a comprehensive overview on these issues, summarizing data derived from research that may be useful to the routine clinical practice.

92.2 Epidemiology

Comorbid anxiety and alcohol or substance use disorders are highly prevalent both in general and clinical populations. Data from the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) on 43,093 adults shows that the 12-month prevalence of any DSM-IV substance use disorder among respondents with a 12-month DSM-IV independent anxiety disorder is 15.0% [20]. As regards specific drug use disorders involved, cannabis use was the most common (15.1%), followed by cocaine (5.4%), amphetamine (4.8%), hallucinogen (3.7%), opioid (3.2%), sedative (2.6%), tranquilizer (2.5%), and inhalant/solvent (0.6%) use disorders [16]. People suffering from any anxiety disorder had an odds ratio (OR) of 1.9 (95% CI: 1.7–2.1) for any substance use disorder and of 1.7 (95% CI: 1.5–2.0) for any alcohol use disorder. The likelihood to develop a dependence syndrome was high with ORs of 2.8 (95% CI: 2.4–3.2) and 2.6 (95% CI: 2.2–3.0) for substance and alcohol dependence, respectively [20]. Panic disorder with agoraphobia seems showing the strongest association with a co-occurring substance use disorder.

Other relevant data from North American samples, are provided by the Mental Health Supplement to the Ontario Health Survey [21], a Canadian study on 7195 individuals aged 15–64 years and interviewed using the World Mental Health Composite International Diagnostic Interview (CIDI). A lifetime alcohol abuse or dependence by diagnostic subgroup was found in 8.7% of people with any anxiety disor-

der (OR vs. healthy controls: 3.4; 95% CI: 1.6–7.1), and in 18.0% of people with comorbid anxiety and depressive disorders (OR vs. healthy controls: 7.6; 95% CI: 3.5–16.7).

Relevant epidemiological data are available also from European populations. Data from the French representative sample of the Mental Health in General Population (MHGP) survey [29] on 36,105 adults, showed a prevalence for alcohol abuse of 7.1%, 6.5%, 4.9%, and 3.6% among subjects suffering from agoraphobia, panic disorder, social phobia, generalized anxiety disorder, respectively. The results highlighted an OR of 1.7 (1.4–2.0) for alcohol abuse among people with any anxiety disorder. Similar results were found for drug addiction, with a prevalence of 6.5%, 4.4%, 3.7%, and 2.8% among individuals suffering from panic disorder, social phobia, agoraphobia, and panic disorder, respectively. Drug addiction was significantly associated with the diagnosis of any anxiety disorder, with an overall OR of 2.1 (95% CI: 1.8–2.5).

Baseline data from the Netherlands Study of Depression and Anxiety (NESDA), including 2329 subjects with lifetime DSM-IV anxiety (social phobia, generalized anxiety disorder, panic disorder, agoraphobia) or depressive disorders and 652 controls, showed a significant association between alcohol dependence and comorbid anxiety disorder (OR: 2.4; 95% CI: 1.5–3.8) or for an anxiety disorder associated to a depressive disorder (OR: 4.3; 95% CI: 3.0–6.2) [9].

Epidemiological data are available also from the National Survey of Mental Health and Well Being (NSMHWB), a cross-sectional survey conducted in 1997 and based on 10,641 Australian adults. This study showed that the respondents with an alcohol use disorder (abuse or dependence) were three times more likely to suffer from a 12-month anxiety disorder. On the other hand, people suffering from any anxiety disorder had a prevalence of 16.0% for any past-year alcohol use disorder [13]. More recently, updated data from the NSMHWB, involving 8841 Australians aged 16–85 years, confirmed high rates of comorbidity, especially considering generalized anxiety disorder and social phobia [41].

Finally, some relevant epidemiological information is available also from Latin America. For example, a cross-sectional household survey in a sample of 2302 Brazilian adults from Bahia, Brazil [2], highlighted a prevalence of comorbid anxiety disorders and alcoholism of 14.4%, with an OR of 2.7 (95% CI: 1.7–4.2).

Generally, the comorbidity between anxiety and alcohol or substance use disorders appears a worldwide phenomenon, with similar prevalence rates and high and significant risk of co-occurrence as compared with general population.

A systematic review of 22 unique epidemiological surveys (1990–2014) confirmed the concerning interplay between anxiety and substance use disorders [28]. Relevant meta-analysis showed an association between any anxiety disorders and alcohol abuse (OR: 1.6; 95% CI: 1.3–2.0), abuse/dependence (OR: 2.1; 95% CI: 2-0-2.2), and dependence (OR: 2.5; 95% CI: 2.2–2.9), with similar effect size considering 12-month or lifetime alcohol use disorders. Consistently, anxiety disorders were associated with illicit drug abuse (OR: 2.4; 95% CI: 2.0–2.8), abuse/dependence (OR: 2.1; 95% CI: 1.2–3.9) and dependence (OR: 4.2; 95% CI: 3.4–5.1). Also in this case, no significant differences were found considering 12-month or lifetime illicit drug use disorders [28].

92.3 Etiological Hypotheses and Temporal Relationships of Comorbid Anxiety and Substance Use Disorders

The underlying mechanisms influencing the association between anxiety and alcohol/substance use disorders are unclear because of relevant clinical heterogeneity as different drugs and alcohol may not share identical relationships with different anxiety disorders. This comorbidity is a complex and heterogeneous psychopathological entity and a number of explanatory models have been proposed. Three main etiological hypotheses are worth to be mentioned.

First, an anxiety disorder may be a direct predictor of addictive behaviors. This direction of

the association is supported by evidence suggesting that some individuals may use alcohol and/or illicit substances to self-medicate their anxiety or depressive symptoms (the "self-medication" hypothesis) [26]. For example, alcohol shares several pharmacological effects with sedatives, anxiolytic, hypnotics, or anticonvulsants agents. Further scientific support for the "self-medication" hypothesis comes from longitudinal studies. Data from the NESARC on 34,653 US adults showed that those who had used alcohol or other drugs for reducing their fear, anxiety, or avoidance, had a significant risk of incident alcohol or substance dependence, with adjusted ORs of 2.6 (95% CI: 1.0–6.7) and 5.0 (95% CI: 1.7–14.2), respectively [42]. However, further findings from NESARC [32] did not support the self-medication hypothesis, highlighting that both mood and anxiety disorders may influence the transition from substance use to abuse and/or dependence rather than from abstinence to use. The representative National Comorbidity Survey (NCS) showed that a self-medication intent was present in 21.9% of individuals with any anxiety disorder, with the highest prevalence (35.6%) among people with a generalized anxiety disorder [7]. Longitudinal data seem to support the occurrence of 'primary' mood or anxiety disorders and subsequent substance use disorders among those who self-report self-medication [46]. More generally, social phobia (social anxiety disorder) has been predominantly identified as a primary disorder preceding substance use, although the temporality of other anxiety and substance use disorders is less clear. Indeed, individuals with comorbid social or specific phobia and alcohol dependence are more likely to experience anxiety disorder as primary diagnosis. On the other hand, among individuals with comorbid panic disorder or generalized anxiety disorder and alcohol dependence, it is more likely that individuals had an alcohol dependence as primary diagnosis [38]. A study based on 2801 adult Norwegian twins recently confirmed that social phobia had the strongest association with alcohol use disorder, predicting it over and above the effect of other anxiety disorders, which were better explained by shared genetic risk factors [45].

The second etiological hypothesis posits that alcohol and other substances directly promote the development of anxiety syndromes, in terms of consequences of chronic alcohol/substance use and/or related withdrawal syndromes. For example, although alcohol is a fast-acting and effective anxiolytic agent, it can also increase the levels of anxiety, when the consumption is excessive and the subjects develops withdrawal symptoms, which determine a vicious cycle between anxiety and alcohol use. Another relevant example involves early cannabis exposure that may be related to the subsequent development of an anxiety disorder. A recent study [17] on a cohort of 1756 young Australians recruited in secondary schools showed that the continuity of cannabis use from adolescence to the age of 29 was associated to a risk 3–4 times higher of having a comorbid anxiety disorder. Data from the Netherlands Mental Health Survey and Incidence Study (NEMESIS), a prospective study on 3854 adults who had no lifetime anxiety disorders at baseline, highlighted a significant association between baseline cannabis use and 3-year incidence of any anxiety disorder (especially generalized anxiety and panic disorders), after adjusting for age, gender, education, urbanicity, employment, partner status [47]. Furthermore, the existence of anxiety disorders induced by specific classes of substances, such as alcohol, cannabis, cocaine/other stimulants, and opioids, is supported by different neurobiological findings. Recent advances on the complex relationships between stress, anxiety, and alcohol use disorders, show that synaptic communication in brain regions regulating stress and anxiety-related behaviors, such as amygdale and bed nucleus of the stria terminalis, are modulated by endogenous factors like dopamine and corticotrophin-releasing factor (CRF) as well as by acute and chronic use of alcohol [44]. The CRF, a stress-related neuropeptide, has been implicated also in the anxiogenic effects of cocaine withdrawal, as well as in some of long-term effects of cocaine [18]. Cannabis, mainly through the cannabinoid type 1 (CB1) receptors, can induce biphasic responses on anxiety- and fear-related behaviors. Generally, low doses of cannabis tend to induce anxiolytic-like effects,

whereas high doses often cause an increase of anxiety symptoms [35]. Finally, as regards heroine, morphine or other opioids, it should be highlighted that the opioid system seems to play a key role in the neural modulation of anxiety. The activation of opioid system leads to anxiolytic effects both in healthy subjects and in individuals suffering from anxiety disorders since the opioid neurotransmission may serve as an adaptive mechanism addressed to blunt acute negative and distressing affective responses [15]. At the same time, blockade or down-regulation of opioid systems and second messengers is associated with the occurrence of severe anxiety, similar to opiate withdrawal [15].

The third hypothesis is that there may be an independent mediator explaining the relationship between anxiety and alcohol/substance use disorders rather than a direct causal association. Generally, studies on the common-factor models for anxiety and substance use disorders are limited, and publications directly addressing this topic are sparse and focused on alcohol use disorders. Anxiety and alcohol or substance use disorders may share genetic and environmental factors, including family history for anxiety or substance use disorders or traumatic experiences. A representative study showed that, despite it was unlikely that a family history was the third factor explaining this comorbidity, childhood trauma, at least in women, might be partially responsible for the association between these disorders [31]. Mediators of the relationship between anxiety disorders and addictive behaviors may be also some personality traits characterized by a high level of anxiety sensitivity. Individuals with increased levels of sensitivity to anxiety, and who do not have a diagnosable anxiety disorder, may be more likely to develop both anxiety and alcohol or substance use disorders. Furthermore, it has been investigated whether some molecular mechanisms could represent the common factor between anxiety and alcohol/substance use disorders. For example, it has been hypothesized that a decreased function of cAMP response element-binding protein (CREB) in the central nucleus of the amygdale might regulate both anxiety and alcohol intake via the reduced expression of neuropeptide Y (NPY), and, therefore, might provide a common link between anxiety and alcohol use disorders [39].

92.4 Diagnosis and Classification

Anxiety disorders among people suffering from substance use disorders, as well as alcohol or drug addictive behaviors among people with an anxiety disorder, remain often unrecognized and, consequently, untreated. Despite the scientific background of this comorbidity being mainly based on DSM-IV-TR criteria [3], diagnostic issues should necessarily take into account the modifications approved by the recently released DSM-5 [4]. As regards anxiety disorders, these no longer include neither obsessive-compulsive disorder (now in the chapter "Obsessive-Compulsive and Related Disorders"), nor post-traumatic and acute stress disorders (included in the chapter "Trauma- and Stressor-Related Disorders"). At the same time, DSM-5 includes several changes in criteria of the new chapter "Substance-Related and Addictive Disorders", such as the exclusion of the abuse/dependence dichotomy, the introduction of craving as a diagnostic criterion, and the dimensional classification of alcohol and substance use disorders.

Actually, all subjects suffering from any anxiety disorders should be screened for alcohol or substance use disorders at the initial assessment. Early diagnosis and treatment can improve consistently course, prognosis and treatment outcomes of both disorders. However, often it is difficult to ascertain the diagnosis and to assess whether anxiety symptoms are alcohol or substance-induced or represent signs of an independent anxiety disorder. Because of the overlapping of symptoms, a detailed interview is often a step needed to fully differentiate symptoms, which should resolve with abstinence, from anxiety and alcohol/substances use disorders. Therefore, it is important to carefully assess not only symptoms but also distinct diagnoses and clinical syndromes using standardized structured diagnostic interviews, such as SCID (Structured Clinical Interview for DSM Disorders), CIDI

(Composite International Diagnostic Interview), or MINI (Mini-International Neuropsychiatric Interview).

Observing symptoms over a sustained period of abstinence may represent the best way to differentiate substance-induced from independent anxiety disorders. Anxiety may return to baseline levels after the period of withdrawal, so clinicians should always re-evaluate and re-assess clinical features after an appropriate period of abstinence. The minimum duration of abstinence to establish the presence of an independent or substance-induced anxiety disorder is heterogeneous and based on half-life of involved drugs. For example, some benzodiazepines or methadone may require several weeks of abstinence to exclude a secondary anxiety disorder, whereas alcohol or cocaine necessitate shorter periods of abstinence to make valid diagnoses [5].

To diagnose a primary, and not substance-induced, psychiatric disorder, clinicians should verify whether (a) the onset of symptoms occurred before the substance use disorder, (b) the symptoms persist after a period of abstinence according to the characteristics of withdrawal course of each substance, and (c) symptoms exceed those produced by the specific misused substance. On the other hand, clinicians should suspect a secondary anxiety disorder if (a) the anxiety syndrome develops only during periods of active alcohol or substance misuse, (b) the symptoms are well-matched with specific symptoms of intoxication or withdrawal of the involved substance, and (c) the age at onset is atypical for a primary anxiety disorder.

Significant amounts of alcohol and substance use screening tools are available and may be helpful in detecting potential disorders. For example, the ASSIST (Alcohol, Smoking and Substance Involvement Screening Test), developed for the World Health Organization (WHO), is used to detect substance use and related problems in primary and general medical care settings [24]. As regards alcohol use disorders, AUDIT (Alcohol Use Disorders Identification Test) [43] is probably the most widely used screening tool. Relatively recent data from the NESDA [8], including 1756 individuals suffering from a past-year depressive and/or anxiety disorder, showed that AUDIT accurately detected alcohol dependence in depressed and/or anxious men and women, as compared to the gold standard of a CIDI-based diagnosis. However, the overall accuracy in detecting alcohol abuse was limited, without appropriate and identifiable cut-off scores for sensitivity and specificity.

The Addiction Severity Index (ASI) is a multidimensional and semi-structured interview used to measure substance use severity, health-related outcomes, and social problems in individuals suffering from alcohol and other drug use disorders, both at admission to treatment and at follow-up [34]. The ASI can be used appropriately for screening of anxiety disorders, since the clusters of psychological composite scores are significantly related to a current psychiatric diagnosis, especially depressive and anxiety disorders. Therefore, this instrument may be useful for both the assessment of substance use severity and the screening of patients who need an additional evaluation or treatment for their comorbid mental disorder.

However, psychometric scales and diagnostic interviews need to be always integrated with all other information sources useful to assess and differentiate primary and secondary anxiety disorders. Laboratory data, age of onset of anxiety and substance disorders, collateral information, and a family history for anxiety and/or substance use disorder, should be accurately collected.

92.5 Clinical Features, Course, and Prognosis

According to a recently published systematic review [49], anxiety, illicit drug, and alcohol use disorders accounted, respectively, for 14.6%, 10.9%, and 9.6% of overall disability-adjusted life years (DALYs) caused by mental and substance use disorders.

The comorbidity between anxiety and substance use disorders makes difficult treatment and management of both disorders, with mutual negative effects. Individuals with an alcohol use

and co-occurring anxiety disorders are significantly more disabled and use health services more than individuals without this comorbidity [13]. Furthermore, subjects with comorbid generalized anxiety and substance use disorders are more likely than those with a generalized anxiety disorder only to have a lifetime history of any psychiatric disorder, pathological gambling, and an antisocial personality disorder [1]. A severe current alcohol dependence represents an important risk factor for unfavorable course of depressive and/or anxiety disorders, with persistent and unremitted symptoms [10]. The relationship is bidirectional, since the severity of depressive/anxiety symptoms are additional independent predictors of the recurrence of an alcohol dependence [11]. Data from Wave 1 (2001–2002) and Wave 2 (2004–2005) of NESARC showed that substance users with a comorbid generalized anxiety disorder had a worse health-related quality of life, higher rates of treatment seeking, and greater self-reported drug use, supporting the need to define specific treatment options for this clinical population [30]. Similar results were found from the NCS in a variety of clinical domains, such as rates of health care utilization, additional psychiatric diagnoses, physical health problems, and interpersonal stress. Among most of comorbid individuals, social anxiety disorder onset predated that of alcohol dependence, with the former increasing the vulnerability for misusing alcohol [12].

Anxiety disorders are well-known conditions associated to suicidal behaviors. Patients with anxiety disorders are 3.0–3.5 times more likely to complete suicide, 2.5–3.0 times to have suicidal ideations, 2.5 times to attempt suicide [25]. A comorbidity for an alcohol or a substance use disorder may consistently increase this risk. Findings from NESARC study [37] highlighted that individuals with both substance use and any anxiety disorder had an OR of 3.2 (95% CI: 2.4–4.3) for suicide attempts as compared with people without these psychiatric conditions. In particular, substance users with co-occurring anxiety disorders showed a significant higher risk (OR: 1.6; 95% CI: 1.3–2.0) of suicide attempts than those without this comorbidity.

All these findings support the need of further research on innovative intervention strategies to optimally treat co-occurring anxiety and substance use disorders and to prevent clinically severe consequences.

92.6 Treatment and Management

Although several pharmacological and psychological treatments such as cognitive-behavioral therapy have been studied for treatment of anxiety disorders, there is a paucity of evidence on effective treatments for the comorbidity with alcohol or substance use disorders [33]. Furthermore, relevant management is complicated because of different patterns of anxiety and substance use disorders may interact, making difficult to generalize results [48]. New research directions for treatment of comorbid anxiety and substance use disorders are actually needed and should be focused on the following: (a) identification of specific comorbid relationships between these disorders and their underlying processes (e.g., anxiety sensitivity), (b) mechanisms that may maintain the comorbidity, and (c) well-conducted evaluations of treatments that target these mechanisms [6].

Treatment of co-occurring anxiety and alcohol or substance use disorders can be oriented either by dealing primarily with one of the two disorders (generally the more compelling in terms of severity) or, alternatively, by addressing these together. Over the past several decades, empirical studies and clinical guidelines recommendations have undergone a broad shift in approaching this comorbidity, highlighting the importance to provide simultaneous and integrated treatment for both disorders, regardless of the status of the comorbid condition [48]. However, the availability of substances but also the social contexts in terms of individual and local issues might influence treatment outcomes in different countries, where integrated models might perform differently [14]. Consistently, research conducted in this field has yielded inconsistent results, with some studies demonstrating no clear advantage for the simultaneous treatment of anxiety

disorders and addictive behaviors. For example, a meta-analysis [23] suggests that, due to the potential serious consequences of unsuccessful treatment for alcohol use disorders, an integration with interventions addressing co-occurring anxiety disorders could be important, even if the amount of absolute benefit is moderate or even smaller. Inconclusive results were shown also by a systematic review [22] analyzing integrated psychosocial treatment for substance use and comorbid anxiety or depressive disorders, as, although promising, these did not give any significant additional benefit. Generally, a potentially effective strategy may be the early treatment of the disorder the patient is ready to address, while, simultaneously, a motivational approach may be used to improve readiness to change the comorbid problem.

At the same time, there is a lack of consistent evidence for effective pharmacological interventions for both anxiety and substance use disorders, whereas only sporadic interventions studies are available from the scientific literature, e.g., for alcohol use disorders. Selective serotonin reuptake inhibitors (SSRIs) seem effective in reducing and preventing anxiety symptoms, but there is a lack of clinical trials assessing their efficacy in comorbid patients. Among them, paroxetine may be effective for co-occurring social anxiety and alcohol dependence [19]. In addition, preliminary data are available for buspirone in comorbid anxiety and alcohol use disorder [19]. Relevant studies have shown mixed results on comorbid generalized anxiety and alcohol use disorders, but no significant improvement in anxiety or substance use outcomes among subjects with opioid dependence receiving methadone maintenance treatment [5, 33]. Despite benzodiazepines are effective in the treatment of anxiety disorders, their use in individuals with current or lifetime alcohol or substance use disorders may be complicated by their potential for abuse and dependence. More generally, although the use of medications for comorbid psychiatric disorder is encouraged, it is still unclear whether a full detoxification should be achieved before starting psychopharmacological treatment [48].

Finally, use of agents specifically addressed to substance use disorders in individuals suffering from comorbid anxiety disorders is underexplored [5]. In one randomized study conducted at three Veterans Administration outpatient clinics on 254 patients with mental disorders and alcohol dependence, the efficacy of disulfiram and naltrexone, or their combination, was investigated. Subjects treated with an active medication showed more consecutive weeks of abstinence and less symptoms of craving than those treated with placebo, but there were no significant differences in other measures of alcohol consumption. Furthermore, subjects treated with disulfiram experienced significantly fewer obsessive-compulsive and phobic symptoms over time, whereas no clear advantage of combining medications was observed [40].

A secondary analysis of a study evaluating efficacy of naltrexone in veterans suffering from alcohol dependence, showed that among subjects taking antidepressant medications for mood and anxiety symptoms, those randomized to naltrexone had significantly smaller percent drinking days than those receiving placebo. On the other hand, for patients not on antidepressant medication the difference between naltrexone and placebo was not significant [27].

92.7 Conclusions

The dual diagnosis between anxiety and co-occurring alcohol or substance use disorders is a common and serious clinical issue. This comorbidity tends to complicate treatment, management, and prognosis of both disorders. Clinicians face a number of heterogeneous combinations of anxiety and substance use disorders. The prevalence of alcohol or substance use disorders among subjects with anxiety disorders is high worldwide. Etiological links and temporal relationships of this comorbidity are still unclear and, probably, multi-factorial. Individuals may misuse alcohol and substances to self-medicate their anxiety and avoidant and phobic symptoms, although these symptoms often remain unrecognized and untreated. Clinicians should assess this

comorbidity using structured diagnostic interviews, and observing symptoms over a sustained period of abstinence to differentiate substance-induced from independent anxiety disorders. A comprehensive diagnostic evaluation should include also alcohol and substance use assessment. While some pharmacological and psychosocial treatments have shown effectiveness for separate treatment of anxiety and substance use disorders, there is a lack of evidence on treatments addressed to both disorders as dual diagnosis label means more complex needs rather than two distinct problems.

Contents

Abstract

Post-traumatic stress disorder (PTSD) and substance use disorders (SUDs) frequently co-occur. Among individuals seeking treatment for SUDs, it is estimated that 30–50% meet criteria for lifetime PTSD. Epidemiologic surveys demonstrate that individuals with PTSD are 4–5 times more likely to have a SUD at some point in their lives compared to individuals who do not have PTSD. Self-medication and susceptibility are two hypotheses that have been proposed to help explain the etiological relationship between PTSD and SUDs. It is also possible that common factors, such as genetic, neurobiological, or environmental factors, contribute to the high rate of PTSD-SUD co-occurrence. Integrated psychotherapeutic approaches for the treatment of patients with both disorders show promise. There are also a number of pharmacotherapeutic agents that have demonstrated preliminary efficacy in the treatment of co-occurring PTSD/SUD, but further investigation is needed. This chapter reviews these and other advances in the study of comorbid PTSD and SUDs, and suggests areas for future research and clinical activity.

93.1 Introduction

Post-traumatic stress disorder (PTSD) is a psychiatric disorder that occurs after exposure to an event (experienced or witnessed) involving actual or threatened death, serious injury, or threat to the physical integrity of oneself or others. The traumatic event must be followed by at least 1 month of symptoms, such as intrusive recollection, avoidance or emotional numbing, and hyperarousal, which interfere with the individual's ability to function. Substance use disorders (SUDs) commonly co-occur with PTSD. Moreover, comorbid PTSD/SUD is associated with a more complex and costly clinical course when compared with either disorder alone, so identification and treatment of both illnesses in individuals with comorbidity is essential to optimize clinical care.

Discussions of international issues in co-occurring PTSD and substance use are complicated by a number of factors. Definitions and experiences of trauma are culturally bound and in many countries can be connected with issues of politics and social justice. There is also debate about the cross-cultural application of the DSM-defined PTSD criteria. Modifications of the DSM criteria and textual modification have been suggested to improve cross-cultural applicability [47]. Similarly, patterns of substance use and definitions of SUDs also occur in cultural contexts that can tremendously alter the perspectives of acceptable use and willingness to honestly report use. In addition, we do not have accurate estimates of prevalence of either SUDs or PTSD alone or the comorbidity in many areas of the world. Thus, in the sections that follow, much of the data that is presented is based on studies conducted in a few countries. However, the diagnostic, phenomenologic, and neurobiologic underpinnings of the relationships and treatment options for PTSD and SUDs discussed are likely to apply broadly.

93.1.1 Epidemiology of PTSD/SUD Comorbidity

93.1.1.1 United States

Prevalence estimates for PTSD, SUD, and comorbid PTSD/SUD among US adults are primarily garnered from three sources: national epidemiological surveys and Veteran and treatment-seeking populations. Early estimates were provided by the National Comorbidity Survey (NCS; *N* 8098), conducted from 1990 to 1992, indicated a 7.8% lifetime prevalence for PTSD and a 26.6% lifetime prevalence for SUD among the general population (aged 15–54), [54]. Individuals with PTSD were between two and four times more likely to meet criteria for an SUD than those without PTSD. A decade later, the National Comorbidity Survey – Replication (NCS-R; *N* 5692) indicated a 6.8% lifetime prevalence of PTSD and 35.3% lifetime prevalence of any SUD [55]. The 2010 National Epidemiologic Survey on Alcohol and Related Conditions (NESARC; *N* 34,653) estimated that 6.4% of the population met lifetime criteria for PTSD, more than one in five (22.3%) of those with PTSD met criteria for drug abuse or dependence, and nearly half (46.4%) met criteria for any SUD [71]. The most recent NESARC interviews, conducted between 2012 and 2013, found a 29% lifetime prevalence of AUD [42]. Approximately 69% of respondents had experienced a PTSD qualifying event and 9% of this group met criteria for PTSD. Individuals with PTSD were 1.5 times more likely to meet criteria for SUD as compared to those without PTSD [40].

Veterans constitute a population of particular interest due to their increased risk for developing both PTSD and SUDs in comparison to the general population [79]. Post-deployment prevalence rates have been estimated at approximately 21% for SUDs and between 15% and 20% for PTSD among Veterans of Operation Enduring Freedom/Operation Iraqi Freedom (OEF/OIF) [92]. Severity of combat exposure has been directly linked to risk for development and chronicity of PTSD symptoms and misuse of substances [82]. Administrative data from the Department of Veterans Affairs indicate that among Veterans serving in the Vietnam era or later, almost half (41.4%) with an SUD were also diagnosed with PTSD [69]. Conversely, a recent study followed a large cohort of Veterans diagnosed with PTSD (*n* 272,509) over a three-year timeframe and found that nearly one in five (19.33%) were diagnosed with a comorbid SUD and presence of a comor-

bid SUD was positively associated with mortality at follow-up (hazards ratio 1.70; [17]).

Treatment-seeking individuals have rates of comorbid PTSD and SUD that are consistently higher than the general population. Patients seeking treatment for PTSD are up to 14 times more likely than patients without PTSD to have an SUD [38]. Conversely, among patients seeking treatment for SUDs, lifetime PTSD rates range from approximately 30% to over 60% [20]. Finally, a multimodal assessment of comorbidity among patients at a level I trauma surgery center indicated that 79% had one or more SUD and/or PTSD comorbidity; three in four (74%) met criteria for an SUD, whereas one in four patients endorsed symptoms consistent with PTSD [100]. Variations in prevalence estimates among treatment-seeking populations are most likely attributable to methodological differences, including differences in patient populations sampled and measurement techniques.

93.1.2 International Prevalence Estimates

As mentioned above, we do not have accurate prevalence estimates of the rates of either PTSD or SUDs in much of the world. While the World Health Organization (WHO) has sponsored a series of international studies of mental health disorders, the complexity of the trauma questions used, cultural differences in the definition of trauma, and reluctance to discuss traumatic events likely led to underestimates of PTSD prevalence [53]. In general, the estimates for lifetime PTSD prevalence range from a low of 0.3% in China to 6.1% in New Zealand [32]. The International Consortium to Predict PTSD (ICPP) [29, 93, 9, 23] compiled data from 13 longitudinal studies of acute trauma performed in six different countries found a wide range in baseline PTSD (3.1–61.6%; [75]). As might be expected, some evidence suggests that the risk of PTSD is higher among people from less developed countries who have been exposed to prolonged traumatic experiences associated with wars and political and ethnic violence. For example, 65% of Bosnian refugees resettled in the United States have PTSD [96] and 73% of Palestinian children exposed to war trauma experienced PTSD [91]. In a recent WHO survey, disability from common mental and physical disorders was assessed in nationally representative samples from 26 countries [22]. While physical disorders were considerably more common than mental disorders, there was more disability associated with mental disorders as compared to physical disorders at an individual level. Of all physical and mental disorders, PTSD was associated with the highest level of disability.

While little is known about the prevalence of PTSD in many countries, even less is known about the prevalence of co-occurring PTSD and SUDs. An epidemiologic survey conducted in Australia in 2007 found that the 12-month prevalence of PTSD was 6.4%, higher than the prevalence of any other anxiety disorder [66]. SUDs were much more common in individuals with mental illness as compared to those without mental illness, and nearly 40% of those with anxiety disorders reported daily drug misuse. Data for PTSD specifically was not presented. In a 2004 analysis of a survey of the general population in six European countries, individuals with PTSD were twice as likely to have alcohol abuse and three times as likely to have alcohol dependence [3]. This suggests that the common co-occurrence of PTSD and SUDs, which has been found in the United States, exists in other countries. However, in an investigation of the prevalence of psychiatric disorders in South Africa [88], the authors note that local factors such as poverty and lack of access to substances may change the occurrence of certain psychiatric disorders and comorbidities.

93.2 Etiologic Relationship Between PTSD and SUD

93.2.1 Self-medication Hypothesis

A number of theories have been posited to explain the etiology and functional associations between PTSD and co-occurring SUDs. The most prominent theory is the *self-medication hypothesis* [56]. According to the self-medication

theory, substance use is negatively reinforced when it alleviates PTSD symptoms, such as sleep impairment, intrusive memories, nightmares, hyperarousal, and feelings of estrangement. In support of this theory, Saladin et al. [80] compared individuals with PTSD only vs. PTSD/SUD and found that hyperarousal and avoidance symptoms were more severe among the comorbid PTSD/SUD group. Laboratory-based findings also provide support for the self-medication model. One study examined responsivity to trauma cues (i.e., presentation of personalized trauma narrative) and found that individuals with comorbid PTSD/SUD demonstrate increased craving for substances in response to the trauma cues [24]. Moreover, research has shown that trauma cue-elicited craving is significantly reduced following exposure therapy for PTSD [25]. Finally, increases in craving have been shown to be positively correlated with severity of PTSD symptoms [81].

Among patients with PTSD/SUDs, the drug of choice (e.g., central nervous system depressant or stimulant) may reflect an attempt to alleviate a particular cluster of symptoms. For example, Saladin et al. [80] found that PTSD/SUD individuals with more severe hyperarousal symptoms (Criterion D) were more likely to be dependent on alcohol than cocaine. Likewise, PTSD/SUD individuals with more severe avoidance (Criterion C) and flashback symptoms (Criterion B) were more likely to be dependent on cocaine. More recently, Tull et al. [95] observed a significant relationship among PTSD hyperarousal symptoms and dependence on heroin, as opposed to crack/cocaine and alcohol dependence. In addition to self-medication of PTSD symptoms, individuals with PTSD/SUDs may also use substances to self-medication withdrawal symptoms, which may mimic symptoms of PTSD. For example, withdrawal from alcohol or drugs may result in sleep disturbances, difficulty concentrating, irritability and anger, and feeling "on edge." Thus, withdrawal symptoms may contribute to a reinforcing cycle of self- medication among individuals with PTSD/SUD.

Research examining the temporal order of onset of development of PTSD and SUDs also provides some insight with regard to etiology. In the majority of cases, the development of PTSD precedes the development of the SUD [10, 51]. Furthermore, PTSD and SUD symptoms have been shown to covary over time. For example, Ouimette et al. [68] tracked weekly fluctuations in PTSD and SUD symptoms among 35 PTSD/SUD outpatients for the self-medication hypothesis and showed that increases in PTSD symptoms were associated with increases in SUD severity. More recently, Simpson et al. [85] used daily interactive voice response (IVR) to examine the relationship between PTSD symptoms and same-day as well as next-day alcohol craving among 29 outpatients entering SUD treatment (26/29 had PTSD). The findings showed that greater PTSD severity was associated with greater alcohol craving and greater hyperarousal symptoms were particularly associated with craving. Next-day craving was predicted by nightmares the previous night, emotional numbing, and hypervigilance. Finally, several studies investigating civilian and Veteran patients' perceptions of the interrelationship of PTSD and SUD symptoms demonstrate support for the self-medication hypothesis [10]).

The *high-risk hypothesis* [1] posits that the lifestyle of an individual with an SUD increases the likelihood of being exposed to a traumatic event and subsequently developing PTSD. For example, individuals with SUDs often spend time in dangerous environments and engage in high-risk behaviors associated with obtaining or using substances (e.g., prostitution, theft) that may put them at risk for experiencing a Criterion A event. The *susceptibility hypothesis* posits a biological vulnerability to developing PTSD among individuals with SUDs. Individuals who engage in chronic substance use often experience anxiety and arousal and exhibit poor coping skills (e.g., more avoidant or emotion-focused coping vs. problem-focused coping) [87]. Lastly, there is some evidence that other common factors, such as genetics, common neurophysiologic systems, described below, and prior exposure to traumatic events, may play a role in the etiology of comorbid PTSD/SUD [67, 89].

93.2.2 Neurobiology

A growing body of evidence from basic science and translational studies implicates common neurobiologic pathways and abnormalities involved in anxiety disorders and SUDs. One of the bridging neurobiologic constructs between anxiety disorders and SUDs involves the role of stress. Corticotrophin-releasing factor (CRF), one of the key hormones involved in the stress response, has been implicated in the pathophysiology of anxiety, affective, and addictive disorders. Stress stimuli that activate CRF circuits are also known to potentiate mesolimbic dopaminergic reward pathways in laboratory animals. Similarly, human laboratory studies have shown that emotional stress and negative affect states increase drug craving in drug- and alcohol-dependent individuals. Animal models indicate that early-life stress and chronic stress result in long-term changes in stress responses, which can alter the sensitivity of the dopamine system to stress and increase susceptibility to self-administration of substances of abuse. While it is difficult to systematically delineate the specific neural basis of comorbidity, these studies provide potential pathways to explore in attempts to understand the well-established relationship between early-life adversity, PTSD, and SUDs in adolescents and adults [19, 90].

93.3 Assessment

Symptom assessment is critical to the effective treatment of PTSD/SUD and should ideally encompass detection of trauma exposure and substance misuse, evaluation of diagnostic criteria for PTSD and SUD, and monitoring of symptom severity [94]. Historically, instruments assessing PTSD and SUD were predominantly developed for use with in English-speaking, westernized cultures. However, in 1990, recognizing the need for cross-cultural assessment of mental illness, the World Health Organization (WHO) developed a tool that addressed criteria for both the American Psychiatric Association's Diagnostic and Statistical Manual and the International Classification of Disease (ICD). The resulting Composite International Diagnostic Interview (CIDI; [77]) was a comprehensive, structured, modular interview designed to assess mental disorders – including but not limited to PTSD and SUD. As of 2011, versions of the CIDI have been translated into approximately 25 languages for use in at least 20 countries [99]. Recognition of the important roles that culture and language play in the conceptualization, experience, and expression of PTSD and SUD is increasing [48]. Consequently, increased efforts have been made to translate and adapt a range of instruments previously validated with English-speaking populations (e.g., [2]) as well as to develop culturally specific instruments, to screen, diagnose, and monitor symptoms of PTSD and SUD in a variety of international populations (e.g., [57]).

Regardless of cultural context, there are several general constructs relevant to the assessment of PTSD and SUD. These constructs include determination of the presence, order of onset, frequency, duration, and severity of symptoms, as well as the degree to which symptoms interfere with or impair daily functioning, employ- ment, and interpersonal relationships (for review, see [78]). Several reviews of PTSD assessment (e.g., [78, 98]), SUD assessment [35], and PTSD/SUD assessment (e.g., [51]) are available in the extant literature. When assessing comorbidity, special consideration should be given to the relationships between symptoms, including PTSD symptoms as potential motivators for substance misuse. Validated self-report, semi-structured, and fully structured interview instruments are available to assist with (1) screening for trauma exposure, (2) screening for PTSD/SUD symptoms, (3) determining diagnosis, and (4) monitoring symptom change over time. Table 93.1 presents a sampling of validated measures frequently used in the assessment of PTSD and SUD.

In addition to self-report and interview, biological testing is recommended in assessing SUD and may overcome some of the culture-bound limitations of self- report and clinician-administered assessments. Urine drug screening (UDS) is the

most common and preferred method for detecting illicit drug use given that it is cost effective and minimally invasive and provides a quantitative means for measuring the use of substance.

Additional biological assessment options exist for use as either adjunctive or alternative assessments of SUD: testing of bodily fluids, such as blood and saliva, breathalyzer analysis for recent alcohol use, hair analysis techniques, and a blood- based testing method known as percent carbohydrate-deficient transferrin [6]. These methods are less frequently used due to higher cost, increased invasiveness, false positives, and/or narrow detection windows [52].

93.3.1 Psychotherapeutic Treatment

Historically, psychosocial treatment approaches for individuals with PTSD and SUDs have adhered to the *sequential treatment model*, in which the SUD is treated first and trauma work is deferred until a period of sustained abstinence (e.g., 3–6 months) has been achieved. This generally entails two separate providers (i.e., one provider addresses SUD and another addresses PTSD) in two separate clinics with little cross-communication. Proponents of the sequential model state that (a) continued substance use will impede therapeutic efforts and/or (b) trauma-focused work may increase risk for relapse [72]. However, there is little empirical data to support these concerns. Given the high co-occurrence of PTSD and SUDs, the covarying interrelationship between PTSD symptoms and substance use severity, as well patients' preferences for treatment (e.g., less than 30% of patients prefer sequential treatments; [10]), recent advances in psychosocial treatments have focused on the development and testing of *integrated treatment models*. In contrast to sequential treatments, integrated treatments are provided by the same clinician and address both the SUD and PTSD concurrently. The integrated model posits that addressing the PTSD symptoms early in treatment will likely improve recovery from SUDs, particularly if substances are being used to self-medicate trauma-related symptoms [7, 45, 63].

Compelling support for the integrated model is provided by recent investigations examining the temporal course of symptom improvement among PTSD/SUD patients. Among 94 outpatients with alcohol dependence and PTSD, improvements in PTSD symptoms had an impact on improvements in alcohol-dependence symptoms, but decreases in drinking did not impact PTSD symptoms [10].

Hein et al. [45] replicated these findings using data from a larger sample (*N* 353) from a National Institute on Drug Abuse (NIDA) Clinical Trials Network (CTN) study. For every unit of PTSD improvement, the odds of being a heavy substance user at follow-up decreased more than fourfold [45]. A growing body of literature examining the tolerability and efficacy of addressing PTSD among SUD patients demonstrates that substance use typically decreases significantly and does not increase with the addition of trauma-focused interventions [11, 45, 63].

Prolonged exposure (PE; [37]) therapy has been deemed one of the most effective treatments available for PTSD [50], but there is limited research exploring its efficacy in substance-abusing populations. PE involves having the patient revisit the traumatic memories (i.e., imaginal exposures) and approach safe but anxiety-producing situations in real life that are avoided by the patient (e.g., in vivo exposures). A recent meta-analysis demonstrated large effect sizes for PE in comparison to control conditions [73]. Furthermore, a longitudinal study conducted among 65 patients 5–10 years after receiving PE demonstrated maintenance of effects with only 17.5% of patients meeting diag- nostic criteria for PTSD [76]. PE has demonstrated effectiveness in addressing PTSD among a variety of traumatic stress populations, including victims of rape, physical assault, refugees, motor vehicle accidents, combat, terrorism, childhood abuse, and mixed trauma types [37, 64, 76]. Despite that fact that PE is one of the most effective treatments for PTSD, the majority of integrated treatment interventions developed to date generally do not include PE components. Rather, treatment tends to focus on psychoeducation, exploring the relationship between PTSD symptoms and substance use, self-management of symptoms and negative emotions, and devel- opment of cognitive behavioral coping skills [61].

One of the most widely used and investigated integrated treatments to date is *Seeking Safety* (SS), a non-exposure-based 24-session manualized therapy that prioritizes establishing and maintaining safety [65]. Other key concepts include anticipating dangerous situations, setting boundaries, anger management, and affect regulation. In a study of 107 women comparing SS to relapse prevention [44], both treatments resulted in improved substance use and PTSD severity; however, no significant between group

differences in PTSD or SUD symptoms were observed. In a larger national multisite community study, SS was compared to a women's health education (WHE) group [46] in 353 women. Both SS and WHE resulted in significantly improved PTSD symptoms; however, neither group resulted in a significant reduction in abstinence rates over time. Of interest, modified versions of Seeking Safety have been used successfully to treat intergenerational trauma in Aboriginal peoples in Canada [60].

Back and colleagues developed an exposure-based, manualized cognitive behavioral therapy for PTSD/SUDs [8] called *COPE* (*Co*ncurrent Treatment of PTSD and Substance Use Disorders Using *P*rolonged *E*xposure), which combines evidence-based cognitive behavioral therapy for SUDs with the key components of prolonged exposure for PTSD [37], and includes both in vivo and imaginal exposure techniques. COPE was initially trialed as a 16-session, individual intervention and tested in an uncontrolled psychotherapy development study among patients (*N* 39) presenting with comorbid PTSD and cocaine dependence [18]. In this study, no signs of increased substance were observed with the inclusion of PE. Treatment completers demonstrated significant improvements in all PTSD symptom clusters and a significant reduction in cocaine use from baseline to end of treatment (Brady et al. 2001). Reductions in PTSD and SUD symptoms were maintained at six-month follow-up. Mills et al. [63] recently completed a randomized control trial of COPE plus treatment as usual (TAU) vs. TAU alone. Participants were 103 patients (62.1% female) with civilian PTSD and SUDs in Sydney, Australia. For this trial, COPE consisted of 13, individual sessions. From baseline to nine-month follow-up, significant reductions in PTSD symptom severity were found for both groups; however, the COPE group demonstrated a significantly greater reduction in PTSD symptom severity (mean difference − 16.09) and lower rates of PTSD diagnosis as compared to the control group (56.4% vs. 79.2%). No significant between-group differences in rates of abstinence, number of SUD dependence criteria met, or retention were found. The findings suggest that integrated PTSD/SUD treatments employing PE techniques for PTSD can be used safely without an increase in substance use, can lead to sustained improvements across various domains (e.g., depression), and produce greater improvements in PTSD than TAU. Currently, COPE is being evaluated as a 12-session intervention in a randomized controlled trial among Veterans, and the preliminary findings are positive [11]. Recently, prolonged exposure has been incorporated into existing residential SUD treatment with promising preliminary results supporting its safety, feasibility, and efficacy [14].

93.3.2 Pharmacological Treatment

A recent review pharmacotherapeutic treatment for co-occurring PTSD and alcohol use disorders (AUDs; [70]) found nine double-blind, placebo-controlled trials; three focused on medications to treat PTSD (serotonin reuptake inhibitors); three focused on agents to treat AUD (naltrexone and disulfram); three used agents targeting both disorders (topiramate, alpha-adrenergic agonists; neurokinin-1 receptor antagonist) and one study with a medication to treat PTSD and a medication to treat AUD (naltrexone and sertraline). All but one of the studies found that PTSD symptoms and drinking outcomes improved significantly over time and there was not one agent with clear evidence of efficacy in this comorbid group. In general, there was evidence to suggest that individuals with comorbidity can be safely prescribed medications generally used to treat either PTSD or SUDs and evidence to support the use of medications to treat AUD among those with comorbid PTSD. Two pilot studies of glutamatergic agents targeting both PTSD and AUD have shown promise. Batki et al. [13] found that topiramate (300 mg/day) improved drinking outcomes and reduced hyperarousal symptoms in 30 veterans with co-occurring PTSD/AUD. Back and colleagues et al. [12] found that N-acetylcysteine (2400 mg/day) improved PTSD symptoms and decreased craving but not alcohol/drug use in

35 veterans with PTSD/SUD. While these studies show promise, clearly more work needs to be done to explore pharmacotherapeutic treatments of co-occurring PTSD/SUDs.

93.4 Conclusion

In summary, while we do not have information about the international prevalence estimates of co-occurring PTSD and SUDs, many studies suggest that these two disorders commonly co-occur. A number of theories have been posited to explain the functional relationship between these disorders, and there are clear neurobiologic connections. Medication treatments have shown some promise, but more investigation is needed. In terms of psychotherapeutic approaches, integrated treatment has been accepted as a safe and effective model of treatment. Although non-trauma-focused treatments offer some PTSD symptom reduction, data suggests that trauma-focused, exposure-based treatment offers greater symptom reduction than non-exposure-based treatment in SUD treatment programs. There are promising pilot developments in the pharmacotherapy of PTSD/SUD, but more work needs to be conducted before there is a significant clinical impact. Recent evidence demonstrates that improvement in PTSD positively impacts substance use outcomes, clearly supporting a more rigorous approach to the assessment and treatment of PTSD among patients with SUDs.

Psychotic Disorders and Substance Use Disorders

Abstract

The comorbidity of psychotic and substance use disorders (SUDs) is a major issue in mental health, because of its high frequency and poor prognosis. Moreover, it is often neglected both for the difficulty to assess SUDs in psychotic patients and for scarce attitude to evaluate and treat substance misuse by psychiatric services staff. On the other hand, patients with psychosis and SUDs can receive inadequate treatment for psychosis by SUDs services, for similar reasons.

Assessing and treating this comorbidity requires the knowledge and the integration of specific tools and interventions, which should be tailored towards patients' clinical condition and that can be difficult to manage in daily clinical practice.

94.1 Introduction

Since the 1980s, a strong literature evidence has shown that psychotic disorders are frequently associated with substance consumption or clinically relevant substance use disorders (SUDs), namely alcohol use disorders (AUDs) or drug use disorders (DUDs).

This comorbidity contributes to the definition of "dual diagnosis", known as the simultaneous presence of a mental disorder and a substance use disorder.

Psychotic disorders typically arise at young ages, when people are laying the foundations of their own life, often seriously compromising the process, leading to unfavourable social, residential and occupational outcomes. SUDs are frequently associated with these disorders, generally with a further pejorative effect on the prognosis [1].

94.2 Epidemiology

94.2.1 The United States of America

The past-year prevalence of schizophrenia and other psychotic disorders among adults (age of 18 or older) in the United States (US) is estimated to be 0.3%, while the lifetime prevalence is about 0.5% [2].

SUDs are more common than psychoses. The third National Epidemiologic Survey on Alcohol and Related Conditions (NESARC III), carried out between 2012 and 2013 among US adults according to the definitions of the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5), shows prevalence rates of 13.9% for AUD in the past year and 29.1% for AUD lifetime [3], as well as 3.9% for other DUDs in the past year and 9.9% lifetime [4].

A great part of the evidence about prevalence of dual diagnosis among people with psychotic disorders in the US general adult population comes from three large studies, the Epidemiologic Catchment Area (ECA) Study, the National Comorbidity Survey (NCS) and the already cited National Epidemiological Survey of Alcohol and Related Conditions (NESARC). These studies confirm the high prevalence of alcohol and substance misuse among people affected by psychoses. Moreover, psychotic disorders are more frequent among alcohol and substance misusers than in general population, even if prevalence rates are lower than observed for alcohol and substance consumption in psychoses.

The ECA study was carried out between 1980 and 1984 on a sample of more than 20,000 subjects aged over 18 years, and found that, among individuals with schizophrenia, SUDs had a prevalence of 47% (odds ratio = 4.6, $p < 0.001$). Indeed, 34% of subjects had an AUD (OR = 3.3, $p < 0.001$), and 28% a DUD (OR = 6.2, $p < 0.001$). Conversely, comorbid schizophrenia was found in 3.8% of subjects with an AUD and in 6.8% of those with a DUD [5]. The NCS study was conducted between 1990 and 1992 on a sample of approximately 8100 individuals between 15 and 54 years of age, and found a prevalence of SUDs of 44.8% among those suffering from chronic psychotic disorders [6]. Finally, the NESARC study interviewed more than 40,000 non-institutionalised adults in 2000–2001, finding that psychotic disorders have a prevalence of 1.5% among people affected by AUDs and of 4.2% among people affected by DUDs [7].

The high prevalence of SUDs among people suffering from psychotic disorders is confirmed by a meta-analysis that pooled the results from ECA, NCS and NESARC with those from other smaller studies, all published from 1990 to 2017. The authors report an overall prevalence of SUDs of 41.7%, a prevalence of 30% for AUDs and a prevalence of 33% for DUDs [1].

94.2.2 Europe

European evidence about psychotic and substance use disorders show prevalence rates in the general population of about 1% and between 0.3% and 3%, respectively [8, 9]. In Europe, unlike the USA, there are no studies that routinely and comprehensively investigate the prevalence of dual diagnosis across all the countries [10]. However, the European Schizophrenia Cohort (EuroSC), a multicenter prospective study carried out in Europe on a cohort of 1200 patients with schizophrenia, found a prevalence rate of 24% for comorbid dependence from alcohol or other substances, mostly due to alcohol, albeit with some differences between countries where the study was carried out. Dual diagnosis had a prevalence rate of 35% in the UK, 21% in Germany and 19% in France [11]. Smaller studies have shown similar prevalence rates across European countries. Moreover, according to various local studies, psychotic disorders have a prevalence of about 5–15% among individuals affected by SUDs [12, 13].

In summary, in Europe prevalence rates of substance misuse among people with psychotic disorders seem lower than in the USA [11]. The differences between USA and Europe may, at least partly, depend on important differences in lifestyle and care pathways of the surveyed populations. Thus, there is the need of a prudential approach, as the epidemiology of dual diagnosis depends upon many factors, which may vary across different countries. Evidence must be interpreted considering local settings' features.

94.2.3 Critical Issues of Dual Diagnosis Epidemiological Studies

Most of the studies on the comorbidity of psychotic and substance use disorders deal only with schizophrenia, neglecting other psychoses, so very scarce evidence is available for the latter [8]. Furthermore, most of the evidence on dual diagnosis comes from the USA, which limits its generalisability, because of the specific features of their health care system.

Moreover, available epidemiological studies on dual diagnosis have shown various methodological limitations. First, it must be considered that recruitment of people with dual diagnosis may not be so obvious: the assessment techniques show variable validity [14]. Secondly, the DSM-5 merged alcohol and substance "abuse" and "dependence" in a unique category, which may bring an increase in the prevalence of these disorders [15]. This may be useful to elicit attention to the problem, but will make difficult to make comparisons between studies based on DSM-5 and those based on its previous editions, even if many studies used to merge the categories of abuse and dependence [16].

There are also issues regarding sampling: convenience samples help to ascertain and explain the critical aspects of treating specific populations, but they may provide misleading findings about the real prevalence of dual diagnosis. It is well known that dual diagnosis is significantly more common among some special populations, e.g., patients admitted to acute psychiatric settings, the homeless and users of the criminal justice system [17]. Finally, two interrelated problems must be considered: the spread of polysubstance abuse, including alcohol, and the difficulties in ascertaining a problematic substance use. Polyabuse is particularly common among patients suffering from psychotic disorders [16, 14, 18], so each patient might have more than one SUD, making almost impossible distinguishing them. However, patients often deliberately hide their consumption of substances, leading to an underestimation of their prevalence [19].

As a whole, the epidemiological research about dual diagnosis shows many uncertainties, partly due to organisational problems and partly due to the very nature of the patients. In fact, psychotic disorders and SUDs are severe illnesses, and suffering from these conditions makes people exposed to several confounding factors, which can hamper validity of correlations and

causal links. However, an epidemiological understanding is needed to implement appropriate treatment programmes.

94.3 Potential Aetiological Relationships Among Psychotic and Substance Use Disorders

Substance use and psychotic disorders seem to be linked by a mutual risk relationship [20]. Their strong epidemiological, biological and clinical association has worked as a springboard for a large number of research initiatives aimed at understanding the aetiology of this association. The efforts have been mainly directed in ascertaining if one has a significant role in the aetiology of the other. Furthermore, some authors have hypothesised that both these disorders may be due, at least partly, to a common cause [21]. However, there are no firm conclusions about any etiological links between SUDs and psychosis, but various risk factors for dual diagnosis have been found and some aetiological models have been developed.

94.3.1 Correlates and Risk Factors for Dual Diagnosis

Psychotic disorders and alcohol and substance use disorders seem to share many genetic and psychosocial risk factors [21] that seem to promote the development of both conditions. Moreover, the risk factors associated with dual diagnosis are largely similar to those for substance misuse found in the general population [22]. In this paragraph, an overview of them will be presented.

94.3.1.1 Genetics

Both SUDs and psychotic disorders have their own genetic risk factors, namely a polygenic inheritability with multiple genes giving each one a small contribute to the global risk of developing these diseases [23].

Until a few years ago, it was thought that vulnerability to SUDs and psychosis depended on distinct mechanisms of inheritance [24]. However, more recently some genes have been identified contributing to the pathogenesis of both disorders, with many of them involved in brain development and neuronal plasticity, such as the genes for neuregulin-1 (NRG1), neurexins (NRXN1 and NRXN3), the cathecol-O-methyl transferase (COMT) and the monoamine oxidase A (MAOA - 21).

94.3.1.2 Male Sex and Young Age

These characteristics are strongly associated with comorbid psychotic and SUDs, regardless of the substance considered or setting [1, 19]. This is probably due to the propensity of young men in experimenting risky behaviours, while females tend to take alcohol or substances to self-medicate stress, depressive or trauma-related symptoms [1].

94.3.1.3 Low Educational Level and Unemployment

These factors seem associated with both conditions [21], probably because they favour drift towards social relationships and situation with high risk of substance consumption [25].

94.3.1.4 Substance Availability and Attitude Towards Substance Consumption

Living in social contexts characterised by high availability of substances and belonging to a social network familiar with consumption seems to favour its spread among individuals with psychotic disorders [19].

94.3.1.5 Personality and Neurodevelopmental Disorders

Personality disorders are relevant risk factors for SUDs, as they can be found in up to 50% of problematic alcohol or drug users. Antisocial and borderline personality disorders are the most exposed ones, because of their diathesis to risky behaviours, impulsive search for gratification and inability to make long-term plans [10].

Attention Deficit Hyperactivity Disorder (ADHD) is a risk factor for SUDs, with prevalence rates of 5–33% among users seeking treatment for these conditions [10], and is frequently associated with schizophrenia, posing an even greater risk for SUDs [26]. Even Autism spectrum disorders (ASD) are often comorbid to schizophrenia [26]. They have been considered protective towards alcohol and substance use disorders, because of the limited social relationships of the affected individuals. However, prevalence of alcohol and substance consumption among individuals with ASD varies from 0.7% to 36%, being more common than expected [27].

In summary, ADHD and ASD are frequent comorbidities of schizophrenia, and ADHD is by itself a well-recognised risk factor for alcohol and substance misuse. Therefore, AUDs and SUDs should be assessed in presence of a psychotic disorder associated to a neurodevelopmental disorder.

94.3.1.6 Early Onset of Illness and Good Premorbid Functioning

Individuals with good premorbid functioning and earlier onset of schizophrenia are more prone to AUDs and SUDs. As a good premorbid functioning usually correlates with later onset of illness, the anomaly of earlier onset of psychosis has been explained with the hypothesis that using alcohol or illicit drugs may have anticipated the emergence of schizophrenia [14].

94.3.1.7 Subthreshold Psychotic Symptoms

Subclinical psychotic symptoms, typical of prodromal manifestations of psychotic disorders, are risk factors for both subsequent onset of psychotic disorders [28] and for alcohol or substance consumption [23].

94.3.2 Etiopathogenesis: Models and Evidence

It is not known why AUDs and SUDs are so common among people suffering from psychotic disorders. Various etiopathological models have been proposed and will be presented below.

94.3.2.1 The Self-Medication Model

The self-medication model is a long-standing hypothesis. In its original shape, it claims that alcohol or other substances should be chosen by individuals affected by psychosis to counteract specific symptoms of this disorder or side effects of the pharmacological treatment [23, 14]. This model is supported by numerous research results that show how the toxicodynamic properties of various substances of abuse may compensate dysfunctions in the neuronal circuitry of affected patients [21, 17].

The self-medication model should imply a correlation between certain symptoms or pharmacological side effects and specific patterns of substance consumption, but research evidence has refuted this model showing that substance consumption patterns among individuals suffering from schizophrenia are similar to those shown in general population of the same environmental context [25, 24]. Furthermore, it has been argued that if drugs of abuse improved symptomatology, probably the prognosis of patients with dual diagnosis would be better, but the literature is almost unanimous in affirming the contrary [25], and some experimental results have questioned the effectiveness of some substances in relieving symptoms of psychotic disorders [23].

Some evidence, however, supports a less mechanistic form of the self-medication hypothesis. According to this one, substance consumption in psychosis is interpreted as an attempt to get high or relieve dysphoria, anxiety or depressive symptoms, similarly to what happens in general population, rather than as a way to medicate specific psychotic symptoms [24, 14]. The long-term counterproductive effect of substance consumption seem to be a consequence of patients' choice of the temporary benefits at the expense of a broader and less immediate negative impact on their lives, maybe sustained by the deficit in planning long term actions in schizophrenia [29].

94.3.2.2 Environmental Stress Vulnerability

According to this model, the problematic substance use would be one of many factors that can precipitate the development and exacerbation of psychotic disorders in susceptible individuals [17]. Even if alcohol, cannabis and methamphetamines have been proved capable of causing persistent psychoses, along with transient psychotic syndromes [30], this model seems simplistic, as several studies have reported that psychotic disorders are not merely caused by SUDs, given the mutual risk relationship that seems to bind these two syndromes [21].

94.3.2.3 Vulnerability to Comorbid Dependence

In this model, suffering from a psychotic disorder is per se a risk for substance use disorders, as both illnesses may share various biological substrates. The model is supported by evidence at various levels.

From a psychosocial point of view, the cumulative risk factor hypothesis motivates the vulnerability seen in schizophrenia to SUDs with the cumulative effects of marginalisation, exposure to deviant environments and poor cognitive and social skills, a lacking that hampers both the capability of avoiding drugs offers and the capacity of anticipating and counteracting the negative consequences of substance consumption [23, 25, 19].

From a neurobiological point of view, the primary addiction or reward deficiency syndrome hypothesis suggest a role for a deficit in the reward system and related neuronal networks. The reward system consists of the dopaminergic neurons that project their axons from the mesencephalic ventro-tegmental area (VTA) to the nucleus accumbens (NA), located in the ventral striatum. In schizophrenia, functional magnetic resonance imaging studies have shown a deficit in the activity of the reward circuit coupled with hypersensitivity to substance-related cues. These findings may explain both the attempt of patients to self-medicate the dysfunction of the reward circuit and the diathesis to the development of an alcohol or substance use disorder. The dysfunction of the reward system may in turn be due to developmental abnormalities in hippocampus and frontal cortex [23].

All these hypotheses about the etiopathogenesis of dual diagnosis probably describe only some of its facets, so they should not be conceived as mutually exclusive. For instance, attempts to self-medicate psychotic or unspecific symptoms could be reinforcing elements for substance consumption, and people with schizophrenia may be highly vulnerable to such reinforcement. It is also possible that pathogenesis mechanisms shared by all or most of drugs of abuse coexist with mechanisms related only to specific psychotropic substances [21].

94.3.3 Cannabis and Psychotic Disorders

Cannabinoids are both the most used illicit substances in the world and a source of possible pharmacological treatments for several conditions, including chronic pain, multiple-sclerosis and Parkinson Disease [31]. Cannabis contains more than 100 phytocannabinoids, of which the most abundant and studied are (−)-trans-Δ9-tetrahydrocannabinol (THC) and cannabidiol (CBD). THC is considered the main responsible for the psychoactive effects of cannabis, while CBD seems to reduce them. THC acts as a partial agonist on the cannabinoid receptors CB1 and CB2, whose major endogenous ligands are arachidonylethanolamine or anandamide and 2-arachidonylglycerol [32, 33]. CB1 seems the only one involved in the psychoactive effects of cannabis [31]. CBD seems to act as an allosteric negative modulator of CB1, a reuptake and hydrolysis inhibitor of anandamide and an agonist on 5HT1A, α1 and μ receptors [32].

Many countries have shown a tendency towards cannabis legalisation, both for pleasure and medical purposes, so contributing to the already ongoing increase in its consumption [31]. However, since the 1960s, there has been a growing concern about its impact on mental health, including its role in the onset and exacerbation of psychotic disorders [32].

Research evidence show that cannabinoid consumption can induce acute psychotic episodes, as well as clinical exacerbations of already existing chronic psychotic disorders [34]. A still debated question is the capability of cannabinoids of causing schizophrenia or other chronic psychotic disorders.

The epidemiological data elaborated by various meta-analyses show that there is a dose-dependent correlation between cannabinoid consumption and the onset of chronic psychotic disorders, whose age of onset is significantly earlier among cannabis users. Cannabinoids also seem to erase the gender differences in the onset of these disorders, which typically arise in men before than in women [32, 23].

Clinical research has confirmed that, despite robust epidemiological evidence, the correlation between cannabis consumption and psychosis is complex: for instance, various cross-sectional studies report that it seems mediated by comorbid psychopathology [28].

From a neurobiological perspective, cannabis exposure and psychotic disorders share many neurobiological features, widely described in several reviews. For instance, cannabis use has been correlated to an increase in striatal levels of dopamine, similarly to what happens in acute psychosis. Moreover, chronic cannabis consumption has been correlated to a reduction in dopamine synthesis and release, which has been associated to impairment of executive functions and negative symptoms. Cannabinoids can reduce the activity of the inhibitory interneurons that use γ-aminobutyric acid (GABA) as a neurotransmitter, including those located in hippocampus and prefrontal cortex, two regions in which there have been found several structural abnormalities in schizophrenia. In these two regions, moreover, cannabinoids can induce a reduction in glutamate levels, similarly to what is seen in schizophrenia [31].

Bossong and Niesink formulated two hypotheses about the role of cannabis in psychotic disorders. The former starts from the evidence that the CB1 receptor has a role in the brain development, both in prenatal age and in adolescence. Adolescence is crucial for the development of the superior brain functions, so heavy exposure to exogenous cannabinoids may disturb this process, causing alterations that might result in schizophrenia [34]. This hypothesis is sustained by various studies showing that heavy cannabis users may present hippocampal and amygdalar atrophy and several alterations in neural connectivity, as well as, from a functional point of view, alterations in cognitive and emotional processing. Taken together, all those structural and functional alterations show similarities to findings related to schizophrenia, so suggesting an etiopathological role in its development [32]. The latter hypothesis speculates that cannabinoid consumption, altering perception and memory, might alter the perception of exogenous stimuli, relevant for brain maturation in adolescence [34].

Despite the consistent neurobiological evidence correlating cannabis consumption and chronic psychosis, several experimental results have not been unanimously replicated, probably because of methodological heterogeneity and the role of unknown confounding factors [31]. Therefore, Bloomfield and colleagues have speculated that cannabis may cause chronic psychotic disorders in two not mutually exclusive ways: catalysing the same etiopathological pathway that leads to idiopathic chronic psychotic disorders and through alternative ways that lead to a similar syndrome [32].

Altogether, the research results about the link between cannabis and chronic psychotic disorders point out that cannabis consumption seems to be neither a necessary nor a sufficient cause for the onset of chronic psychotic disorders. It is one of the many factors, partly known and partly unknown, that interact to give each person a specific risk for chronic psychosis, but its contribution in the genesis of the disorder may be bonded to the presence of other factors.

Two additional sources of complexity are the proportions of exogenous cannabinoids contained in cannabis products and the role of synthetic cannabinoids. The cannabis products sold in the legal and illegal market contain different amounts of THC and CBD, so adding heterogeneity to epidemiological and clinical findings. Moreover, the last 20 years have shown an

increase in the concentration of THC, both in USA and Europe, from about 4% to about 12–13%, as well as an increase in the THC/CBD ratio [33]. Given the psychoactive role of THC and the opposite effects of CBD, this variation, besides representing a public health concern, makes difficult to make comparisons among the oldest and the most recent research results.

Synthetic cannabinoids are another source of concern, both from a medical and from a research point of view. They appeared in the European market in 2006, and then their consumption has progressively grown. They are sold as a mixture of different compounds, generally with a stronger agonist activity on CB1 receptor than THC. Besides their capability of inducing acute psychosis and acute recurrences of chronic psychotic disorders, they seem capable of inducing chronic psychotic disorders by themselves, although with the uncertainties described above [35]. However, their high potency legitimates the suspicion that they may represent, from a toxicodynamical point of view, a menace even higher than the one posed by phytocannabinoids.

Taken together, all these research results suggest that preventing or reducing the use of both phytocannabinoids and synthetic cannabinoids may be useful to delay or maybe avoid the onset of psychotic disorders, especially in people at high risk. This is important especially in the age of development, so health education interventions are highly appropriate especially for pregnant women and adolescents. In fact, even if the onset of psychosis were inevitable, delaying the onset could allow many patients to reach a developmental level sufficient to have a decent life.

94.4 Clinical Features, Course of Illness and Diagnosis

94.4.1 Clinical Features and Course of Illness

After tobacco, the most frequently used substances among people suffering from psychotic disorders are alcohol, cannabis and, slightly less frequently, cocaine or amphetamines [23, 10, 19], similarly to what happens in the general population [31].

Clinical pictures of comorbid psychotic and substance use disorders may be complex, as they often appear as a mixture of signs and symptoms of acute or chronic psychosis, intoxication, withdrawal, and chronic substance use, which may involve multiple substances. The clinical picture may be further complicated by a substance-induced psychosis, namely a psychotic syndrome due to substance intoxication or withdrawal [10, 19].

Any substance, if taken in large quantities and over a long enough period can induce a psychotic state, as well as a relapse of a chronic psychotic disorder. The clearest psychotogenic effect has been shown for stimulants (e.g., amphetamines and cocaine), cannabinoids and NMDA receptor antagonists (e.g., phencyclidine and ketamine). Lysergic acid diethylamide (LSD) and 3,4-methylenedioxy-N-methylamphetamine (MDMA or ecstasy) can cause hallucinations, but usually only during acute intoxications. Alcohol and benzodiazepines can induce psychotic symptoms only in acute withdrawal states, while opiates and nicotine have not clearly shown psychotogenic properties. Acute presentations of schizophrenia and substance-induced psychoses may be indistinguishable. The main instrument to differentiate them is longitudinal observation, as substance-induced psychoses usually remit after days or weeks after the cessation of substance consumption [36]. However, some psychotic disorders may last for several months, years or also lifelong even after cessation of the substance use [30].

Endogenous psychoses in people who misuse substances may be different from the abstinent ones in frequency and intensity of positive, negative and cognitive symptomatology. There is evidence about a higher frequency of positive symptoms, with less negative and cognitive ones, in those with substance use disorders [19, 14].

In terms of clinical course, each disorder can worsen the other, and both may be exacerbated by environmental stressors [30, 21]. Moreover, dually diagnosed people are prone to adverse outcomes in several domains. They have a high risk

of treatment noncompliance, poor clinical response, more frequent psychotic relapse and hospitalisation, violent behaviour, suicide attempts and medical problems, such as infectious diseases, so being frequent users of emergency services. They also face some adverse social and economic outcomes. They are in fact more at risk of victimisation, housing instability and homelessness, unemployment, poverty and committing offences with related criminal justice issues. Besides, dual diagnosis imposes a high emotional and economic burden on families and friends of patients, increasing the risk of social drift [1, 30, 19].

94.4.2 Assessment

An adequate assessment starts from clinical suspicion. Cues of a history of substance abuse can be found in risk factors described above or in a childhood history of ADHD [10]. Moreover, because of the high prevalence of comorbid severe mental illnesses and substance use disorders, the presence of one of them should be considered by itself a reason to search for the other [30, 20].

The assessment can be difficult for various reasons, especially in emergency settings. Patients' clinical conditions may be complex and their cooperation is not warranted, for instance, because of agitated or violent behaviour, disorganised speech, high sedation or paranoid psychotic symptoms, and acute or chronic cognitive impairment. The patient may not want to talk about his symptoms or his substance use because of embarrassment, fear of negative responses or scarce insight [19]. Therefore, it could happen that the clinician has to achieve a diagnosis based only on scarce and fragmentary data. The most reliable approach consists in combining data from more sources, namely clinical history, physical examination, clinical interview, laboratory tests and neuroimaging [30].

Firstly, it is essential to establish a positive therapeutic alliance with the patient, setting a non-judgemental and trustful relationship [37, 18]. The clinical history can be evaluated asking the patient. It is important to ascertain if he has ever attended psychiatric services, received a psychiatric diagnosis or the prescription of a psychopharmacological treatment. The clinician must ask about any psychotropic substance consumption, substance use disorder or related treatment. If the patient assumes substances, it is important to know what substances, or at least what substances the patient believes to have assumed, as well as quantity and frequency of consumption [20]. The patient's last drug consumption time is very important for diagnostic assessment, especially in case of emergency [38]. Patients' collaterals, such as family members, friends or partners may be a source of reliable information. However, even patients' collaterals can be unreliable, for various reasons. They may be interested in hiding the patients' drug consumption, for example because of legal reasons, or they simply may not know how the patient lives.

The clinical interview can be integrated with structured interviews or questionnaires. They have been found to produce highly reliable diagnoses [14], but they must be tailored toward the patient's clinical conditions. For example, for patients with higher functioning and less severe mental illness the Addiction Severity Index (ASI), the Drug Abuse Screening Test (DAST) and, for alcohol, the CAGE and the Alcohol Use Disorders identification Test (AUDIT) have shown adequate reliability [30, 20]. However, these instruments may not be reliable for patients with the most severe mental illnesses, for two reasons. First, these tools focus on substance related dysfunction, of which the most severely ill patients could be unaware. Secondly, they may not be sensitive to the cognitive impairment common among the most compromised patients [30]. Two screening tools developed for such patients are the Dartmouth Assessment of Lifestyle Instrument and the Substance Use Event Survey for Severe Mental Illness. Regardless of the chosen screening tool, it is important to verify if it can be easily administered to a patient and if it has been validated for dually diagnosed populations [39]. Furthermore, these instruments should be used when the patient is stabilised and self-report tools should not be too lengthy. Repeating

the administration of these tools may help to assess variations in the clinical course [18].

During the physical examination, every sign or symptom must be evaluated [36]. Its main purpose, besides looking for any condition that deserves medical or surgical treatment, is to search for the physical stigmata of a drug use disorder or of a mental illness. Cues of a substance use disorder can be signs of intoxication, withdrawal or chronic use, but they can overlap each other and with signs of comorbid physical illnesses and unspecific vegetative symptoms (i.e., tachycardia and diaphoresis because of anxiety [20]). Signs and symptoms of intoxication and withdrawal by psychotropic substances are described elsewhere in this book. Here it will be stressed only the importance of evaluating if the patients' behaviour suggests delusions or hallucinations, and if there are physical signs of activation or inhibition, including pupils' diameter. A horizontal, vertical or rotary nystagmus can suggest an intoxication by NMDA receptor antagonists, such as phencyclidine or ketamine [36, 30]. Further, the chronic stigmata of a substance use disorder must be searched for, such as signs of cirrhosis or of intravenous drugs use [30]. A poor nutritional state could be observed both in case of a SUD and of different severe mental disorders.

Laboratory tests provide objective evidence of substance consumption, as well as signs of medical illness or somatic consequences of drug use. Urine tests are a cost/effective tool to assess drug consumption. They usually detect drugs taken in the previous 48 hours. THC is an exception: due to its lipophilic structure, it can be stored in fat cells, and found in urine samples for up to 6 weeks after consumption. Other instruments include breath analysis for alcohol, which can detect consumption only in the last few hours before the test, and plasmatic blood levels, useful to detect many substances of abuse. Blood cells, liver function and carbohydrate-deficient transferrin (CDT) are indirect measures of alcohol consumption [30, 18]. In addition, the hair radioimmunoassay can be useful [30].

Structural neuroimaging, such as computed tomography (CT) or magnetic resonance imaging (MRI), could be useful to exclude an organic aetiology of neuropsychiatric signs and symptoms [36].

In summary, differentiating a primary psychosis, a psychosis due to substances or organic disease or a condition with comorbid psychosis and SUDs can be challenging. It requires a holistic, integrated approach that must be tailored toward patients' conditions, setting and available tools.

Overlooking one of these conditions or incorrectly assuming multiple diagnoses can respectively affect the prognosis or lead to unnecessary treatment and iatrogenic harm [30].

94.5 Treatment and Prognostic Issues

Treating people with comorbid psychosis and substance related disorders can be very difficult. It can follow a sequential, parallel or integrated approach. The sequential treatment takes care of one disorder at a time, from the first to the second once that the former is stable or in remission. In the parallel treatment psychosis and the substance abuse disorders are treated simultaneously but separately. It is mostly up to the user to follow and coordinate both of them. The integrated model of treatment provides that treatment for both the disorders is provided by the same team [40].

The sequential and parallel treatment have often been proven to be unable to meet users' needs, especially because of the lack of coordination [41]. Thus, patients may be referred from one service to another and users can be treated only for one of their two disorders. They may also receive incompatible or inconsistent and fragmented treatment. It is also possible that, facing many difficulties and seeing their needs unmet, they give up both treatments [42].

The integrated model is designed to reduce the gap between mental health and substance misuse services [40]. However, in many countries it is hard to be implemented because national health systems keep this services separate, and unifying them would implicate complex political choices and administrative efforts [38, 19]. Thus, manualised integrated treatment, with one team look-

ing after both disorders, is difficult to be broadly implemented. Furthermore, evidence about the efficacy of integrated treatment models is inconclusive, partly because of several methodological issues of research on this topic [43]. However, many authors have observed that integrated treatment, although not harmful, might not be more effective than standard care 40,43). Indeed, even if there is uncertainty about its effectiveness, it is reasonable to implement part of its philosophy to counteract daily practice problems. In fact, many obstacles due to the services' dichotomy can be managed establishing a strong synergy between them [38].

The aim of ensuring a good quality of care to dually diagnosed individuals should start with setting formal collaboration protocols between local services. For each patient with dual diagnosis they should set out their respective responsibilities, first of all agreeing on which are patients' main needs and which service has to coordinate treatment interventions [41]. In case of psychosis, the British National Collaborating Centre for Mental Health states that coordination should be kept by psychiatric services, due to the complex care needs of psychosis. Second, services have to regularly communicate and share information, to reduce redundant interventions and to fill care gaps. Similar agreements and collaborations should be set with other services and institutions involved in patient's life, such as assisted housing institutions or the judiciary system [38, 19].

Besides organisational aspects, an appropriate treatment strategy should consider two further issues, i.e., the stage of patients' motivations and coexisting physical, social and financial problems [41, 44]. People suffering from severe mental disorders have commonly low motivation to change. This is partly due to low self-esteem, low tolerance of frustration, and scarce social skills. Positive, cognitive and negative symptoms of psychosis and being in contact with a substance-promoting social context are all factors that may further limit motivation [41]. It is important to consider the role that the substance consumption has in patients' life, keeping in mind that different substances can have a different functional meaning in patients' life (e.g., cocaine against depressed mood and cannabis to facilitate socialisation), and to evaluate patients' opinions and emotions about their personal situation and the treatment course, given that motivation can be hampered by many factors, including social and financial problems [37].

Although treatment interventions in dual diagnosis are the same used for substance misuse and severe mental disorders, it is paramount to coordinate the efforts and to tailor care programs according to patient's characteristics. Irrespective of which of the two disorders may have supposedly come first, they should be treated simultaneously as for people with a single disorder [44].

94.5.1 Pharmacological Treatment

Pharmacological treatment of dual diagnosis involves treatment for both psychosis and substance use disorders. The risk of pharmacokinetic and pharmacodynamic interactions should not be overlooked. There is currently poor evidence to support one antipsychotic over another or first versus second generation antipsychotics when treating schizophrenia with comorbid harmful substance use, abuse or dependence, either in relation to superiority in reducing substance use or improving psychiatric symptoms. However, a recent systematic review with meta-analysis on this topic reported that clozapine and risperidone may have better efficacy in reducing substance use and craving, and that clozapine, olanzapine and risperidone performed better than other antipsychotics in reducing the symptoms of psychosis [45].

Mood stabilisers can be useful in case of schizoaffective disorders. Valproate has been proven to be effective in comorbid AUDs, and carbamazepine in DUDs. The efficacy of lithium among other drugs is scarcely known and controversial [46, 38].

Methadone brings some risk of interactions. It is metabolised by the CYP3A4 cytochrome, so inductors of this cytochrome, such as barbiturates, carbamazepine, phenitoine, rifampicine may decrease its serum level, which may result in a withdrawal syndrome. Cannabinoids, grapefruit

juice, SSRIs and other drugs may inhibit this cytochrome, thus increasing methadone's serum levels [38]. There is also risk of interaction with antiretroviral therapy for HIV infection. For the evaluation of the risk of pharmacological interactions, it can be useful to consult the summary of product characteristics (SPC) of the involved pharmacological treatments.

Lastly, is important to pay attention to prescribing anticholinergics for extrapiramidal side effects and benzodiazepines, as they can be abused for their stimulating and sedative effect, respectively [47].

94.5.2 Psychological and Psychosocial Interventions

It is difficult to state which types of psychological and psychosocial interventions are more effective for comorbid substance use and psychotic disorders [40]. Patients' stage of motivation it is fundamental to tailor the intervention [44]. A rationale framework for treatment includes several phases, i.e., engagement, motivation, active treatment and relapse prevention [41, 44]. Engagement means establishing a trustful relationship between the clinician and clients. In this phase is important to pay attention to the social and cultural background of users and to work for their gradual involvement, being flexible in interacting with them. Outreach interventions can be useful in this phase [44]. About motivation to treatment, motivational interviewing is the instrument of choice, especially in the early stages of treatment, to explore and try to modify the actual availability of clients to be engaged in treatment. Typical psychosocial interventions include cognitive-behavioural psychotherapy and contingency management, namely setting rules about facilities and penalties depending on treatment compliance and substance consumption [41]. Motivational interviewing, cognitive-behavioural therapy and contingency management have been largely tested in dually diagnosed patients, but for now, there is no evidence to claim that one intervention is better than others or than treatment as usual. Several trials have shown initial benefits of these interventions when compared to standard care, but the benefits were lost in a short time after the end of the trial. It is possible that these interventions, developed for people not affected by severe mental illness, may need to be specifically tailored to those suffering from the most disabling mental disorders [48].

Treatment can be delivered in group form or in residential settings. On group approaches, they are mainly derived from cognitive-behavioural therapy, and have proven to be useful across several types of populations, maybe depending on nonspecific factors such as education, skills building and peers support [41]. However, not all group interventions may be suitable for people with psychosis. 12-step programs may be unhelpful, because patients' limitations in emotional expression and low social skills could hamper adherence, as this approach requires some introspection, and talking about several intimate aspects of one's life [41].

Residential treatment may be useful for dually diagnosed people, as it provides a protected context in which therapeutic interventions are not hampered by an uncooperative environment [38].

94.5.3 Admission to Psychiatric Wards

People with comorbid psychotic illness and SUDs have more frequent hospital admissions and use of emergency services. Thus, it happens quite frequently that they need to be admitted to a hospital ward, often a psychiatric one, for a psychotic relapse or for an intoxication syndrome [20, 25]. However, they could be difficult to be managed because of their craving for substances or for drug or alcohol trafficking, violent or manipulative behaviour or for inappropriate relationship with other inpatients. Indeed, psychiatric and substance misuse services, being a sort of safe and non-judgmental environment, can become a favourable setting for substance consumption, dealing and related issues [49]. Therefore, it is important that some rules are set about their hospitalisation, especially regarding visits arrangements, search procedures and other security

issues. Drug tests should be part of the routine. The aim is to have an environment free from drugs and alcohol, and these procedures should be explained to patients and their families. Treatments proven to be effective in outpatient settings are to be continued during the admission [38].

94.5.4 Prognostic Factors and Course

Dually diagnosed patients usually make slower progresses and have higher dropout rates [41]. To deliver an effective treatment, it is important to frequently monitor patients' stages of motivation, and to monitor retention in treatment as this is directly related to psychosocial outcomes [41, 37].

Factors that may affect outcomes include dissatisfaction for quality of life, peer pressure, lack of an alternative daily occupation or of a satisfying social network once attained abstinence. All of these can make patients relapse into consumption [37]. Positive prognostic factors include availability of regular and interesting activities (other than substance consumption), a decent housing, a loving, caring relationship with someone sober and sensible about patient's mental illness and a positive relationship with a mental health professional. Negative prognostic factors are related to patient's history, especially having experienced dire poverty, violence or abuse and being grown up with someone in the family or in the household affected by a SUD or a severe mental illness [37].

Treatment of dual diagnosis challenges what we know about treatment of both SUDs and psychosis. It needs great efforts and even greater flexibility. Nonetheless, treatment needs of the comorbid population need to be met to guarantee a subjective quality of life at least as high as that of their nondependent counterparts.

94.6 Conclusions

The aim of this chapter was to give a brief overview of the epidemiological relevance, the main clinical features and the treatment options of the comorbidity of psychotic disorders and substance use disorders. However, a large proportion of the etiology and physiopathology of these two syndromes is still unknown, and recent progresses in the knowledge of their neurobiology have a scarce impact on clinical practice.

Actually, the cornerstone of dual diagnosis treatment seems to be the coordination in the treatment of psychosis and substances consumption. A bulk of evidence has shown that this strategy is crucial for the efficacy of various treatment options, with great relevance both at health delivery and at individual level. An effective coordination should be achieved first of all in physicians' and other professionals' minds.

Besides the need of coordinated treatment, it is important that every person involved in the care of dually diagnosed individuals understands the role of substance consumption in patients' life, as treatment should be tailored to give patients the opportunity to conceive and live a reliable alternative to drug abuse.

However, the need for further knowledge in this field cannot be quenched. Evidence about treatment outcomes in substance consumption are still scarce and partly contradictory, mainly because of methodological issues and, probably, because of the effect of undetected confounders.

Therefore, the comorbidity of psychosis and SUDs is a largely unexplored field, in which the clinical practice greatly relies on experience, flexibility and common sense, but such a situation must be an even stronger trigger to the development of methodologically reliable scientific evidence.

Contents

Abstract

Attention-Deficit/Hyperactivity Disorder (ADHD), often diagnosed in childhood, is a neurodevelopmental disorder characterized by disruptive symptoms of inattention and/or hyperactivity/impulsivity and is associated with significant impairment across several domains, particularly when untreated. ADHD can often persist into late adolescence and adulthood, conferring an increased risk of co-occurring psychiatric problems such as alcohol and substance use disorders (AUDs, SUDs). This chapter reviews the etiology of ADHD, risks and outcomes across the lifespan, prevalence and diagnostic challenges of co-occurring ADHD and SUDs (ADHD+SUD), and pharmacological and non-pharmacological treatment approaches for this challenging population.

95.1 Introduction

Attention-Deficit/Hyperactivity Disorder (ADHD) is a neurodevelopmental disorder associated with impairing symptoms of inattention, impulsivity and/or hyperactivity across multiple settings [2]. Often persisting into adulthood, those with ADHD are at greater risk of developing an alcohol or substance use disorder (AUD or SUD) when compared to their non-ADHD peers [34]. Further, those with ADHD often initiate alcohol and/or substance use at an earlier age, escalate their use at a faster rate, are more likely to engage in polysubstance use, and have higher rates of relapse in treatment settings [15, 26, 34]. Individuals with co-occurring ADHD and SUD (ADHD+SUD) present a uniquely challenging clinical population to both identify and treat given the numerous overlapping symptoms and the effects one diagnosis has on the presentation of the other. Etiology, phenomenology, risk factors, and outcomes in the ADHD+SUD population will be reviewed. Clinical approaches for screening, diagnosing, and treatment for ADHD+SUD will be discussed, including pharmacotherapy and psychosocial treatments.

95.2 ADHD & SUD Prevalence Rates

According to the *Diagnostic and Statistical Manual of Disorders – 5th Edition* (DSM-5), Attention-Deficit/Hyperactivity Disorder (ADHD) is a neurodevelopmental disorder distinguished by symptoms of inattention and hyperactivity/impulsivity, across multiple settings, and often associated with impairment and/or reduced functioning in academic, social, or vocational domains [2]. In children and adolescents, the estimated worldwide prevalence of ADHD is 5.29% [37], based on a meta-analysis spanning three decades and including data from non-Western regions. In the United States (US), the prevalence of pediatric ADHD diagnoses is higher at 9.4% [10].

For many individuals, ADHD symptoms can remit over time, although up to 65% of those diagnosed in childhood have reported symptoms in adulthood [13]. The estimated global prevalence of ADHD in adults is 3.4%, with significant variation between countries (e.g., 1.2% in Spain, 7.3% in France) [16]. In the US, the estimated prevalence of adult ADHD diagnoses ranges from 2.5% to 4.4% with up to 40% of these adults presenting as "severe" [24]. Importantly, even for those who may not meet full DSM-5 criteria for persistent ADHD in adulthood, these individuals experience significant impairment [13]. Lastly, the variety in estimated ADHD prevalence rates across countries may not be indicative of the true percentage of affected individuals as much as it may reflect the mental health resources available to identify, diagnose and treat individuals with ADHD.

ADHD is associated with a number of adverse health and functional outcomes in adolescence and adulthood, including an increased risk for an alcohol use or substance use disorder (AUD or SUD) [7]. This risk is largely attributed to shared genetic vulnerabilities and/or environmental influences, some which increase the likelihood of delinquency in adolescence [33].

The prevalence of co-occurring ADHD and SUD can vary significantly by country and treatment setting. Among substance use populations, rates of co-occurring ADHD can range from 7.6% (Hungary) to 32.6% (Norway) [45]. High rates of ADHD have been observed in both treatment and non-treatment seeking SUD populations, with an estimated prevalence of 25.3% (C.I. 20.0–31.4%, $I^2 = 93.2\%$) in adolescent and 21.0% (C.I. 15.9–27.2%, $I^2 = 91.3\%$) in adult populations [46]. While identifying ADHD can pose its own challenges, as symptoms of inattention and hyperactivity can change in presentation over time, diagnosing ADHD in substance use

populations presents perhaps a greater challenge due to neural changes in attention, inhibitory control, motivation, and reward pathways associated with both acute and prolonged alcohol and/or substance use.

95.3 ADHD Diagnostic Criteria & Phenomenology

ADHD is a neurodevelopmental disorder with considerable heterogeneity in its presentation. Persistent symptoms can evolve over the course of development and manifest differently in children, adolescents, and adults. Continued research has resulted in modifications to the DSM diagnostic criteria for ADHD in the DSM-5 [2]. Criterion A is largely unchanged; the authors have added additional behavioral examples of how symptoms may manifest in adolescence and adulthood, as well as reduced the minimum number of symptoms required in each domain for older adolescents and adults, from six to five [11]. Age of onset, or Criterion B, was changed from before the age of 7 to before 12 years old. This was to account for several factors that resulted in cases of ADHD not identified until adolescence or early adulthood. For example, some individuals with ADHD may not experience significant impairment due to highly structured environments. Then, when their academic and/or organizational demands exceed their resources, the ADHD symptoms become more prominent and adversely affect academic performance, prompting clinical intervention.

Criterion C was modified such that the requirement of "evidence of impairment" was changed to "evidence of symptoms" in two or more settings. The criterion for "clinically significant" impairment (Criterion D) was also updated so that individuals must instead indicate that their symptoms have reduced the quality of their psychosocial, academic, and vocational functioning [2, 11]. Criterion E was adjusted so that Autism Spectrum Disorder (ASD) was no longer exclusionary to an ADHD diagnosis, given clinical and research evidence that these two disorders can co-occur. Lastly, rather than "subtypes," the different specifiers for ADHD are called "presentations," to reflect how ADHD symptom manifestations can evolve over the course of development (e.g., a child with ADHD may grow into a less hyperactive but more inattentive adult) [2, 11]. In summary, children and adolescents must display at least six symptoms of inattention and/or six or more symptoms of hyperactivity/impulsivity such that they cause distress and/or reduce functioning in at least two settings. At least some of these symptoms must have been present before the age of 12. For older adolescents and adults, only five symptoms in one or each category is required for a diagnosis of ADHD [2].

95.3.1 ADHD in Childhood

Symptoms of ADHD can look different across developmental stages due to a confluence of biological maturation and environmental factors. Children, who are physically and mentally immature, require significant adult supervision and scaffolding, with parents, caretakers, and/or authority figures structuring their schedules and keeping track of personal belongings and important dates. Thus, inattention in young children may not be as evident until academic demands exceed their capacity and they begin to struggle in keeping up with lectures, making careless errors in their schoolwork (not checking answers, not writing their name or the date), forgetting important dates, misplacing assignments, losing notebooks, jackets, and daydreaming. Inattentive children are easily distractible, have difficulty following multi-step instructions, and often take longer to complete assignments. They may need things repeated multiple times, have trouble being ready on time, and have messy rooms and/or desks or bookbags. Many parents of children with ADHD may deny that their children have these symptoms until queried about how much they are involved in structuring the lives of their children. Parents find themselves breaking down complicated tasks into smaller, more manageable ones, frequently checking in, communicating often with teachers, constantly reminding their

child of important dates/assignments, scheduling play dates, and more, past the age when this is typically necessary. Other symptoms of inattention include avoiding tasks that require a lot of concentration, such as reading and/or writing. Children with ADHD symptoms of inattention may also be easily distracted by external stimuli and may have difficulty following along in classes unless they are seated in the front of the class.

Children with symptoms of hyperactivity/impulsivity are probably the most easily identifiable early on, as they tend to require more supervision and engagement than their peers. While more severe cases may be referred for an evaluation in Pre-K or Kindergarten, typically hyperactive children have difficulty with the transition to the more structured and sedentary classroom experience of elementary school and beyond. Children with hyperactivity/impulsivity often stand when they should sit, run instead of walk whenever possible, grab at items without asking, interrupt others and blurt out answers, have difficulty waiting their turn in games or even for the bathroom or water fountain. They may have trouble playing quietly, such that they are one of the loudest voices you would hear on the playground. Children with hyperactivity/impulsivity often talk a lot and can be distracting to their peers. They have trouble controlling their impulses and regulating their emotions compared to their peers, so they present as emotionally immature, which can make socializing a challenge. Novelty and sensation-seeking behaviors with poor consideration of adverse consequences or even the desire for social acceptance can result in older children and adolescents experimenting with alcohol and substances at an early age.

95.3.2 ADHD in Adolescence & Adulthood

Physiological and neurological changes coupled with increasing social and academic demands play significant roles in how ADHD symptoms manifest across the lifespan. The Diagnostic Interview for ADHD in adults, 3rd edition (DIVA-5) is a semi-structured interview used to diagnose ADHD in adults based on DSM-5 criteria [25] and provides useful examples of ADHD symptom presentations in childhood and adulthood. While children are frequently supervised and follow structured schedules, academic and social demands increase as they get older.

Adolescents are physically more mature and typically enjoy a greater degree of independence than children. Therefore, with less scaffolding, impairment related to symptoms of inattention may become more evident. As academic demands become greater, teens with ADHD may struggle with meeting deadlines and completing assignments. They may forget test dates, misplace handouts, and/or complete assignments incorrectly. Adolescents may engage in truancy due to boredom, avoidance of tasks they find challenging, and/or difficulty sitting still in lectures, placing them at risk for delinquency [33]. Although they have more autonomy, adolescent brains undergo an important period of neural development that can result in more impulsive, risky behaviors [3]. Those with ADHD are at an increased risk for poor, impulsive decision-making without considering negative consequences of their behavior. Thus, adolescents with ADHD may have poor sleeping and eating habits, engage in thrill-seeking behaviors such as risky sex practices, reckless driving, and experimenting with drugs and alcohol.

By late adolescence and adulthood, individuals with ADHD have likely found ways to adapt to their cognitive and behavioral limitations, so the symptoms may look different from those observed in childhood. For example, an adult who has a history of making careless mistakes may work slowly on detailed tasks to avoid making errors, although others may still miss details or make errors when working too hastily on a task. Other examples of inattention symptoms in adults include difficulty sitting through a film or reading a book (unless the topic is of particular interest), trouble following lectures or conversations and/or changing the topic of conversation, asking questions that have already been discussed, difficulty completing administrative tasks, struggling to finish a task through to the end without being distracted and/or

initiating a new task before the first is completed. For example, someone may forget to put wet laundry in the dryer after becoming engaged in another activity.

Additionally, adults with inattentive symptoms have difficulty with planning and time management. They may often arrive late, double-book events, have difficulty meeting deadlines, and/or have a messy or disorganized space. Adults with inattentive symptoms may also avoid doing tasks that require a great deal of concentration or organization or that they may find dull, such as completing reports, reading, and administrative tasks. Those who are forgetful often misplace items such as keys, wallets, glasses, etc. They spend a great deal of time looking for items and often leave personal items behind. They may also frequently forget appointments and can be late in paying bills and running household errands.

Hyperactivity in adults also looks different than in children, particularly since adults have more autonomy. For example, those who have difficulty sitting still for long periods of time may take frequent bathroom breaks during meetings, fidget with their hands and/or feet, or skip lectures and long meetings altogether. Restless adults may often appear that they are in a hurry, due to trouble relaxing and feeling like they always need to do something. Some adults often have trouble doing activities quietly and speak loudly at inappropriate times and settings. Those who talk excessively find it difficult to stop talking, do not provide space for others to participate in the conversation, and often use more words than necessary to communicate. Adults with hyperactive/impulsive symptoms often interrupt others, finish another's sentences, answer questions before the person is finished asking, may be tactless and say what they are thinking. Adults who are impatient and/or have difficulty waiting in lines may struggle during delays and traffic congestion. They may avoid driving altogether due to this frustration. Additionally, they may leave places where there is a long wait for the bathroom or for service. These individuals may have frequent job changes and numerous short-term relationships because of impatience.

In both children and adults, these symptoms are not only disruptive in school, work, and social settings, but they can make it difficult to maintain jobs and interpersonal relationships, place individuals at risk for physical accidents (such as driving offenses) and mental health disorders such as depression, anxiety, and substance use problems [7, 33].

95.3.3 Etiology of ADHD

Research on the etiology and phenomenology of ADHD is ongoing, although studies have supported a combination of environmental and genetic risk factors contributing to the likelihood of an ADHD diagnosis.

Twin and familial risk studies have long established that ADHD is an exceedingly heritable and phenotypically diverse neurodevelopmental disorder. Familial risk studies have shown that having a first-degree relative with ADHD greatly increases one's odds of developing the disorder [51]. Depending on the methods, used, the heritability of ADHD is estimated at 76% based on a meta-analysis of 20 twin studies [14], or between 77% and 82% in a sample of 1,480 prospectively followed Swedish twins [6].

95.3.4 Neural Correlates of ADHD

Continued research on the phenotypically observed symptoms of inattention, impulsivity, and hyperactivity characteristic of ADHD has sought to identify corresponding cognitive impairment, structural and functional abnormalities, and associated neural pathways. Neuropsychological studies, particularly in children, have been inconsistent, in part due to the varying rates of prefrontal brain maturation. Broadly, neuropsychological deficits in areas of attention and executive function, memory, motivation and reward systems, timing, and inhibitory control have been implicated [1]. Structural imaging studies comparing individuals with and without ADHD have found reduced overall brain volume and 3–5% reductions in gray matter in

both pediatric and adult ADHD groups [5], specifically in frontal, parietal, striatal, and cerebellar regions, areas associated with attention and executive function [9].

Functional imaging and positron emission tomography (PET) studies have linked these structural differences between ADHD and control groups to variations in connectivity between neural networks and to cognitive performance in neuropsychological tasks. Dopamine pathways have been a primary focus of neural models and dopamine transporters targets for genetics studies. Aberrant connectivity between striatal pathways involved in attention and executive function, and alterations top-down connectivity from the pre-frontal cortex (PFC) to sub-cortical areas involved in reward and motivation have been observed [9].

Pathways originating from the pre-frontal cortex have been a focus in structural and functioning imaging studies because of its role in attention, executive function, motivation, and other cognitive processes. It is important in ADHD phenomenology as well as in addiction and compulsive behavioral disorders (such as gambling).

Different regions of the PFC have been conceptualized as "hot" executive function (EF) or "cool" EF processes. Accordingly, PFC regions associated with planning, attention, inhibition, cognitive flexibility, and working memory (dorsolateral prefrontal cortex and inferior frontal cortex), represent the "cool" EF pathways whereas regions associated with reward-based tasks and motivation (ventromedial prefrontal cortex and the orbitofrontal cortex), are considered the "hot" EF pathways [1, 9]. Following the hot/cool EF systems framework, researchers propose that cognitive impairment and impulsive behaviors characteristic of ADHD are the result of failures in top-down regulation of "hot" EF functions by the "cool" EF processes of inhibitory control and attention regulation. Another possibility is that *both* "hot" and "cool" EF systems are affected by inadequate connectivity between regions, such that heightened sensation-seeking and reward salience regulated by the mesoaccumbens region overwhelms an underdeveloped PFC, resulting in poor planning and inadequate inhibitory control [44].

95.3.5 SUD Diagnostic Criteria & Risk

The DSM-5 modified its diagnostic criteria for alcohol and substance use disorders in several important ways. First, rather than distinguishing between substance-specific abuse and dependence, individuals are diagnosed with an alcohol (AUD) or substance use disorder (SUD), with the substance or class of substance specified. Severity of the presentation is determined by the number of symptoms out of a total of 11, such that the presence of two to three symptoms indicates a mild presentation, four to five symptoms is moderate, and six or more symptoms denotes a severe presentation [2].

To receive a diagnosis of a SUD, an individual must present with a problematic pattern of alcohol or substance use resulting in significant impairment or distress as evidenced by the presence of at least two of the following symptoms during a 12-month period:

1. Use more than intended
2. Repeated failed attempts to reduce or limit use
3. Increased time spent obtaining, using, or recovering from effects of substance
4. Craving
5. Less time meeting occupational, social, or personal responsibilities because of use
6. Continued use despite problems with family and/or others
7. Use of substance in risky situations
8. Continued use despite worsening psychological or physical problems
9. Giving up occupational, social, or recreational activities in favor of substance use
10. Tolerance, as indicated by requiring a greater amount to have the same effect or having a reduced effect with the same amount
11. Withdrawal (symptoms vary by substance, but typically manifest as physiological and/or psychological changes)

Thus, to meet diagnostic criteria for a SUD, individuals must experience repeated negative consequences in multiple settings due to their use. Individuals with ADHD with poor planning and time management skills, sensation seeking temperaments, and problems with inhibitory control may be more likely to experience these adverse outcomes despite comparable rates of drug and/or alcohol use as their peers.

95.4 ADHD & Co-occurring Substance Use

This theoretical model of the neural underpinnings of ADHD is an important one to consider in terms of vulnerability to developing an SUD in adolescence. Adolescence marks an important period in neural development, specifically one in which the PFC lags behind subcortical brain regions in maturation [3]. Thus, adolescents can exhibit poor planning, impulsive and risky behavior typically characteristic of ADHD. This also marks a vulnerable period in adolescents who initiate drug and alcohol use, as excessive use of these substances can have a lasting impact on neural development [3]. Children and adolescents with ADHD may then have an increased risk of drug and alcohol use initiation and escalation due to already vulnerable brain connectivity in regions regulating attention and reward. Individuals with ADHD are at an increased risk of developing an SUD [7], with longitudinal studies consistently finding that individuals with ADHD tend to initiate drug and/or alcohol use earlier and escalate their use faster than their non-ADHD peers [34]. Although some studies have suggested that this risk is mediated by a co-occurring conduct disorder [33], others have shown that ADHD confers a risk for an SUD or AUD independent of conduct problems [41].

One of a number of diagnostic challenges with co-occurring ADHD and SUD is determining whether alcohol or substance use exacerbate pre-existing ADHD symptoms or whether symptoms of inattention and/or hyperactivity/impulsivity were caused by prolonged use of psychoactive substances. Individuals with co-occurring ADHD and SUD are at an increased risk of adverse consequences, particularly with alcohol. A 2012 study on college students with and without ADHD showed that those with ADHD reported similar rates of alcohol consumption but greater alcohol-related impairment than their non-ADHD peers [39]. One compelling study of alcohol effects on inhibitory control in a go-no-go task found that adults with ADHD were more sensitive to the disinhibiting effects of alcohol, thus putting them at increased risk for impulsive, reckless behavior when intoxicated [48]. However, this study was limited by a small, largely male sample. Thus, additional research is needed.

95.4.1 Assessment and Diagnosis of Co-occurring ADHD & SUD

The diagnostic assessment of ADHD is challenging, as it requires a systematic review of symptoms and impairments across one's lifetime and the clinical presentation of ADHD itself may interfere with the evaluation process [19]. The diagnostic complexities increase when screening and assessing co-occurring SUD in individuals with ADHD and vice versa.

Guidelines for evaluating ADHD+SUD [8, 28, 29] note that a standardized diagnostic clinical interview should be conducted by a clinician with training in addiction, differential diagnoses of ADHD, and the specific population (pediatric vs. adult). In addition to toxicological assessments and common substance use screening measures, feasible and reliable ADHD screening instruments have been used in ADHD+SUD populations with good sensitivity and specificity [8, 28]. The most commonly used screening measures include the Adult ADHD Self-Report Scale Short Version (ASRS-SV), the Conners' Adult ADHD Rating Scale (CAARS), and the Wender Utah Rating Scale (WURS) that assesses childhood ADHD.

A comprehensive evaluation with the patient and collaterals (i.e., family or partner) aims to obtain the history of ADHD symptoms before the initiation of substance use and the presence

of ADHD symptoms during periods of abstinence across multiple settings [8, 29]. Available diagnostic interviews include the Conners' Adult ADHD Diagnostic Interview for DSM-IV (CAADID) - the gold standard for assessing co-occurring ADHD and SUD, the Structured Clinical Interview for DSM-5 (SCID-5), and the Diagnostic Interview for ADHD (DIVA), which has yet to be validated in SUD populations [8]. For clinicians, under- and over-diagnosing ADHD in SUD population is a concern given the tendency for individuals to minimize or inaccurately recall substance use patterns and periods of abstinence as well as recall childhood history and underreport current ADHD symptoms, potentially due to low self-awareness, a diminished ability to perceive impairments as related to ADHD symptomology, or due to the acute and/or chronic effects of substance use [8, 26, 28]. One study found that individuals with AUD and co-occurring ADHD seemed to underreport symptoms on ADHD self-report measures [26]. Recent or current substance use can also confound the diagnostic process. Research notes various options: one can initiate the evaluation once serious intoxication and withdrawal symptoms cease or allow a 2 to 4-week period of abstinence [8]. The setting of the evaluation will also play an important role, as abstinence may be difficult to achieve in outpatient treatment. Additionally, while neuropsychological assessments measuring attention, planning, organization, and memory capacities may not be able to diagnosis ADHD [36], they can help provide additional information about core ADHD-related dysfunctions [19, 29, 36].

Mental, physical, and psychosocial functioning should be assessed to understand the impact of ADHD and SUD impairments, independently and when they co-occur. Many educational and professional consequences associated with ADHD (e.g., inconsistent performance, difficulties with tasks that challenge executive function capacities) can also be found in SUD populations. Notably, compensatory strategies have often been used by patients and others for many years across multiple settings to address and ease ADHD symptoms, thus obscuring the clinical picture. A medical examination should also be incorporated to evaluate potential somatic conditions (i.e., neurological, endocrine and metabolic disorders) that may mimic ADHD symptoms and to assess for contraindications related to pharmacological ADHD+SUD treatments [29]. Lastly, Matthys and colleagues [29] highlight the need to account for differences in gender, socioeconomic status, and culture when evaluating and diagnosing ADHD and SUD.

95.5 Pharmacological Treatments for ADHD+SUD

Psychopharmacotherapy, in the form of psychostimulant and non-stimulant medication, is the first-line treatment for ADHD and has been proven efficacious in reducing symptoms and associated problems in children and adults. In SUD individuals, clinicians often raise valid concerns regarding prescribing medications in the context of addiction, given the potential risk for abuse, difficulties with medication compliance, and the higher tolerance that may require doses higher than those administered in clinical trials [27]. Yet, evidence shows initiating psychostimulant treatment of ADHD earlier in childhood can reduce the risk of subsequent substance use compared to those who begin treatment at a later age [38]. Early identification and treatment of ADHD in childhood appears to be protective against substance use escalation and poor outcomes [20, 32]. When addressing ADHD+SUD in SUD treatment settings, additional challenges arise that affect treatment adherence and potentially increase rates of relapse: poly-substance use, riskier drug use behaviors and more severe SUD symptoms than their non-ADHD peers, as well as additional psychiatric comorbidities [27, 50]. Furthermore, SUD individuals are often excluded from ADHD studies and practitioners may be hesitant to treat and prescribe ADHD medications due to fears of misuse. Research has largely shown psychostimulants to be safe and effective in treating ADHD symptoms in SUD populations, with low abuse potential, particularly for longer acting formulations [4, 8, 12, 17, 28, 29].

95.5.1 Stimulant Medications

Amphetamine (AMP) is a potent central nervous system stimulant whose primary mechanism of action is to stimulate neurotransmitter release and block the reuptake of dopamine [17, 28]. Amphetamine analogues are available and widely used as an ADHD treatment although one, methamphetamine, is rarely prescribed due to concerns of non-medical use and diversion. Lisdexamfetamine (LDX) is an efficacious, US Food and Drug Administration (FDA) approved AMP analogue ADHD stimulant treatment (30–70-mg per day dosage) that remains a therapeutically inactive molecule until after oral ingestion and is associated with a longer duration of effect and reduced abuse potential in individuals with a history of stimulant abuse [17, 23].

Methylphenidate (MPH), another AMP analogue psychostimulant, is available in immediate and extended-release formulations for the treatment of ADHD. This drug allows for increased dopamine and norepinephrine availability, which have been shown to impact brain regions associated with cognitive, executive functions, risky decision making, and regulation of reward processes in preclinical and human studies [17, 28]. Common side effects of AMP and MPH are mostly related to their stimulant properties and include insomnia, palpitations, increased heart rate and elevated blood pressure, nervousness, emotional lability, and gastrointestinal disturbances such as nausea and vomiting. Rare but serious adverse effects include severe hypertension, seizures, psychosis, and myocardial infarction. Active substance users pose an additional challenge when treating the effects of ADHD. In ADHD+SUD populations, oral MPH has shown efficacy in treating ADHD symptoms without producing significant effects of euphoria in intravenous cocaine and methylphenidate users [27]. A recent systematic review of RCT's for DSM-IV ADHD and co-occurring stimulant dependence [49] note that Osmotic-Release Oral Systems (OROS)-MPH, a long-acting formulation of MPH, in higher than usual doses (e.g., up to 180-mg per day) for longer durations can effectively treat ADHD and lessen use in amphetamine users. For adolescents known to misuse stimulants or suspected of selling or diverting medication, research suggests prescribing a long-acting stimulant, such as OROS-MPH or LDX, given its lower abuse potential [20, 23]. Results from two national CTN studies found no differences in subjective levels of euphoria with OROS-MPH, or in patterns of medication misuse in adolescents with and without SUD [27]. While these findings are promising, there is a need for clinical and dosing guidelines specific to ADHD and SUD populations. One study of Swedish adult ADHD patients treated with MPH found those with co-occurring SUD were prescribed 40% higher doses 2-years into treatment than their non-SUD peers [43]; those using stimulants or diagnosed with co-occurring DUD and AUD had a significant increased risk of exceeding the FDA recommended maximum dose of 72-mg per day (up to 360-mg of MPH daily).

The FDA has approved a transdermal methylphenidate system (MTS) for ADHD treatment. This drug-in adhesive matrix patch (available in varying sizes and corresponding dosages) delivers a once-daily MPH dose over the course of 9-hours [17, 30]. Research has found the MTS to be safe and efficacious in children and adolescents across multiple settings and well received by parents; in adults, it was found effective in treating ADHD [17, 30]. For individuals who have previously used oral MPH medications, have difficulty swallowing pills, or have concerns about competitive metabolism of other medications, MTS appears to be an effective alternative. Adverse reactions to MTS include mild dermal or application site reactions, decreased appetite, and headaches but are otherwise similar to those of other MPH formulations. One study of adults with ADHD and a history of illicit stimulant use found MTS to be safe and effective at reducing ADHD symptomology and stimulant use over 8 weeks, although participants did consume other drugs [30].

Lastly, Modafinil is an FDA-approved stimulant drug that acts as an histamine, unlike typical stimulants. Modafinil primarily promotes wakefulness and treat sleep disorders; its utility in treating ADHD lies in its ability to boost cogni-

tive functions while improving the symptoms of ADHD without resulting in hyperarousal [31]. While Modafinil RCTs have only shown slight efficacy for children and adults, its lack of activation in regions that mediate the reward system and its single route of administration (oral) results in a low abuse potential, allowing it to serve as an alternative, second line treatment for ADHD, particularly in SUD populations [31]. Modafinil has demonstrated reductions in substance use in cocaine and methamphetamine dependent individuals [31].

95.5.2 Nonstimulant Medications

ADHD symptoms have also effectively been treating with nonstimulant medications. With the exception of atomoxetine, a first line FDA approved nonstimulant ADHD medication, nonstimulants are considered off-label, second-line ADHD treatments [12, 17, 28]. In ADHD+SUD adults, nonstimulant medications have shown efficacy in reducing ADHD symptoms, with mixed results in reducing substance use.

Atomoxetine (ATX) increases norepinephrine and dopamine in the frontal cortex to effectively treat inattention and impulsivity symptoms in children, adolescents, and adults with ADHD [4, 12, 17, 49]. The therapeutic effects of ATX are produced more gradually than with stimulants, often taking several weeks to manifest. Furthermore, ATX may be used with individuals who are unresponsive to or have difficulty tolerating stimulants [17]. Common side effects of ATX include sedation, appetite suppression, nausea, vomiting, and headache. Rare but serious side effects reported in children and adolescents include increased suicidal ideation and hepatotoxicity. ATX has no known non-medical use potential and is less vulnerable to abuse and diversion, compared to stimulants, so it is an appealing medication option in the treatment of ADHD+SUD. Although published data are limited, the pharmacology of ATX can be associated with improved ADHD symptoms and reduced substance use [49]. An RCT comparing the efficacy of ATX versus placebo in cannabis dependent individuals found that ATX in combination with Motivational Interviewing (MI) was effective at reducing some ADHD symptoms, but did not significantly reduce substance use [12]. Similar results were seen in an open-label trial of ATX in adults with ADHD and cocaine dependence [29]. Another RCT of ATX versus placebo in ADHD+SUD adolescents found no significant differences between groups on these factors of interest [12].

Antidepressants have been considered for off-label treatment of ADHD. Bupropion, a dopaminergic antidepressant tricyclic antidepressant, which blocks the reuptake of norepinephrine, demonstrated less effectiveness than stimulants and evidenced no benefit over placebo in SUD patients [4, 8, 28]. In an adolescent sample with ADHD+SUD and co-morbid mood diagnoses, sustained-release bupropion reduced ADHD symptoms and substance use [29]. Of note, monoamine oxidase inhibitors (MAOIs) are contraindicated in SUD populations given the potential for hypertensive crises associated with tyramine-containing foods and medications, limiting their utility [28].

Guanfacine extended release, a norepinephrine alpha-2 agonist, is another non-stimulant medication shown to be nearly as effective as stimulants in improving ADHD symptomology in children and adolescents after just 1-week of administration [22, 28]. While guanfacine has limited findings in adult populations, it has demonstrated an ability to further reduce ADHD symptoms when co-administered with stimulants among children and adults who have had a limited response to stimulants alone [22]. Common side effects of guanfacine include somnolence, headaches, sedation, and hypotension. Lastly, extended release Clonidine, a non-stimulant molecularly similar to guanfacine, evidenced a reduction in ADHD symptoms for those with only a partial response to stimulants [28]. However, it is generally less effective than stimulant and other FDA-approved nonstimulant medication [28]. Side effects include sedation, dry mouth, depression, confusion, electrocardiographic changes, and hypertension with abrupt withdrawal.

Luo and Levin [27] suggest computational modeling as a method to identify clinical, genetic and biological markers that support patient-treatment matching and precision addiction medicine, facilitating individually tailored treatment ADHD+SUD patients. Similarly, research has assessed whether the development of a risk score can help clinicians select individualized ADHD treatment options based on patient and diseases characteristics [40]. Indeed, findings from numerous studies suggest certain treatments are optimal for specific subpopulations. OROS-MPH was found effective at reducing substance use in adolescents with co-occurring CD [4] and revealed improved nicotine abstinence in combination with a nicotine patch for adults with more severe ADHD [27], while ATX may be particularly beneficial in ADHD and AUD populations [8, 12]. In patients with high-risk scores of OROS-MPH failure, characterized by older age, higher scores on ADHD rating scales, and longer duration of symptoms, the benefit of LDX was more pronounced than the average benefit of LDX over OROS-MPH observed in the overall population [40]. Developing a risk score to guide optimal treatment for ADHD+SUD individuals would be very beneficial given the varied clinical presentations and patterns of substance use in this population.

95.5.3 Psychosocial Interventions for ADHD+SUD

Challenges for clinicians working with ADHD+SUD individuals include deciphering between symptoms associated with ADHD and those with SUD and developing a patient's capacity to link the two to support, integrate, and optimize long-term treatment outcomes. Evidence-based psychosocial substance use treatments, such cognitive behavioral therapy (CBT) and relapse prevention (RP), emphasize the identification of beliefs and behaviors that trigger and maintain substance use. ADHD psychosocial treatments include specific psychoeducation and/or CBT that focus on manualized skills training targeting executive functions, regulating emotions, impulsive behaviors and prosocial competence as well as negative cognitive schemas that maintain poor self-efficacy, avoidance, procrastination, and psychological mood symptoms [25]. Psychosocial treatments for ADHD have demonstrated effectiveness at reducing ADHD symptoms, its related functional impairments in daily living, and associated cognitive distortions and emotional dysfunctions [25].

There is a lack of research assessing the efficacy of psychosocial treatments for ADHD+SUD. Given that ADHD-related impairments in cognitive processes can affect gains made in psychosocial SUD treatments, integrating interventions for ADHD+SUD populations that target cognitive and executive functioning deficits may support progress and success in skills-based behavioral interventions, particularly for adolescents. A recently published RCT compared CBT for SUD only and Integrated CBT in 119 Dutch ADHD+SUD individuals receiving SUD treatment [47]. Integrated CBT consisted of 15 weeks of individual sessions employing motivation enhancement, relapse prevention, and coping skills to target SUD and planning skills, problem-solving skills and managing emotions for ADHD. With an additional five sessions, results showed a reduction in ADHD symptoms post-treatment; as these participants were predominantly not on ADHD medication, these findings hold promise for the efficacy of specific evidence-based psychosocial ADHD+SUD interventions.

For ADHD individuals, coaching offers a collaborative/mentoring approach to providing support and feedback for implementing ADHD skills and improving functioning in daily living; uncontrolled studies assessing its clinical efficacy have found preliminary evidence for positive outcomes [25]. Additionally, Dialectical Behavior Therapy (DBT) and mindfulness-based therapies (MBT) have been used to address ADHD symptomology and its associated dysfunctions [25]. Group DBT was modified to address ADHD+SUD in Swedish men in compulsory care for severe SUD [35]. Results showed that while low treatment acceptability and feasibility was low compared to outpatient studies, likely due to the more

severe clinical characteristics and inpatient setting, patients reported increased general well-being and decreased ADHD symptoms and externalizing behaviors [35]. A meta-analysis of nine RCT studies assessing Mindfulness-Based Relapse Prevention (MBRP), an intervention that integrates traditional substance use treatment with meditation practices to target the psychological distress associated with craving, withdrawal, and/or encountering triggers that leave individuals vulnerable to relapse, in adults with SUD did not find that it improved long-term substance use outcomes or have a greater clinical effect beyond comparable treatments, such as CBT and RP [18]. However, given the presence of target symptoms, mindfulness and MBRP may be an area of future exploration for co-occurring ADHD+SUD.

Reviews and census statements on treating ADHD and ADHD+SUD recommend a multimodal approach, thus psychosocial treatments are best used in conjunction with pharmacotherapy [25, 29]. Results from an RCT examining the efficacy of CBT or relaxation with educational support for adults with persistent ADHD on medication show this intervention reduced ADHD symptoms and maintained gains 12-months post-treatment [12]. A 16-week, multi-site, RCT of OROS-MPH + CBT for ASU versus CBT for ASU + Placebo in adolescents demonstrated overall comparable significant decreases in ADHD symptoms and drug use, but the combined active treatment group had better secondary outcomes, greater drug use reduction, and greater self-reported improvements in problem-solving abilities and focused coping skills [4, 27, 49]. Involving supportive family/partners is an important component of ADHD treatment, particularly for adolescents. Family-based ADHD interventions for adolescents have been developed and appear promising for treating ADHD+SUD in a developmentally appropriate manner. The Medication Integration Protocol (MIP) integrates medication into behavioral treatment planning for adolescents with ADHD and is therefore a useful tool for ADHD+ SUD populations [21]. The MIP includes ADHD and medication psychoeducation, reframing patient issues into family problems with potential family solutions, and medication management to enhance adherence. Supporting Teens' Academic Needs Daily (STAND), another psychosocial ADHD treatment that has yet to be used with co-occurring adolescent SUD but may be applicable in this population, is an 8 to 10-week protocol integrating behavioral management and academic training to emphasize organization skills, parenting skills, and family problem solving [42].

95.6 Conclusions

Independently, ADHD and SUD are associated with a number of adverse health and functional outcomes in adolescence and adulthood. Research shows that ADHD confers significant risk for PSUDs and is overrepresented in SUD populations; thus, ADHD+SUD are at significant risk. Yet, individuals with this comorbidity are underserved and present diagnostic and treatment challenges due to shared cognitive, emotional, and behavioral features of both disorders. Validated screening instruments are useful in identifying probable ADHD and SUD, as patients often underreport symptoms and/or lack insight into associated problems, and should be followed by a thorough clinical or diagnostic interview to better assess the impact of ADHD symptomology on SUD and tease out the effects of active or chronic SUD on ADHD and general functioning. While pharmacological treatment, primarily psychostimulant medication, is the first line and most effective treatment for ADHD, clinicians may be reluctant to prescribe them to individuals with co-occurring SUD due to fears of non-medicinal use, abuse, and diversion. Published findings on the efficacy of stimulant and non-stimulant medication in adolescents and adults with ADHD+SUD demonstrate multiple options available that reduce ADHD and/or SUD symptoms and improve functioning. Psychosocial and combined interventions for ADHD+SUD have also been shown to be effective at targeting the emotional and behavioral difficulties associated with this comorbidity. In conclusion, a review of research and interventions regarding treating

ADHD+SUD populations underscore the need for additional research, potential revisions of dosing guidelines, and further development of diagnosis specific and individualized treatment options.

Abstract

Addictive disorders and personality disorders (PD) have been connected since the early days of psychiatry to such an extent that initially substance use disorders (SUD) were conceptualized as personality pathology rather than distinct disorders in and of themselves. Admittedly, these two sets of disorders have

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment*, https://doi.org/10.1007/978-3-030-36391-8_96

many common features and indeed frequently co-occur in the same individual. Similarly, the presence of one disorder significantly impacts prognosis of the other disorder. Individuals with comorbid PD and SUD usually present with an earlier onset, an increased addiction severity, and greater impairment in functioning, and failure to accurately diagnose PDs could have an impact on their recovery and clinical prognosis. Severity of symptoms, resistance to treatment, and increased risk of relapse can potentially result in the presence of a comorbid personality disorder in individuals with addictive disorders. There is only a small amount of data available on treatment approaches for co-occurring addiction and PDs, but it seems that these patients are likely to respond to structured integrative psychosocial care and evidence-based relapse prevention pharmacotherapy for addiction. This chapter explores the interface between addictive disorders and personality disorders, attempting to highlight the complex interaction of the respective disorders and how this might inform treatment choices, specifically the need for comprehensive approaches for patients suffering from PDs and addiction, who tend to be stigmatized and marginalized.

96.1 Introduction: Conceptualization and Evolution of Personality Disorders

The initial Diagnostic and Statistical Manual of Mental Disorders (DSM) was conceptualized and actualized in 1952. Upon the DSM's inception, psychiatrists were generally consigned to hospitals and asylums for the severely mentally unwell and the focus was generally pragmatic rather than academic. There was minimal interest in nosology beyond practical uses. Classification of mental disorders was inclined to be broad and fluid. Consequently, there was much overlap of diagnostic groupings and radical differential diagnoses from one psychiatrist to the next. With the introduction of mental disorder classifications in the DSM, psychiatry began to have statistics. This brought into awareness prevalence rates, demographic patterns, disease courses and as a result, mental health public policy and increased funding came into play [9]. From this, professionals began to be able to better screen, assess, treat and monitor people who met criteria for psychiatric diagnoses. Initially, the DSM-I defined alcoholism as a form of sociopathic personality disturbance. The first actual mention of personality disorders (PDs) was in the DSM-II (1968) and at that time substance abuse was defined as a personality disorder [15]. In DSM-III (1980) and the successive DSM III-R (1987) and DSM-IV (1994), PDs were defined as distinct types, assembled into three clusters, positioned on different axis (Axis II). This categorical approach was in step with the medical model previously brought forth by Emil Kraepelin. Borderline and narcissistic PDs, which came into play in the DSM-III, were revised from psychoanalytical concepts [15]. With the introduction of the DSM-5, the multi-axial classification was dropped as it had become apparent that rather than allowing diagnoses on Axis II to receive the attention necessary by highlighting them as originally intended, the system had inadvertently resulted in even further marginalization of these diagnoses. By eliminating the Axis I and II dichotomy it was hoped to reverse this trend and promote a sense of equal legitimacy between various diagnoses.

96.2 DSM-5 Personality Disorders

The DSM-5 outlines the diagnostic criteria for a general personality disorder, and later provides the diagnostic criteria for the ten principal personality disorders. In general, an individual who has a personality disorder dem-

onstrates a long-standing pattern of thinking, behaving and emotional expression that is not consistent with what would be expected from within that individual's cultural background. Personality disorders develop in adolescence or early adulthood and must be pervasive in multiple domains leading to either significant clinical distress or functional impairment [2]. Typically, personality psychopathology involves four key components:

1. Cognition – the manner in which the individual conceptualizes themselves, others in their social sphere, and the world around them differs from the perceptions of their peers; for example, the individual with paranoid personality disorder would be perceived by others to be overly suspicious and distrustful without good reason.
2. Affective expression – the individual demonstrates emotional range, reactivity, intensity and appropriateness that is markedly different from what would be expected; for example, the individual with antisocial personality disorder would be observed to be overly aggressive and potentially explosive.
3. Interpersonal functioning – the individual has interpersonal relationships that are potentially chaotic and unstable, or simply not as satisfying in nature as might be expected by others in their community; for example, the individual with schizoid personality disorder who does not desire interpersonal contact with others including romantic or sexual relationships.
4. Impulse control – this can either be present as a lack of impulse control or as excessive behavioral inhibition; for example, the patient with BPD may exhibit tremendous self-destructive impulsivity in the form of substance misuse, shoplifting, self-injury or binge eating, whereas individuals with avoidant personality disorder may present as so inhibited that they are unable or unwilling to initiate simple social interactions.

DSM-5 divides the personality disorders into three Clusters and in two other categories [2]:

- *Cluster A – "Odd and Eccentric"* – consists of Paranoid Personality Disorder (PPD), Schizoid Personality Disorder (SPD), and Schizotypal Personality Disorder (STPD).
- *Cluster B – "Dramatic, Emotional, and Egocentric"* – consists of the most clinically prominent personality disorders, and includes Antisocial Personality Disorder (ASPD), Borderline Personality Disorder (BPD), Histrionic Personality Disorder (HPD), and Narcissistic Personality Disorder (NPD).
- *Cluster C – "Anxious and Fearful"* – includes Avoidant Personality Disorder (AVPD), Dependent Personality Disorder (DPD), and Obsessive Compulsive Personality Disorder (OCPD).

Other Personality Disorders (OSPD) and Unspecified Personality Disorder (UPD) are probably the two most common diagnosed personality disorders in the general population. They are diagnosed when individuals present with general features of the personality but do not meet the more specific diagnostic criteria for one of the ten major categories or there is insufficient clinical information to determine which specific personality disorder they have at the time of assessment.

96.3 Personality Disorders and Addiction: A Common Comorbidity

It is estimated that, in 2017, 14.8% of Americans aged 16–23 years and 6% of those over 26 years struggled with a substance use disorder [58] and approximately 10% of the general population have a personality disorder [61], with this rate being much higher (50%) in those receiving psychiatric treatment [7]. Among individuals who suffer from either of these mental illnesses, the lifetime joint comorbidity is very high. Adults diagnosed with these two disorders are a greatly impaired subpopulation and present significant challenges for addiction rehabilitation services [12].

96.3.1 Prevalence of Personality Disorders Among Individuals with SUDs

According to different systematic reviews, personality pathology is present in 5–91% of individuals with SUDs [45, 64]. Among individuals treated for their addiction, which represent only a small proportion of individuals with SUDs [20], the probability of co-occurring personality disorder is much higher. The overall prevalence of PDs among patients in treatment ranges from 35% to 73% (median of 56.5%) in Verheul [67] and from 33% to 91% in Casadio et al. [12].

Such significant variations across studies in reported rates of comorbidity between PDs and SUDs suggest the presence of large differences in the methodology used. Differences in the assessment procedures (standardized diagnostic tool vs. self-report vs. chart review, current vs. lifetime prevalence, drug abuse vs. dependence, etc.) as well as in the sampling (inpatient, outpatient, community, selective inclusion of gender, small sample size, etc.) have strong effects on observed prevalence [12, 48, 68]. Furthermore, large variations in reported prevalence rates reflect the fact that many studies have not investigated the full range of PDs. For these reasons, all prevalence rates should be interpreted with caution as should be ranking attributed to the most commonly detected PDs [51]. Nonetheless, all studies consistently report evidence of high comorbidity between these two disorders. They also highlighted that some types of PDs are more prevalent in SUD population, while some forms of SUD are more often associated with specific personality disorders.

96.3.1.1 Cluster B

Most research investigating the presence of PDs among individuals with SUDs, has focused on Cluster B PDs with the strongest and most consistent association found with BPD and ASPD [29], regardless of whether participants were from inpatient, outpatient, or community settings [64]. In a systematic review of 70 articles in 2018 [62] and a meta-analysis of 26 studies in 2000 [64] found a weighted prevalence of respectively 27.4% and 22% of patients in addiction treatment met BPD criteria. The literature further suggests that BPD is present in 24% of individuals with alcohol dependence, and in 46% of those with drug dependence [24]. ASPD is also highly comorbid with SUDs with reported rates ranging from 14% to 27% (review by [12, 68]). These figures are even more remarkable when one realizes that BPD and ASPD has a prevalence of only 1–2% in the general population.

These two PDs are prevalent among individuals who use a variety of addictive substances. Individuals with ASPD often report alcohol misuse [21] while patients with either of these PDs often have problems with illegal drugs, mainly cocaine [41, 29]. Finally, as patients with BPD often display chronic pain syndromes and might be prescribed opioid medications, they are more likely to misuse medication and at risk of developing opioid use disorder; in an outpatient buprenorphine maintenance clinic, 44% of those in treatment had BPD [53]. The incidence of cocaine, opioid, or alcohol use disorder is markedly high in patients with BPD [62].

A small number of research studies have looked at other Cluster B PDs with a suggested 12.4% lifetime prevalence of Narcissistic PD among individuals with alcohol dependence and 22% lifetime prevalence among those with any drug dependence (NESARC; [57]). Verheul [68] study reported a 12% rate for Histrionic PD. These PDs are often linked with alcohol misuse.

96.3.1.2 Cluster C

Studies of the association between Cluster C PDs and SUDs have extended the possible comorbidities beyond the focus on Cluster B [21, 51]. Results from the Wave 1 NESARC epidemiologic survey [24] reported a prevalence of 25.2% of OCPD among those with any drug dependence and of 15.9% among individuals with alcohol dependence. Casadio et al. [12], review of articles on substance-addicted patients, report prevalence rates varying from 0.7% to 26% for OCPD, from 2% to 35% for DPD and from 2% to 27.4% for AVPD. In a clinically large sample of individuals seeking treatment, Roncero

et al. [51] noted that Cluster C PDs was present in 18.5% of those in treatment for benzodiazepines (the most common substance for consultation), 9.4% of individuals in treatment for alcohol abuse, in 6.1% of those treated for opioids, in 9.7% for cocaine and 12.2% for those in treatment for cannabis. Patients who consumed benzodiazepines presented mainly with DPD while the presence of OCPD was more common among patients who consumed alcohol, opioids, cocaine, and cannabis.

96.3.1.3 Cluster A

Very few articles present rates of comorbidity between SUD and Cluster A PDs. Casadio et al. [12] reported prevalence rates varying from 0.9% to 7% for SPD and from 3% to 26.7% for PPD. In the NESARC survey [50], presence of STPD among participants with any drug dependence was 19.4%.

96.3.2 Prevalence of SUDs Among Individuals with Personality Disorders

As seen in the previous section, numerous studies have demonstrated that the prevalence of PDs among patients with SUDs is substantial. The opposite is also true. However, this has been established by a smaller number of studies [67], and has focused mainly on BPD and ASPD [48], the two PDs most likely to be diagnosed in clinical settings. In two systematic review articles examining the lifetime prevalence of SUDs in PD patients, Newton-Howes and Foulds [46] and Guy et al. [27] reported a similar pooled estimate of around 60%, while a register-based study of all people in Denmark treated for a PD in a 44-year period reported a 46.4% prevalence of any SUD [60].

The extent of comorbid addiction disorders among individuals with PDs varies according to types of PD [27]. A comprehensive overview provided by Trull et al. [62] on the co-occurrence of BPD and SUDs across different settings reported that 75% of participants with BPD received a lifetime unspecified SUD diagnosis and 59.5% a lifetime AUD diagnosis. Results from the NESARC study reported a very similar lifetime prevalence of 73% for substance use disorder for people with BPD [24], while review from Guy et al. [27] suggested a lower average prevalence rate of 52%. Using a strict diagnosis rule for diagnosing PDs, Trull et al. [63] reported high comorbidity rates of lifetime alcohol dependence for individuals with ASPD (52%) while comorbidity rates for lifetime drug dependence was 27%.

Minimal research exists on other personality disorders and addiction. In Guy et al. [27] review, lifetime prevalence of SUD in PDs other than BPD and ASPD, was 39% (29–49%). NESARC study reported a lifetime SUD prevalence of 64% for individuals with NPD [57] and of 68% of any SUDs for individuals with STPD [50]. Trull et al. (2010) reported high comorbidity rates of lifetime alcohol dependence for individuals with HPD (49.8%), while comorbidity rates for lifetime drug dependence, was 29.7%.

To summarize these data, there is extensive comorbidity between many PDs and a variety of SUDs regardless of whether the samples originate from a population of patients with PDs or conversely from a population of patients with SUDs.

96.3.3 Prevalence of Personality Disorders Among Individuals with Gambling Disorder

Literature has shown that there is high prevalence of personality disorders in individuals with gambling disorder. Some studies that have looked specifically at the prevalence of PDs in the general population of pathological or problem gamblers report a prevalence of around 42% for any PDs (Pietrzak et al. 2007 in [8, 65]) and a prevalence 28.8% specifically for comorbid ASPD (review article by [38]).

A review conducted by Brown et al. [11] reports that 43% of treatment-seeking problem gamblers met criteria for a PD. Another sys-

tematic review and meta-analysis among this population revealed a similar weighted average estimate of 47.9%, ranging from 12% to 93% for any PDs [18]. This review suggested that Cluster B PDs are the most prevalent with a mean of 17.6% with the highest prevalence for Narcissistic (16.6%), followed by Antisocial (14.0%) and Borderline (13.1%) PD. There was also a weighted mean effect of 12.6% for Cluster C PD (12.6%) with both AVPD and OCPDs at a prevalence of 13.4% and a mean effect of 6.1% for any Cluster A PDs with the highest.

96.4 Risk Factors for Persistent SUDs in Individuals with PDs

The presence of a PD seems to be a significant risk factor for persistent substance abuse issues, as illustrated in Table 96.1. Over a three-year period, ASPD, BPD and STPD consistently predicted persistence of alcohol, cannabis, nicotine, and drug disorder (cannabis, other illicit substances, and/or nonmedical use of prescription drugs) controlling for demographics and concurrent Axis I and II disorders. Among PD traits that influenced the persistence of SUD, deceitfulness

Modified from [a][28] and [b][20]

Studies based on DSM-IV. Data from National Epidemiologic Survey on Alcohol and Related Conditions (NESARC/USA)

Odds ratios were controlled for demographics, axis I and II, as well as other factors depending on the study

OCD – Obsessive-compulsive disorder; Drug use disorder – abuse and dependence assessed in ten classes: cannabis, cocaine, inhalants, hallucinogens, heroin, opioids, stimulants, tranquilizers, sedatives, and other drugs

$^{*}p < 0.05$; $^{**}p < 0.01$; $^{***}p < 0.0001$

and lack of remorse (antisocial traits), identity disturbance and self-damaging impulsivity (borderline traits) and ideas of reference and social anxiety (ST traits) were the strongest predictors.

96.5 Screening and Assessment

Standardized clinical semi-structured interviews are regarded as the most reliable and valid assessments for PDs. Self-report questionnaires may have poor specificity and may be rather tiring for patients as they require significant concentration. Cooperatively, one could administer a short semi-structured interview in conjunction with a brief screening tool. A study completed by Gonzalez [23] described the use of two quick screening instruments for PDs: the self-report Standardized Assessment of Personality – Abbreviated Scale (SAPAS-SR) [44] and the Iowa Personality Disorder Screen (IPDS-SR) [33]. The study involved screening 53 inpatients dependent on drugs or alcohol, with a 42% prevalence of a personality disorder [23]. Both instruments were found to be quick and easy to administer, taking approximately 2 minutes to complete, and were deemed satisfactory to be used in clinical practice.

The Standardized Assessment of Personality – Abbreviated Scale [44] consists of an eight yes/no items screening questions focused on personality features interview, taken from a much more comprehensive the opening section of an informant-based semi structured interview (Standardized Assessment of Personality (SAP). It produces a dimensional score that signifies the probability that an individual has a PD in general and does not screen for any specific PD [43]. Please see Fig. 96.1.

The Iowa Personality Disorder Screen (IPDS) is a brief interview-based measure developed from the DSM III version of the Structured Interview for Personality Disorders (SIPD). This screen takes approximately 5 minutes to complete having 11 items to evaluate whether a PD is present. It was designed for use in out-patient settings. Most of the items have supplementary questions totaling 19 potential questions. The

Standardised Assessment of Personality – Abbreviated Scale (Moran)

Please ask your patients the following questions. Only tick a response if the patient thinks that the description applies *most of the time* and *in most situations*.

1.	In general, do you have difficulty making and keeping friends?	☐ **Yes**	☐ No
2.	Would you normally describe yourself as a loner?	☐ **Yes**	☐ No
3.	In general, do you trust other people?	☐ Yes	☐ **No**
4.	Do you normally lose your temper easily?	☐ **Yes**	☐ No
5.	Are you normally an impulsive sort of person?	☐ **Yes**	☐ No
6.	Are you normally a worrier?	☐ **Yes**	☐ No
7.	In general, do you depend on others a lot?	☐ **Yes**	☐ No
8.	In general, are you a perfectionist?	☐ **Yes**	☐ No

Responses in bold should be scored as 1, those not in bold as 0.

A total score of 3/8 or more indicates personality disorder is likely. (A score of 3 or more on this tool correctly identied 90% of psychiatric patients with DSM-IV personality disorder. Sensitivity 0.94 and specificity 0.85).

Fig. 96.1 The Standardized Assessment of Personality – Abbreviated Scale (SAPAS). (Reproduced from [44])

IPDS can be simply incorporated into standard diagnostic clinical interviews and primary validation research supports that it is satisfactory in detecting people necessitating additional testing to conclude if they meet criteria for a PD [33].

96.6 Treatment of Comorbid Addictions and Personality Disorders

96.6.1 The Role of Integrated Treatment

Historically, clinical wisdom held that patients needed to get their addiction successfully treated to subsequently be suitable to receive treatment for their mental health issues, or to receive therapy for their personality disorder before receiving addictions treatment. Patients were often bounced from one service to another because they did not meet specific inclusion criteria and therefore did not receive treatment. This approach is suboptimal and generated a great deal of frustration among clinicians, patients and their families. Resulting from this has been advocacy for the idea of integrated treatment where one clinical team provides treatment for both PD and SUD concerns [32].

For instance, the isolated treatment of SUD in patients with BPD might contribute to the rise of compulsive behaviors in other areas, such as for eating or for sex, while on the other hand, the sole treatment of BPD focusing on self-harm might increase substance misuse. Indeed, it is not possible to assume that substance use is an epiphenomenon that will resolve with remission of symptoms related to the PD. Apart from the limitations of the treatment diagnoses in isolation, another concern pertains to treatments that are held in parallel, as it may not provide a coherent whole and optimal cohesion among service providers and result in unintended mixed massaging.

On treatment modalities, psychotherapy is considered the most effective treatment for PDs, with pharmacotherapy having a possible adjunctive role for specific symptoms, while for SUD combined psychotherapy and pharmacotherapy is the most indicated approach. As for dual diagnosis, different treatment modalities should be offered when possible, considering individual, group and family therapy, medication, and involvement in peer support groups as they may all be useful at different points in the recovery [19]. Current analyses of available studies offer no clear guidelines of which therapy to prefer, and the core feature seems to be a systematic and integrative approach of treating the PD simultaneously with the SUD [31].

When one disorder is treated without addressing the other, the likelihood of suboptimal treatment outcomes dramatically increases. Decrease in symptomology of one, may positively impacts the other. Treatment success increases motivation for continuing treatment and moving towards recovery. Treatment frequently has common foci independently of the origin of symptoms (from addiction or PDs).

96.6.2 The Role of Medication

There are no approved medications with the indication for the treatment of personality disorders. However, medications from all psychotropic classes are frequently used in an attempt to address certain specific symptomatology such as affective instability, anxiety, impulsivity, dissociation, and quasi-psychotic symptoms. This is often in spite of an absence of evidence of pharmacological effectiveness and unfortunately often results in polypharmacy with minimal benefits and potentially significant side effects (particularly metabolic syndromes), as additional medications are often added to earlier medications that were insufficiently effective. Whenever possible, one should strongly consider removing an ineffective earlier medication before initiating a trial of another medication. Also, one should strive to avoid prescribing medications with abuse or dependence potential, such as psychostimulants, opioids, and sedative hypnotics [5]. Instead, in individuals with co-occurring PD and SUD, one should give emphasis to the addiction pharmacotherapies that have quite robust evi-

dence of effectiveness and target the individual's substance use disorder, for example using opioid substitution therapy in opioid use disorder, various anti-craving medications for alcohol use disorder or potentially an opioid antagonist for gambling disorder.

96.6.3 The Role of Psychotherapy

The most effective treatment for individuals with PDs is psychotherapy, with most of the evidence relating to treatment of people with BPD [5]. Studies investigating psychotherapeutic models of intervention for patients with PDs and SUD are limited. Even in the field of PDs, evidence-based treatments are lacking for most disorders outside of BPD, and the level of evidence accumulated so far is not robust. Clinical trials often have limitations such as small sample sizes, and provide variable outcomes [32]. The knowledge on the field is largely empirical. It is not possible to have a definitive postulate of the preferred therapy so far and further research is urgently needed to show which treatment approach is effective for the treatment of PD and SUD [31].

96.6.3.1 Cluster B

Cluster B is the most prevalent and studied group of PDs in association with SUD. As such, most of the psychotherapeutic models for concurrent PD and SUD were tailored for individuals with Cluster B pathology. BPD and ASPD were the conditions most explored in scientific studies so far with some incipient evidence about treatment efficacy.

Borderline Personality Disorder

The few studies that evaluated the efficacy of models to treat both BPD and SUD don't allow for meta-analytic reviews, and the narrative reviews sometimes indicate slightly different conclusions from the same studies [31, 35, 48, 49]. Further research is definitely needed to determine which treatment approaches are effective for these co-occurring diagnoses. Models tested had a treatment length of approximately 1 year and some degree of integration with the current most widespread approaches specific to SUD.

Table 96.2 Hierarchy of targets in DBT-SUD [17]

1st: Reduce behaviors that are imminently life threatening (e.g., suicidal)
2nd: Reduce behaviors that interfere with treatment (e.g., not attending therapy)
3rd: Reduce behaviors that decrease quality of life (e.g., substance abuse)
4th: Increase behavioral skills

Dialectical Behavior Therapy (DBT) for Substance Abusers (DBT-SUD; [36]) is an adapted version of DBT, an evidence-based treatment for patients with BPD [37], developed specifically for patients with both BPD and SUD. In this model, BPD or drug abuse is viewed as attempts to regulate aversive emotions. The goal of DBT-SUD is to both encourage abstinence but also minimize the duration and severity of any potential relapses. Like other DBT approaches, therapeutic goals have a hierarchy of priorities to optimize treatment outcomes (see Table 96.2).

Overall, DBT-SUB studies were felt to be of good quality and demonstrated good clinical outcomes and effectiveness [35]. The first clinical trial of DBT-SUD showed positive results, but medication was a confounding variable. The second trial was better delineated to control for medication and to balance the number of activities and the resemblance between the conditions. The model tested consisted of weekly individual therapy focused in DBT; psycho-educational skills group that comprised mindfulness, emotion regulation, distress tolerance and interpersonal effectiveness; phone coaching for patients; and consultation for therapists, aiming at keeping capability and motivation in the face of intense emotions. The control adopted in this second trial was very rigorous and the results came out mixed; there was a higher likelihood of decreased opiate use after 12 months in the DBT group, but not at 16 months, and no change was observed in the use of other drugs comparing both groups. Also, there was higher dropout in the DBT group [49]. Although results of outcomes studies are not always robust, DBT-SUD has been recommended

as a potentially beneficial treatment for patients with co-occurring BPD and SUD by many authors [32, 35, 48].

Finally, the similarities of DBT-SUD to specific therapies for SUDs such as motivational interviewing and relapse prevention might favor its acceptability among SUD clinicians. For instance, the model proposes a dialectical approach to abstinence, encouraging the patient to stop all harmful substance misuse and adopting abstinence, while also accepting that any relapse that should occur is not indicative of treatment failure and that abstinence is not possible. In this approach, the appropriate level of abstinence for each patient is determined by: (1) targeting the primary drug of abuse (the substance causing the most significant problems); (2) targeting other substances that lead to the use of the primary drug; (3) making sure that the treatment goals are attainable, which might mean gradual goals [17]. Patient will be helped to "fail well", which means learn from the incident through behavioral analysis. Thus, the philosophy of dialectics will play a role to counteract previously held rigid and extreme response patterns.

Another treatment model, Dual-Focus Schema Therapy (DFST), has been adapted from Schema-Focused Therapy [70]. This psychotherapy is not restricted to BPD but can be used for all PDs. The core principle of this approach is that PDs result from early adopted faulty schemas that are a response to failed attempts to satisfy important basic needs, resulting in harmful coping strategies. Maladaptive coping attempts to avoid or compensate for the activation of the schemas are seen as important triggering factors for patients with PD and SUD in this model. While Ball et al. [4] suggest that working on these triggers would be beneficial for the treatment of both PD and SUD, Lee et al. [35], states contrarily that DFST did not appear to be effective and demonstrated limited benefits.

Deconstructive Dynamic Psychotherapy (DDP; [26]) is a model based in psychodynamics developed for treatment-resistant patients with BPD, including those with a concurrent SUD. The goal of this treatment is to activate the ability "to form associations between different aspects of affective experience, to provide integrated attributions to those experiences, and to assess the accuracy of those attributions" [26]. This psychotherapy showed overall good outcomes, especially in reducing alcohol use and suicidal behavior. However, it is not possible to draw firm conclusions from these results due to the small number of studies, with small sample sizes, all from the same research group [32, 35]. These results would need replication. Furthermore, when DDP was studied in patients suffering only from BPD, it performed poorly [47].

Finally, Mentalization-Based Therapy (MBT) has shown efficacy for the two conditions separately, however, it was not tested for concurrent BPD and SUD [40]. Specific evidence on the efficacy of Transference Focused Therapy (TFT), Cognitive-Behavioral Therapy (CBT), 12-Steps programs (12S) or Motivational Interviewing (MI) was not found for this subpopulation of patients. It is also noteworthy that there is some evidence against long-term residential treatments, such as a therapeutic community for substance dependence, for BPD patients due to the high dropout rates [52] (Table 96.3).

Table 96.3 Clinical tips in treating individuals with ASPD and SUD [19]

Substances use may offer a way of coping with both physical and psychological distress
Self-injurious behavior can evoke strong feelings in clinicians, such as anxiety and anger
Dissociation is common
Under significant stress these individuals regress in functioning and become much less adaptable
A crisis management plan developed in collaboration is recommended
Clinicians should develop the professional support structure for both skill development and psychological wellbeing
Responses of clinicians may polarize between over-involvement believing they can "rescue" the patient versus resignation with a growing of a self-protective distancing, with excessive detachment counterproductive for therapy
In self-help recovery groups (12-steps, AA, NA) it may be beneficial to encourage selection of sponsors that are not likely to be potential romantic partners as it might pose a difficulty for the patient dealing with the proximity and the boundaries of these less formal helping relationships

Antisocial Personality Disorder

ASPD is associated with considerable personal, familial and societal adverse consequences. It is linked to poor occupational productivity and increased criminal justice costs, resulting in extensive economic impact. Consequently, the identification of interventions that could reduce these impacts should be a major research priority [22]. Prevention and intervention efforts of both antisocial syndromes and SUD can benefit from integrated approach, and programs that focus on adolescents are particularly indicated as a way to reduce later substance use disorders [14]. Unfortunately, there is scarce research and little good quality evidence as to what might (or might not) be effective for this condition. The Cochrane systematic review and meta-analysis conducted by Gibbon et al. [22] investigated psychological interventions for ASPD. The majority of the included studies were trials with a focus to reduce substance misuse, and ASPD was a subsample studied. Consequently, the interventions applied were not specifically focused on treating the ASPD, as was the case for BPD, where treatments originally tested for BPD were adapted into the scope of dual diagnose with SUD.

Gibbon's study observed some evidence that contingency management plus standard maintenance is effective in reducing substance misuse in ASPD and improving attendance in sessions (not interfering in dropout rates), while the aspects related to the symptoms associated to the personality were not measured. Noteworthy, the attractiveness of the positive reinforcements in contingency management seem to have a weight on the success of the intervention, such as providing high value vouchers [22].

A multi-component intervention utilising motivational interviewing principles plus incarceration [69] was superior to treatment as usual (incarceration alone) on number of drinking days and on consumption quantity in prisoners sentenced for driving whilst intoxicated for individuals with ASPD. Interestingly, the ASPD subgroup had heavier and more frequent drinking but showed significantly greater declines in drinking from intake to post-treatment assessments. Thus, it seems that non-confrontational treatment could be an option to enhance outcomes for individuals with ASPD.

The role of a psychoeducational approach for individuals with ASPD has been explored in one RCT showing some benefit regarding compliance and retention in SUD treatment [48]. The six sessions of the manualized impulsive lifestyle counseling focused on: (1) impulsivity, goals and life dreams, (2) behaviors, consequences, and triggers, (3) streetwise pride and crime, (4) values, and (5) social support. The style is non-confrontational, and the patient is invited to consider whether the themes are relevant to his or her life. Homework, handouts and worksheets are also used [59]. Results of the study suggest an increase inpatients' self-rated perceived help for their personality disorder, which was in turn associated with more days of abstinence, higher treatment satisfaction, and reduced risk of dropping out of treatment [59]. This single study suggests that psychoeducation could be beneficial for the treatment of individuals with SUD and ASPD.

Therapeutic community (TC) treatment is a psychosocial intervention for reducing substance use [16] which has been utilize with individuals with ASPD. It has been developed to the intertwined personality and behavioral issues that are found in severe ASPD and substance misuse. Results from the literature have provided mixed findings. Samuel et al. [52] suggest that the ASPD traits might lead to difficulty accepting the rules and regulations of a well-controlled long-term rehabilitation treatment center at first, and once the initial orientation period is over, those same traits might equip the individual for success within (or at least tolerance for) the confrontive atmosphere of this modality of treatment.

ASPD is also highly prevalent among problem gamblers, and is associated with elevated gambling disorder symptoms. An exploratory study suggested that this subgroup may benefit from specific behavioral therapies targeting the underlying neurocognitive dysfunctions of increased impulsivity, and impaired cognitive flexibility and executive planning [10] (Table 96.4).

Table 96.4 Clinical tips in treating individuals with *ASPD* and SUD [19]

They may be distrustful and entitled, and not show appreciation for the services received. These characteristics may result in clinicians distancing themselves or conversely relaxing boundaries in an attempt to demonstrate the willingness to help
ASPD patients can be seductive and persuasive, and clinicians may find themselves positively responsive to their charm
ASPD patients are likely to push for special treatment or softening of rules, be aggressive and intimidating, and may seek to exploit vulnerabilities in the clinician or the system
Clinicians should demonstrate determination, strength, and incorruptibility. Individuals with ASPD respect power, tough-mindedness and a clear consistent stance, and do not relate well to clinicians that they perceive to be powerless
Major consideration should be given for the safety of the staff and other clients
Recovery should be presented as a road to freedom, reflecting on how antisocial behavior is disadvantageous in present and future, specially focusing on the lack of autonomy and mastery, such as not being able to sustain a job, a relationship, or being in difficulty with the law
Highlight the fact that the strengths inherent in their personality can make recovery possible or can worsen addiction and its consequences. Help them to see clearly potential outcomes

Table 96.5 Clinical tips in treating individuals with NPD and SUD [19]

Clinician's should strive to self-monitor impatience, indignation, counter-arrogance, as these responses are counterproductive. Team consultation or supervision can help support the therapeutic approach
Clinicians can model learning to tolerate one's own faults and frailties
Patients can utilize the motivation to look strong to lead to acceptance of recovery activities
Peer support groups might be beneficial for both SUD and NPD, as they may come to better understand and respond to the needs of others

Narcissistic Personality Disorder

Presently, there is no specific evidence-based treatment for NPD, such that there is also no treatment that has been developed for individuals with NPD who also present with SUD. The patterns of grandiosity, need for admiration, lack of empathy, and fantasies of being the smartest and feeling entitled to special privileges are known to cause negative reactions in therapists, thus challenging the therapeutic alliance and may negatively impact treatment efforts [19]. Stinson et al. [57] hypothesize that "SUD may reflect attempts on the part of men with NPD not only to re-establish or maintain grandiosity, but also to defend against the negative affect accompanying dysthymic disorder that often accompanies aging and life's inevitable limitations" ([57], p. 1042). The NPD cognitive pattern of self-indulgence is seen as characteristic that make them vulnerable to SUD [6]. Helping NPD patients to recognize these patterns and motivations may potentially assist them in their recovery from SUD (Table 96.5).

96.6.3.2 Cluster A

There is a lack of well organized randomized controlled trials of treatment for people with Cluster A personality disorders [5], while specific treatment for the dual disordered have not been developed and tested. Consequently, there are no evidence-based interventions to recommend for those with co-occurring Cluster A PDs and SUD. Some clinicians theorize that Cluster A personality disorders would be better conceptualized as subsyndromal disorders better conceptualized as part of the schizophrenia spectrum, and as such might have better outcome in programs developed for concurrent psychotic disorders and substance abuse, which often focus more on practical skills.

Schizotypal Personality Disorder

STPD differs from other Cluster A personality disorders in that social aversion is accompanied by more behavioral eccentricities and lapses in their sense of reality (dissociation and derealization). Empirical evidence suggests that cognitive therapy can promote change in both the cognitive and social disabilities of patients with STPD [5].

Cannabis has a high prevalence and persistence of use in people within the schizophrenia-spectrum. While the association between cannabis use and schizotypal symptoms is well

known, only one study addressed time order and found that the schizotypal symptoms preceded cannabis use [28], meanwhile the symptoms cannot be fully explained by STPD [1]. Cannabis users are significantly more prone to cognitive and perceptual distortions, and also to disorganization [54].

It is believed in the clinical field that STPD are inclined to use alcohol and other drugs to either manage their anxiety or connect socially, escaping from feeling odd and unaccepted, which needs to be considered to pace the treatment according to the need of the patient. Service providers who do not recognize the cost of abstinence may push too hard without considering their interpersonal losses [19]. Assisting with the development of social skills training and alternative anxiety management techniques may provide the STPD patient with an alternative to substance use (Table 96.6).

96.6.3.3 Cluster C

PDs in Cluster C are characterized by being anxious and fearful and may not be at elevated risk for developing SUD. Hasin et al. [28] demonstrated the odds of persistent SUD for PDs within this cluster as being statistically the same as for the general population. PDs in the cluster characterized by being anxious and fearful are not a major concern for developing SUD. The odds of persistent SUD for PDs within this cluster are statistically the same as for the general population, as can be observed in the data brought by Hasin et al. [28]. Exception should be made for OCPD, which was associated with persistent nicotine dependence [28] and weak evidence suggest associations with any substance and alcohol disorders [24]. Also, individuals with problematic gambling that had OCPD showed lower severity of gambling symptoms and treatments focusing on social support and skills to cope with stress and finances could be more effective to this comorbidity [42]. Specific treatments for Cluster C in association with SUD were not specified. As with Cluster A, unfortunately there are no robust studies demonstrating effective treatment modalities for Cluster C PDs alone, let alone with co^{m}-morbidities. Intuitively, clinicians have focused on traditional evidence-based treatments for addiction, emphasizing those that target anxious affect as a risk factor for use and relapse. Helping individuals develop skills such as distress tolerance, general stress management, relaxation exercises and self-soothing all may be potentially beneficial but any quality studies of efficacy remains lacking.

Table 96.6 Clinical tips in treating individuals with STPD and SUD [19]

Clinicians should be emphatic and show acceptance in face of surprising statements and peculiar ideas, as a trusting therapeutic relationship will allow for reality testing
Clinicians must sustain appropriate involvement in treatment, as STPD clients might elicit boredom or anxiety
Treatment is most effective when structured, supportive, and focused on the teaching of social skills
Group settings are valuable for potential growth, while 12-step groups that meet in mental health centers can often deal with more acceptances with the unusual behaviors, attitudes, or beliefs that may be expressed

96.7 Barriers and Challenges to Treatment

96.7.1 Stigma

It is well documented that individuals with SUD, as well as those with PDs, notably BPD and ASPD, experience stigma, both from family members and society, and from health professionals) [3, 66]. Despite recent advances in the neurobiology of these disorders, SUD continues to be viewed as a result of moral weakness [12], whereas PDs are simply people behaving badly due to character flaws [55]. Thus, according to these societal views, these disorders have not been viewed as requiring "treatment" in the medical sense.

Treating patients with comorbid disorders can be extremely challenging as the behaviors common to both conditions can elicit strong emo-

tional reactions from therapist and the change of rigid patterns can be a slow process.

Patients with concurrent PD and SUD can experience a double stigmatization, with associated multiple negative consequences, including exacerbation of symptoms and reduction in healthcare utilization and treatment adherence [56]. These individuals can also experience difficulties in accessing treatments that are made available to other individuals because of systemic prejudices denying them these appropriate therapies. Stigmatization can also stem from the use of a certain language by health professionals. Research has showed that an individual referred to as 'a substance abuser', as 'an addict' or as 'a PD' instead of individual having a "substance use disorder" or having a "personality disorder" has been judged by service providers as less deserving of treatment [30]. Individuals with SUD and PDs, notably BPD, are also very vulnerable to self-stigma, a 'maladaptive process in which individuals accepts societal prejudices and integrate this evaluation into their self-concept" [25], which result in further discrimination.

As stigma is often based on preconceived ideas and collective myths, and rarely on facts, it is possible to alter negatives attitudes and beliefs from the general population with effective education and with more familiarity with mental illnesses [56]. Stigma can also results in rejection and discrimination on the part of health professionals. This can be changed with knowledge and skills, and could begin with the identification of negative countertransference reactions.

96.7.2 Countertransferential Challenges

A positive therapeutic relationship is central to the management of individuals with PDs and SUDs and mental health professionals, who have negative attitudes toward this clientele and are judgemental and rejecting, make engaging and maintaining an effective therapeutic alliance extremely difficult [39]. It is important for all therapists to recognize their negative countertransference and how it might impact their treatment or their responses to crisis [39]. In her book on PDs and addiction, Ekleberry [19] describes well what it takes to work with dual disordered clientele:

> The work requires uncompromising integrity, a strong commitment to ethical practice, continuous learning, interpersonal skills, personal resilience, and a unyielding honesty about feeling, reactions, and behaviors elicited from interacting with these individuals. (page 207)

On the other hand, many authors also describe the many rewards of working with this clientele [19], which is not often the focus of articles on clients with SUDs or PDs. Choi-Kain and Gunderson [13] describes that the work with a difficult clientele can foster personal growth and can be seen as a "highly personal, deeply appreciated, life-changing role".

Working effectively with this dual disordered population often requires openness on the part of the clinician to receive regular supervision, even if only in the form of peer support. Consulting with colleagues can help tremendously in the challenges that arise from working with these complex clinical cases, and such professional support is often essential in preventing burnout and fostering personal and profession resilience [34, 19]. As the most studied PD, data derived from evidence-based treatments for BPD have in common the characteristic of maintaining regular supervision of therapists. Clinicians discuss cases, including personal reactions, with others professionals [5]. The DBT model have treatment interfering behaviors as the second most important target of treatment, just behind life threatening behaviors. It includes behaviors from both clients and therapists, as they might be highly deleterious of treatment efficacy and contribute to early termination of therapy. In this model, clinicians work as a collaborative team and have weekly consultation meetings to focus on therapist's emotional reactions and motivation to treat patients, sustained in principles like non-judgement and acceptance, in an effort to diminish defensiveness and increase effectiveness [37]. Therefore, self-monitoring and peer-supervision or consultation should be part of

Table 96.7 Strategies to work with negative countertransference [39]

To receive clinical or collegial supervision
To share the responsibility of client management with a team of service providers
To seek external consultation when necessary
To put in place policies to manage difficult behaviors
To seek support from colleagues to "review treatment plan, help identify blind spots, offer alternatives, validate efforts, and hold hope for changes" (p. 378)

treatment when looking for best practices for dual disordered populations.

In this light, some strategies to work with negative countertransference were suggested by experts (see Table 96.7) and are important to consider in working with this clientele.

96.8 Conclusion

Addictive disorders and personality disorders frequently co-occur and the presence of one significantly impacts the expression and prognosis of the other. There is a greater likelihood that people with a PD will use multiple substances at a younger age, as well as having an increased compulsive and severe substance use pattern. They are also more likely to become physiologically dependent, more susceptible to relapse, and more resistant to collaborating with treatment. Individuals with PDs who misuse substances results in an increase their personality disturbance and have reduced treatment outcomes. PDs raise the susceptibility to SUDs while SUDs reduce willingness to adapt for PDs, while both disorders are heavily stigmatized and the combination of the two only worsens this. Recognizing the coexistence of SUDs and PDs early on in treatment allows the opportunity to optimize treatment outcomes by offering structured comprehensive integrated treatment for both disorders concurrently. It is essential that clinical staff have training and supervisory support in dealing with this challenging patient population.

Special Interest Populations

Giuseppe Carrà and Nady el-Guebaly

Special Populations: An Introduction

97

Giuseppe Carrà and Nady el-Guebaly

The challenge of this section is to select special populations with special needs not otherwise covered by the rest of the textbook. Six such groups are highlighted.

The first chapter addresses the special needs of women. We recognize the awkwardness of addressing half of humanity as a "special population," and indeed, a separate section can be devoted to women in future editions. Drs. Moran-Santa Maria and Brady present a masterful synopsis of the scientific endeavors focusing on women. Remaining gender disparities in research are acknowledged. The prevalence difference of various substance use disorders between men and women across the life cycle is outlined. These data for a number of African and Asian countries remain unavailable. This part of the chapter also addresses the increased exposure of female sex workers. While the "telescoping course" of females addicted to alcohol and the related biologic causes are well known, the chapter also addresses parallel reactivity to other drugs as well as areas for further study. The treatment section describes different responses to pharmacotherapy as well as the barrier encountered in the design of gender-specific programs and the parameters of improved outcome.

The second chapter describes the special needs of seniors, soon to become a quarter of humanity but with disproportionately higher service needs as compared to other age groups. Dr. Rao summarizes the available prevalence figures of older people with substance use. The related costs to a developed community are outlined. Distinctive issues in substance use among the elderly provide a window on the higher comorbid health conditions. This perspective leads to a thorough consideration of the issues central to the assessment of older people: the barriers to detection and the benefits and limitations of the available screening instruments in this population. A paucity of data addresses the disproportionate need for pharmacological and psychological treatments. Among clinical trials, there remains a lack of evidence about safety issues in this age group. There are few trials of psychological treatment despite the observation that older people may in fact do better than their younger counterparts. Effective ingredients of comprehensive service programs and models are becoming identified.

The chapter by Dr. McSweeney describes how "drug-related" offending continues to be a significant driver of global prison populations and its associated costs. While a growing number of

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment*,
https://doi.org/10.1007/978-3-030-36391-8_97

countries have implemented alternative policy innovations for dealing with drug-using suspects, defendants, and convicted offenders using forms of depenalization, diversion, or decriminalization, most continue to incarcerate and criminalize people for the possession or use of illicit drugs and rely on punitive sanctions, such as imprisonment, as the default response to "drug-related" crime. This chapter draws upon international evidence for the effectiveness of "coerced" and mandated forms of treatment (which are ordered, motivated, or supervised by the CJS) as a response to "drug-related" offending. It also highlights what this evidence base tells us about how different contexts and mechanisms for implementation and delivery can hinder or enhance the effectiveness of these approaches.

Inevitably, the illness of addiction impacts on the criminal justice system, and in recent years, there has been considerable progress in moving addiction treatment forward into settings outside of those directed specifically at treatment, i.e., prison settings and forensic applications as drug courts, described in the fourth chapter by Dr. Marlowe.

The fifth chapter focuses on the health of physicians with implications for other caregivers as a special group. The chapter by Drs. Braquehais and Casas et al. is based on the experience of the Galatea Clinic in Barcelona. A review of the literature concerning prevalence, possible causes, and drugs of abuse in various medical careers on both sides of the Atlantic is presented. The Physician Health Programs have attracted attention in the field due to their demonstrated excellent outcomes. These programs have evolved from a culture of denial and unrealistic expectations in the medical community to the development of successful strategies aimed at protecting patients and helping the physician recover back to the practice of medicine. Key factors for prevention and treatment of physicians with substance use disorders are identified including, among others, confidentiality, specialized staff training, group approaches, and lengthy monitored follow-up.

The last chapter deals with populations not commonly covered in our textbooks, but appearing regularly in our global media. Dr. Ezard and colleagues report on the staggering 45 million people currently displaced by conflicts across the world, two-thirds of whom are in a "protracted situation" of more than 5 years. Patterns of substance use reflect a combination of predisplacement patterns, host population patterns, and substance availability. The experience of various displaced groups, and they are unfortunately many, is described. While experiences of interventions to reduce substance-related harm among refugees are limited, a harm reduction approach is recommended from thiamine provision for heavy alcohol users to more structural interventions including community mobilization, alternate income strategies, and equity-based initiatives. Quantitative evaluations may be difficult to conduct, and qualitative ones may be more realistic with common end points such as violence prevention.

Women and Addiction

98

Kathleen T. Brady and Jessica B. Lydiard

Contents

Abstract

Over the last 25 years, awareness of the significance of gender differences in addiction has grown exponentially in the United States. International studies of gender differences are scarce but growing in number. Understanding gender differences in epidemiology, etiology, risk and protective factors, clinical presentation, psychiatric comorbidity, course of illness, and treatment outcomes of substance use disorders (SUDs), particularly in developing countries, is critical to the implementation of effective treatment and prevention strategies.

98.1 Introduction

The definition, prevalence, assessment, and management of addictive disorders are dramatically influenced by social, ethnic, and cultural contexts. This is particularly true for addictive disorders in women. Women from various cultures maintain diverse roles in society which can lead to a variety of coping mechanisms and behavioral adaptations that influence the prevalence and presentation of mental health problems and substance use–related issues. In this chapter, we present an overview of SUDs in women with an emphasis on international issues including social and cultural influences.

98.2 Overview of Epidemiology

The number of published research reports from the United States examining multiple aspects of SUDs in women and gender differences has risen in the last 25 years. These studies have provided critical insights into the epidemiology, etiology, risk and protective factors, clinical presentation, psychiatric comorbidity, course of illness, and treatment outcomes. While the number of international studies of SUDs among women is increasing, there are still significant disparities in our understanding of gender differences in SUDs at a global level. In addition, as acknowledgment of the importance of sexual orientation on behavioral health has broadened, the body of knowledge concerning addictions in sexual minorities is growing.

98.2.1 United States

The evolving opioid epidemic that has impacted the United States over the last 20 years has been particularly problematic for women. Between 1999 and 2015, prescription opioid overdose increased 471% in women vs. 218% in men. Between 2002 and 2013, heroin use increased 100% in women vs. 50% in men, and between 1999 and 2015, there was an 850% increase in synthetic opioid-related deaths in women [20]. Consistent with this, data from 2012 to 2013 suggest no difference between men and women with nonmedical prescription opioid use disorder (NMPOUD) as compared to the 2001–2002 survey which found a higher rate of NMPOUD in men vs. women [68].

In 2013, approximately 20.6 million Americans 12 years of age or older met the *Diagnostic Statistical Manual of Mental Disorder* (DSM-IV) criteria for current substance/drug abuse or dependence [72]. The prevalence of SUDs in men (10.8%) was significantly higher than for women (5.8%). In addition, the prevalence of current illicit drug use in men (11.5%) was significantly greater than in women (7.3%). Compared with women, men were more likely to use marijuana (9.7 vs. 5.6%), cocaine (0.8% vs. 0.4%), and hallucinogens (0.7% vs. 0.4%). The prevalence of current alcohol (57.1% vs. 47.5%) and tobacco (31.3% vs. 20.2%) use was also higher in men than women. A similar epidemiological study of adolescents (ages 12–17) found smaller gender differences in general prevalence of SUDs (9.6% vs. 8.0%) [73]. In addition, for adolescents, there were no gender differences in the prevalence of current alcohol use (13.3% for both) and small differences for cigarette smoking (8.2% vs. 7.3%). However, the prevalence of current illicit drug use among adolescent males (10.8%) was greater than the prevalence in adolescent females (9.3%). Adolescent males were more likely to be current marijuana users (9.0% vs. 6.7%). However, adolescent females were more likely to report nonmedical use of prescription pain relievers (2.6% vs. 1.9%) and psychotherapeutic drugs (3.2% vs. 2.4%).

Data from large-scale epidemiological studies demonstrate a relatively high prevalence of certain co-occurring psychiatric disorders among women with SUDs as compared to men. For example, alcohol-dependent women are more

likely to suffer from mood disorders and have a higher prevalence of primary depression than alcohol-dependent men [41, 64]. Moreover, compared with treatment-seeking men, treatment-seeking women are more likely to have multiple comorbidities (i.e., three or more co-occurring diagnoses in addition to the substance use disorder) [5]. Eating disorders (EDs) are particularly common among women with SUDs [24]. A number of studies have found that over 50% of women receiving treatment for a SUD have histories of physical and/or sexual abuse and a high percentage meet criteria for posttraumatic stress disorder (PTSD) [6, 27]. Moreover, the severity of childhood trauma has been associated with an increased risk for cocaine relapse in women but not in men [37].

98.2.2 International Epidemiological Data

The United Nations Office on Drugs and Crime (UNODC) and the World Health Organization (WHO) have provided the most recent estimates of the prevalence of drug use and SUDs among men and women at a global level. Consistent with data from the United States, UNODC reported that the lifetime, 12-month, and past-month prevalence rates of cocaine, amphetamine, marijuana, and ecstasy use were greater among men than women. However, the prevalence of tranquillizer and sedative use among women exceeded that observed in men [79]. In Afghanistan, women were more than twice as likely as men to report daily use of tranquillizers [78]. In South America and Central America, the lifetime prevalence of tranquillizer and sedative use in women was nearly double the prevalence estimates for men (6.6% vs. 3.8%). In Europe, the lifetime prevalence of tranquillizer and sedative use among women was 13% compared with 7.9% for men. These findings are consistent for both adult and adolescent populations [79].

The WHO collected data from 147 countries (representing approximately 88% of the global population) [82]. Estimates were based on international disease classification systems such as the International Classification of Diseases (ICD) and the DSM-IV [65]. Among males aged 15 years and older, the prevalence of alcohol use disorders was estimated to be highest in Eastern European countries, parts of Asia, and the Americas. Among females aged 15 years and older, the highest prevalence rates of alcohol use disorders were found in Eastern European countries, regions of the Americas, and the Western Pacific. The estimated prevalence of alcohol use disorders was lowest among men and women living in African and Eastern Mediterranean countries. The highest prevalence rates of SUDs for both men and women were found in select regions of South, Central, and North America.

There are a number of limitations to the UNODC and WHO reports. Data from a number of African and Asian countries were unavailable and therefore not included. Thus, gender differences in the prevalence of illicit drug use may be not be generalizable to African and Asian countries. In addition, these findings were based solely on data from countries for which gender-disaggregated data were available and thus present an underestimation of SUDs among women globally.

An interesting study investigating birth cohort trends in the global epidemiology of alcohol use and alcohol-related harms in men and women synthesized findings from 68 studies calculating male to female ratios for alcohol problems stratified by 5-year birth cohorts from 1891 to 2001 [69]. The male to female ratio consistently decreased over time, and the closing gap was most prominent in young adults, suggesting a problematic increase in drinking-related problems in women globally.

Socioeconomic and cultural factors continue to be major challenges to accurate and reliable international assessments of SUDs among women. For example, in the United States, childhood sexual abuse is a strong predictor of SUDs in women. Women living in socially conservative cultures may be reticent to disclose childhood sexual abuse with researchers. In addition, logistical challenges can prevent researchers from collecting data from women in rural areas. Interpersonal violence and SUD data have often

been collected in the emergency departments of urban hospitals and may not be generalizable to the entire population.

98.2.3 Substance Use in Sexual Minorities

A recent review of studies of the influence of gender and sexual orientation on alcohol use found that in general, studies have found higher rates of alcohol use and alcohol-related problems among sexual minority (SM) persons than among heterosexuals and greater differences between SM and heterosexual women than between SM and heterosexual men [36]. Data from the 2012–2013 National Household on Drug Use in the United States provides strong evidence of increased risk of substance use and psychiatric disorders among gay/lesbian and bisexual men and women relative to their heterosexual counterparts, with unprecedented heightened risk among bisexual women [40].

98.2.4 Substance Use in Sex Workers

One of the most consistent epidemiological findings is the high prevalence of substance use among female sex workers. Approximately 30% of women who use injectable drugs (IDs) work in the sex trade [15]. A high prevalence of cocaine and alcohol use was found in a study of female sex workers in South Africa [81]. In addition, a community-based survey of sex workers in India found that close to 100% exhibited symptoms of alcohol dependence [9]. Sex workers are often from impoverished backgrounds, so it is not uncommon for them to use the sex trade as a means to support not only their own drug habit but also their partner's habit [46]. Female sex workers have a high risk of exposure to interpersonal violence and are often encumbered with economic challenges and childcare issues. Thus, substance use among female sex workers may be an attempt to self-medicate and alleviate stress and anxiety. Substance use reduces the likelihood of sex workers to engage in harm reduction behaviors. In India, more than half (52%) of female sex workers reported alcohol use prior to sex, and 38% were less likely to use condoms after alcohol use [45]. In India, the prevalence of HIV infection among sex workers who use injectable drugs (IDs) was 16%, which is nearly double the HIV prevalence estimate of 8.4% for female sex workers. A meta-analysis of drug use across 14 countries found that women who use IDs have a significantly greater risk for HIV infection than males that use IDs [12]. Despite these data, few studies have employed a systematic approach to ID use among women at a global level, and countries with the highest prevalence of HIV often fail to provide gender-disaggregated data. Moreover, underestimates of the prevalence of SUDs among women in developing countries could undermine the implementation of effective prevention strategies addressing both sexual risk and drug use.

98.3 Gender Differences in Course of Illness

One of the most consistent findings in studies focused on gender differences in SUDs is the increased vulnerability of women to adverse medical and psychosocial consequences of addiction [30, 31, 51]. Women advance more rapidly than men from initial to regular use and to the first treatment episode. Despite fewer years and smaller quantities of use at treatment entry, substance use severity is generally equivalent in men and women, and women average significantly more medical, psychiatric, and adverse social consequences from substance use [31, 51]. This has been called the "telescoping" of SUDs in women, and differences in biology as well as psychosocial factors contribute to this phenomenon.

98.4 Gender Differences in Biology and Pharmacotherapy

98.4.1 Biological Influences

Important gender differences exist in the physiologic effects of alcohol. Women have higher

blood alcohol concentration after drinking equivalent amounts of alcohol as compared to men. This is primarily because women have a lower percentage of total body water [53] and a lower concentration of gastric alcohol dehydrogenase, the primary enzyme responsible for the metabolism of alcohol [22]. These gender differences contribute to higher blood alcohol concentrations in women which provide a biological basis for the heightened vulnerability to psychological and medical consequences of alcohol consumption in women. Women develop alcoholic liver disease after comparatively shorter and less intense drinking as compared to men, and neuroimaging studies suggest increased sensitivity to alcohol-induced brain atrophy in women as compared to men [32, 51].

There is less data available concerning gender differences in physiologic effects and medical consequences of other drugs of abuse. Women generally metabolize nicotine more slowly than men [3]. Some studies suggest that men are more sensitive to the rewarding effects of nicotine than women [60]. In addition, negative affect regulation may be a stronger motivation for nicotine use in women [54]. Both animal studies and human laboratory data indicate that females are more sensitive to the subjective effects of stimulants [44]. Of interest, cocaine-dependent women experience fewer cerebral perfusion defects and less frontal cortical neuronal loss [10] compared to men with comparable drug use histories, findings that could be related to gender differences in cocaine-induced cerebral vasoconstriction [39]. There have been many gender differences observed in the pharmacologic properties of opiates, including analgesic effects, but gender differences in abuse potential have not been systematically studied in humans. However, animal studies suggest that mu agonists may be reinforcing to females over a broader dose range, and females self-administer greater quantities of opiates as compared to males [11].

Accumulating evidence from preclinical and clinical studies indicate that hormonal changes associated with the menstrual cycle may impact both craving and the behavioral responses to drugs. For example, estrogen augments behavioral responses to cocaine in female rats by modulating the mesocorticolimbic dopamine system [50, 67]. In humans, this may explain reports of increased responsiveness to cocaine cues and higher quantities of use in women presenting for treatment [66]. In one study, women reported less pleasurable effects of cocaine during the luteal phase, compared to women in the follicular phase and men [70]. As such, women may be more vulnerable to relapse during the follicular phase, when progesterone levels are lower. In another study, administration of progesterone to women during the follicular phase attenuated the positive subjective effects of cocaine [19]. This is an area of active investigation which could have important treatment implications.

Neuroimaging studies have also provided important information about the neural processes underlying sex differences in SUDs. During a stress task, female cocaine users showed greater left frontolimbic brain activation than males [48].

Using positron emission tomography (PET) during cue-induced cocaine craving, Kilts and colleagues found greater activation in women in the dorsal striatum and anterior cingulate cortices and lower activity in the amygdala, which assesses the pleasure of an experience and connects it with its consequences [42]. In a recent exploration of sex differences in neurocognitive and brain responses to emotions, stress, and drug-related cues, Potenza and colleagues found that women had greater reactivity to stress-related cues and men showed higher responses to drug cues [63]. Consistent with these findings, a series of animal and human laboratory studies suggest that both the HPA axis and noradrenergic systems in cocaine and opioid dependence are more dysregulated in females as compared to males [25, 55]. This suggests that women may be more responsive to noradrenergic agents as compared to men.

Gender differences in the physiologic and subjective effects and medical consequences of opiates, marijuana, and other drugs of abuse are under-explored. Considering the important gender differences that have surfaced with careful investigation to date, this is clearly an area that warrants future studies and could have major

implications for gender-sensitive prevention and treatment efforts.

98.4.2 Pharmacotherapy

The findings concerning gender differences in the neurobiology of SUDs and the potential impact of hormones on the subjective effects of substances of abuse and relapse suggest that there may be gender differences in response to pharmacotherapeutic treatment. Animal studies also indicate important gender differences in response to the medications to treat addictions. Campbell and colleagues reported that baclofen-treated female rats were less likely to acquire cocaine self-administration as compared to baclofen-treated male rats [7]. In another study, ketoconazole was found to decrease opiate self-administration more in female as compared to male rats [8]. However, there has been little clinical research exploring gender differences in response to agents currently used in the treatment of substance use disorders. Based on animal research studies demonstrating that progesterone decreases response to stimulants, Evans and Foltin explored the impact of exogenous progesterone on smoked cocaine and found an attenuation of the positive subjective effects of cocaine in women, but not in men [19]. This is clearly an area which warrants further gender-specific investigation.

As detailed above, substance-dependent women are more likely to suffer from mood and anxiety disorders and to be victims of physical and sexual abuse as compared to men. As such, medication treatment of comorbid conditions is likely to be particularly important in the treatment of substance-dependent women. In this regard, one study comparing an SRI (sertraline) to a tricyclic antidepressant (imipramine) in the treatment of depression found that premenopausal women had a preferential response to sertraline [43]. A recent study exploring treatment with a combination of sertraline and naltrexone in individuals with alcohol dependence and major depression found significantly improved alcohol-related and depression outcomes in the combination treatment group [61].

As such, while the evidence does not support the use of antidepressant medications in the absence of depression in substance-dependent individuals, addressing depression will likely improve treatment outcomes. Other studies have provided preliminary evidence that bupropion, a pharmacologic agent with FDA approval for both the treatment of depression and smoking cessation, may be more efficacious in women as compared to men [60].

98.5 Treatment

Although women are generally underrepresented in substance abuse treatment programs, retention and relapse rates for women are comparable to men [26]. Data from several studies suggest that women exhibit more favorable treatment outcomes than men. For example, studies have demonstrated that women have shorter relapse periods and a higher incidence of abstinence at 6 months (79.3% women vs. 54% men) and 5 years (odds ratio 1.9) following treatment [30, 57]. In addition, women demonstrate greater improvement in physical health and are more likely to seek support after a relapse episode [33]. A recent Canadian study found that women are more likely to use technology as a recovery support ($p < 0.05$) and more likely to use art, poetry, writing ($p = 0.007$), and yoga ($p < 0.001$), as part of their recovery journey [56].

98.5.1 Gender-Specific Treatment Programs

Arguments in favor of gender-specific treatment include differences in interaction styles and men's traditional societal dominance, which might negatively affect women in mixed-gender programs. Moreover, women and men with SUDs differ significantly in terms of risk factors, co-occurring psychiatric conditions, motivations for treatment, and risks for relapse. Gender-sensitive treatments can address these issues directly and may improve treatment seeking, retention rates, and treatment satisfaction. However, data from

studies examining effectiveness of gender-specific treatment programs for women are mixed [2, 26, 58]. For example, residential programs that allow children to accompany their mothers have higher retention rates [35, 74]. In addition, women enrolled in women-focused outpatient or residential treatments have higher completion rates than women enrolled in standard substance abuse treatment programs [4]. Although other studies have found that women-only programs provide similar treatment outcomes as mixed-gender programs, these studies have noted that socioeconomic status, addiction severity, and comorbid psychiatric diagnoses are significant factors in determining the effectiveness of women's treatment programs [26, 58].

Prevention strategies and treatment programs for women must incorporate the culture and diversity of each region. For example, in India, the UNODC has distributed guidebooks outlining prevention strategies to women's groups, health-care providers, legislators, and the public and also sponsored nongovernment pilot programs aimed at prevention strategies particularly for women at risk for the development of SUDs [77]. In other regions of the country that have a high population of female sex workers and women who are considered "social outcasts," funding has been provided for a SUD treatment center for women that employs peer educators who are often HIV positive and have a history of a SUD [77]. A general lack of awareness of the prevalence of SUDs in women may interfere with the development of gender-sensitive prevention and treatment efforts in some countries. Thus, identifying ways to include women in epidemiological studies of SUDs may be the first step in garnering support for gender-sensitive treatment programs. In addition, education of treatment providers about gender differences in the etiology of SUDs may help overcome the attitude that women do not require specialized treatment options. It is also critical that standards and guidelines for treatment include measures that protect the confidentiality of victims of domestic violence, restore relationships with family and community members, and use a nonconfrontational approach to therapy. Treatment programs, whether mixed gender or women only, that pay special attention to psychiatric comorbidity, family and parenting issues, victimization, and gender-specific barriers to treatment are likely to be more successful for women.

98.5.2 Gender-Specific Barriers to Treatment

In the United States, women are less likely than men to enter treatment programs [26]. Consistent with this finding, studies from countries that have collected gender-specific data demonstrate that women are consistently underrepresented in SUD treatment programs. For example, in Europe, the ratio of men to women in treatment for marijuana, cocaine, and amphetamine use is 4:1, which is significantly higher than the gender ratio of use for these substances [79]. Across substance use treatment centers in India, only 3% of the 16,942 new patients were women. Men represent approximately 76–90% of patients enrolled in substance use treatment programs across South Africa [76, 81].

Globally, women with SUDs have less access to treatment programs and harm reduction services than men with SUDs. For example, although 10% of all substance users in Afghanistan have access to treatment, only 4% of female drug users have access to treatment [78]. In Eastern European countries, budgetary constraints and bureaucratic challenges have excluded incarcerated women from antiretroviral and opioid replacement treatments but have not excluded incarcerated men [21, 62].

Globally, there are a limited number of gender-based treatment programs. This is a particular challenge for women who have been exposed to domestic violence, who may be more reluctant to attend group treatment programs that include men. In addition, there are few treatment programs for individuals with comorbid substance use and psychiatric disorders.

Sociocultural factors (e.g., shame, lack of spousal/family support) can also be significant barriers to women seeking treatment for SUDs. The social stigma attached to substance use in

societies that value traditional roles for women as domestic caregivers can prevent women from seeking treatment. Women who drink alone may transition to alcohol dependence without their family's knowledge. In fact, one study found that in South Korea, women sought treatment only after the physical symptoms of drug withdrawal appeared [47]. In addition, women living in culturally conservative societies may not feel comfortable discussing sexual abuse and/or may not be knowledgeable of their own family history of SUDs. Relationship dynamics can also impact women's decision to seek treatment for SUDs. Women may be more reluctant to leave home for long-term treatment out of fear that separation from the family will lead to divorce and threaten family stability [29]. In addition, women who are exposed to domestic violence exhibit self-destructive behaviors and are more reliant on their partners and thus less likely to engage in treatment and harm reduction strategies [14, 23].

98.5.3 Special Issues: Pregnancy

Although global awareness of the adverse consequences associated with maternal substance use during pregnancy has increased, drug use during pregnancy remains a significant problem. For example, in the United States and Canada, 32% of the 863 pregnant women who were surveyed reported occasional alcohol use, 16% reported regular alcohol use, and 11% reported heavy alcohol use [13]. In utero exposure to alcohol is associated with fetal alcohol syndrome (FAS), characterized by irreversible neurological damage, developmental delay, facial malformations, and behavioral problems [52]. In another study of 1632 mothers, 25% reported using tobacco, 23% alcohol, 6% marijuana, and 1% barbiturates during pregnancy [1]. The growing opioid use epidemic in the United States has been associated with a significant increase in the prevalence of pregnant women with opioid use disorder (OUD) [16] and neonatal abstinence syndrome (NAS)/neonatal opioid withdrawal syndrome (NOW) [28]. Screening for substance use in primary health-care and obstetric clinics is problematic since pregnant women face social stigma and legal problems which may prevent them from discussing substance use habits with health-care providers. In some countries, legislation and health-care policies are significant treatment barriers for pregnant women with SUDs. In the United States, laws that criminalize drug use during pregnancy in some states can prevent pregnant women from speaking openly with clinical care providers about their substance use [59]. In Russia and Ukraine, pregnant women with SUDs risk forced abortion and termination of parental rights [17, 18]. A number of groups, including WHO, have recommended that opioid-dependent pregnant women should be maintained on either methadone or buprenorphine treatment [83, 71]. Relative to methadone, BUP offers the advantages of greater convenience for pregnant women and lower NAS/NOWS severity in their infants [38]. Some disadvantages of BUP include increased risk of diversion, poorer adherence, greater treatment dropout, and daily peak-trough effects [49, 34].

Pregnant women seeking substance abuse treatment often have additional health problems including HIV and other STDs, as well as psychiatric problems and abusive living situations. Thus, routine screening for trauma, victimization, and depression for this at-risk population is necessary [75, 80]. A multidisciplinary approach to treatment that provides state-of-the-art treatment for SUDs integrated with psychosocial support and psychiatric, medical, prenatal, and gynecological care has been implemented in a number of countries, including Austria, Canada, the Czech Republic, and India [77].

98.6 Conclusion

International research clearly indicates that gender-sensitive substance use policies and programs cannot ignore cultural influences. Large cross-national variation in gender differences in substance use disorders makes it clear that biological factors alone do not account for gender differences in substance use and addictions. Policies, education, and prevention and treatment

efforts must take into account both the biological differences and the culturally defined gender roles that specify expected and tolerated drug use behavior in men and women. Cross-national research can help to explicate the complex interactions between biology, individual-level, and societal-level variables that influence alcohol consumption and drug use and allow us to design better-targeted prevention and intervention efforts for both genders worldwide.

Abstract

Over the past decade, older people have shown higher rises in rates of substance misuse compared with younger age groups. This has impacted upon both public health and clinical outcomes such as hospital admissions and the presence of co-morbid disorders such as alcohol-related cognitive impairment.

The presence of accompanying physical and mental disorders and the physiological effects of ageing call for greater vigilance over the adverse effects of substances in older people. Greater complexity in clinical presentations calls for special considerations in assessment, treatment and care planning. This also applies to legal and ethical considerations and alcohol-related cognitive impairment.

Older people with substance misuse experience positive health and social outcomes that are equal if not better than younger people. To sustain and improve the mental and physical health of older people with substance misuse, an integrated approach to care is required. This will need to involve old age psychiatry, addiction psychiatry, geriatrics, primary care and their interface with housing and social care.

Alcohol · Drugs · Addiction · Ageing
Substance use disorders

99.1 Introduction

At a global level, alcohol is responsible for 7% of deaths in people under the age of 70. In the Eastern Mediterranean region, the highest rate of alcohol-attributable deaths occurs in the 45–49 age group. In the African region, although the proportion of such deaths is highest (11.2%) in the 25–29 age group, it remains high (8.1%) even in the 60–64 age group [98].

For all age groups, using disability-adjusted life years (DALYs) to measure both years of life lost and years lived with disability from alcohol use disorders, the 70 and over age group is the only one to have increased over the past 15 years, from 125 to 150 DALYs per 100,000 population [43].

In developed countries, increasing longevity has been associated with large increases in the number of people aged over 50 years. It is also now this population of 'baby boomers' who are at highest risk of increasing rates of substance misuse. This observation is also mirrored in developing countries [56]. The number of older people with drug and alcohol use disorders receiving treatment is expected to treble in the United States and double in Europe by 2020 [99].

For the purposes of this chapter, the term 'older people' will refer to those aged 50 years and over.

99.1.1 Epidemiology

Alcohol remains the most widely used substance in older people. Using disability-adjusted life years (DALYs) as a marker of morbidity, alcohol rose from 16th to the 5th highest risk factor in people aged 50 to 69 years in England between 1990 and 2013. Smoking remains the top risk factor.

There remains a direct association between alcohol misuse and deprivation. Although higher socio-economic status is associated with higher alcohol consumption [67], co-morbidity from physical and mental disorders in areas of high deprivation may explain poorer health outcomes in areas with higher socio-economic deprivation [44].

There are considerable differences in drinking patterns among older people globally [92]. In England, 87% of older people report drinking alcohol over the previous year, compared with 18% in India. For drinking quantity and frequency, the findings are different. Thirty-two percent of older people in China report frequent heavy drinking, compared with 3% in Mexico. The prevalence of tobacco smoking in people over 60 is 13% worldwide (22% of men and 8% of women).

Lifetime use of illicit drugs in older people has increased sharply over the past 15 years, with rises most marked in the 65–74 age group. In this age group, lifetime cannabis use increased from 0.9% in 2000 to 6.8% in 2014 [75].

In the United States, past-year use of cannabis in people aged 65 and above increased from 0.15% in 2003 to a high of 2% in 2014 [79].

Older adults are the largest per capita consumers of prescription and over-the-counter drugs in most developed nations [81].

Prescription drug misuse is also a growing problem. Inappropriate prescribing of these drugs, especially for opioids and benzodiazepines, occurs in up to 20% of older people [29]. There is now also growing evidence for increasing rates of inappropriate prescribing of gabapentinoid drugs in older people [89].

99.1.2 Risk Factors

Approximately one-third of people with alcohol misuse aged 65 years and over have developed this after the age of 50 [34]. People with their first onset of alcohol misuse after the age of 45 years are less likely to have a family history of alcohol misuse, a history of alcohol-related injuries or nicotine dependence. This group also has a lower number of alcohol-related medical disorders [94].

However, older people with alcohol misuse are as likely as younger people to have a history of mental disorder [94] and more likely to have accompanying psychosocial precipitants to alcohol misuse.

Low social interaction [45], fewer responsibilities, bereavement, loneliness [17], increased financial strain [86] and social isolation [25] are all risk factors for alcohol misuse. Homelessness also has a strong association with alcohol misuse in older people [26], but retirement has shown a conflicting association [13, 91].

Risky drinking had positive associations with male sex, depression, smoking and working in an urban area [42].

Alcohol misuse in response to stress is more common in older women, who use alcohol to self-medicate [21]. Anxiety disorders carry a higher risk of alcohol misuse in older women [97].

Chronic pain has a consistent association with alcohol misuse in older people [41] and is a strong predictor of relapse [96], but is not consistently associated with the extent of the pain [15].

Insomnia is also known to be associated with alcohol misuse [88]. As many as 26% of older people use alcohol for medicinal purposes such as insomnia [3].

99.1.3 Low-Risk Drinking

Our Invisible Addicts [75] recommended that 'low-risk' drinking for people aged 65 years and over be defined as drinking no more than 12 UK units per week, or an average of 1.75 UK units per day. These are broadly in line with low-risk drinking in the United Kingdom, which state an upper limit of no more than 14 units per week for both men and women [30]. However, this guideline may still need to be applied with caution to older people, who are likely to be more sensitive to alcohol-related harm through the effects of ageing, accompanied by physical and mental health problems, a higher risk of interactions with prescribed and other medications and a higher likelihood of the cognitive impairment than younger people.

Across all age groups, comparatively higher mortality rate has been found in men drinking above 2.5 UK units per day and women drinking above 1.25 UK units per day, compared with non-drinkers [87]. This equates to 17.5 units for men and 8.75 units for women per week. There is no evidence of increased mortality for older women drinking an average of no more than 1.25 units of alcohol per day [46].

However, any perceived health 'benefits' may be attributable to inappropriate selection of a reference group and weak adjustment for confounders.

99.1.4 Economic Costs

The total cost of alcohol globally is estimated to be 2.5% of gross domestic product (GDP) [7], equivalent to £47 billion in 2016. The majority of these were indirect costs (72% of all costs), followed by healthcare costs (13%), other direct costs (12%) and law enforcement costs (3%).

The direct economic burden of alcohol dependence in Europe accounts for between 0.39% and 2.99% of annual GDP spent on healthcare per country. The main cost driver is hospitalisation for alcohol-dependent patients, which accounts for as much as 15% of this annual spending per inhabitant for a single patient [80].

For direct and indirect costs, harmful use of alcohol ranks among the five top risk factors for disease, disability and injury throughout the world [50].

99.1.5 Premature Ageing and Mortality

Substance misuse is associated with both cellular and organ damages [85]. This can lead to premature vascular damage and neuronal toxicity. Substance misuse is also associated with unprotected sex or intravenous drug use that increases exposure to blood-borne viruses [47].

Alcohol and illicit drug misuse reduce life expectancy by between 9 and 24 years [22]. For tobacco smoking, this reduction is between 8 and 10 years [23].

99.2 Assessment

Table 99.1 illustrates the considerations relevant to the assessment of older people with substance misuse. It is essential to adopt an approach that takes into the account the narrative and experience that comes with age. The interview should not be rushed. It should consider sensory impairment, embarrassment about reporting and more than one assessment may be necessary. Taking a history should include any accompanying physical disorders and mental disorders such as depression and dementia. The impact of problems with activities of daily living from or upon substance use and misuse should be considered, as should social vulnerability and life events such as loss of employment and bereavement. There is a wealth of information to inform diagnosis and further care interventions, covering health, social care and housing, as well as information from carers. Investigations should include both laboratory tests to gauge the extent of liver disease, neuropsychological evaluation and comprehensive medical and functional assessment.

99.2.1 Presentation of Substance Misuse in Older People

The clinical presentation of substance misuse is often atypical and complex. For alcohol misuse, these are outlined in Table 99.2.

Table 99.1 Assessment of substance misuse in older people

General approach	History taking	Collateral information	Investigations
Non-ageist	Co-morbidity	Family practitioner	Cognitive screening
Preserve dignity, privacy and comfort	Cognitive and mood state	Housing	In-depth cognitive assessment
Adjust tempo	Functional abilities, nutrition and self-care	Social care (including domiciliary and day care)	Laboratory blood tests
Hearing and eyesight	Social factors (e.g. abuse and isolation)	Voluntary agencies	Neuroimaging
Stigma and under-reporting	Multiple substances	Hospital summaries	Occupational therapy assessment
Multiple assessments	Loss events	Family and carers	Comprehensive geriatric assessment

Table 99.2 Atypical presentations of substance misuse in older people

Sleep complaints
Cognitive impairment, memory or concentration disturbance
Liver function abnormalities
Incontinence
Poor hygiene and self-neglect
Unusual restlessness/agitation or persistent tiredness
Unexplained nausea and vomiting
Changes in eating habits
Slurred speech, tremor, poor coordination
Frequent falls and unexplained bruising
Masking by other mental and physical disorders

99.2.2 Screening

Screening instruments for substance misuse in older people have only been validated for the identification of alcohol misuse (Table 99.3). The CAGE questionnaire detects the core features of alcohol dependence [33] but is relatively insensitive to harmful/hazardous drinking [2]. Its acronym stands for felt that you should *c*ut down; *a*nnoyed by others criticising drinking; feel *g*uilty about drinking; have an *e*ye-opener on waking to get rid to steady nerves.

The most widely used screening tool for older people is the Short Michigan Alcoholism Screening Test – Geriatric version (SMAST-G; [11]). Questions tap into problems more commonly seen in older people, such as 'drinking after a significant loss' or 'drinking to take your mind off your problems'.

Different adaptations of the Alcohol Use Disorders Identification Test (AUDIT) tool [82] have been validated in older people [73]. A cut-off score of 5 for older men and 3 for older women shows the greatest sensitivity and specificity, using the full AUDIT. The AUDIT-5 [62] is also used in the screening of older people with co-morbid mental disorders [61], as well as the AUDIT-C [20]. Suggested cut-off points for the AUDIT-5 [61] and AUDIT-C [1] are 4 for both instruments.

The total score on the full AUDIT indicates a drinking risk category – low, increasing, higher or possible dependence. The AUDIT also serves as a clinical decision tool as the score provides an indication of appropriate interventions. It can also be used as an outcome measure. A score of 0–7 refers to low risk, 8–15 to hazardous/increasing risk, 16–19 to harmful/higher risk and 20 or higher to possible dependence.

Given a lack of sensitive screening tools for alcohol problems in older people, such tools need

Table 99.3 Screening instruments for alcohol misuse in older people

Screen	Full name	Description
AUDIT [82]	Alcohol Use Disorders Identification Test	10 items, self-administered
AUDIT-C [20]	AUDIT – quantity/ frequency Items	Items 1–3 from AUDIT
AUDIT-5 [62]	Five questions from the AUDIT	Questions 1, 2, 4, 5 and 10 from AUDIT
CAGE [33]	Acronym from keywords in four questions	Four items, self-administered
MAST [83]	Michigan alcohol screening test Test	22 items, self-administered
MAST-G [11]	'Geriatric' version of MAST	24 items, self-administered
SMAST [84]	Short version of MAST	13 items, self-administered
SMAST-G [11]	The short MAST geriatric version	Ten items, self-administered, derived from MAST and MAST-G
ARPS [35]	Alcohol-related problems survey	18 questions, 60 items, self-administered, but requires computer scoring
shARPS [55]	Shortened ARPS	32 questions, self-administered; does not require computer scoring
CARPS [58]	Fully computerised ARPS	18 items, 60 questions self-administered via a computer, requires computer scoring

to be combined with a comprehensive assessment assessing use, misuse and dependence.

99.2.3 Barriers to Assessment

There are several barriers to the assessment of substance misuse in older people (Table 99.4). Assessments may need to be multiple and frequent, with engagement of patient, families and carers. There is often ambivalence about admitting to substance use and resistance to changing drinking behaviour. There may also be awkwardness in practitioners asking about it. There should always be a high degree of clinical suspicion.

A full assessment needs to be supplemented with information from collateral sources. This includes information from relatives, friends and informal carers (taking account of information sharing and confidentiality), GP consultations (including current prescribed medication), hospital discharge summaries, home carer reports, day centre reports, reports from housing officers/wardens of supported housing and criminal justice agencies and results from previous investigations such as psychometry and neuroimaging [77].

Greater prominence needs to be given to social functioning and social networks in older people than in younger adults. In older people, there is comparatively less emphasis on forensic history and occupational history than in younger people. Social pressures such as debt or even substance-using 'carers' or open drug dealing may impact on the older person's welfare. Vigilance about safeguarding is essential.

Functional ability also has greater relevance when assessing older people. This can be assessed using the Barthel Index which rates the ability to perform activities of daily living (ADLs) [93].

Table 99.4 Barriers to identification of substance misuse in older people [75]

Practitioner barriers	Individual barriers
Ageist attitudes	Attempts at self-diagnosis
Failure to recognise symptoms	Symptoms attributed to ageing or illness
Lack of knowledge about screening	Many do not self-refer or seek treatment
Discomfort with topic	Perceived stigma of 'addiction'
Lack of awareness of substance misuse in older people ('If you don't think about it, you won't see it')	Reluctance to report – shame, denial, desire to continue using, pessimism about recovery
Misuse traditionally considered to be rare in old age	Cognitive impairment
Symptoms may mimic or be hidden by symptoms of physical illness	Unwillingness to disclose
Unwillingness to ask	Collusion of informant(s)
Absence of informant(s)	Screening

99.2.4 Diagnosis

There are limitations to using standardised diagnostic criteria for substance misuse in older people [12]. Cognitive impairment may interfere with self-monitoring; there may be reduced incentive to increase harmful use, such as fewer social pressures and fewer personal and family pressures; negative effects may occur at relatively low levels of use; cravings may be attributed to depression or anxiety; roles and expectations may have changed; social or interpersonal problems may not be attributed to substance use; activities may have been given up for other physical or mental health reasons; physical harm may be denied; low levels of substance misuse may lead to tolerance and withdrawal.

99.2.5 Physical Examination

Physical manifestations of alcohol misuse can provide clues to damage from several substances. There may be weight loss and poor self-care. Gait may be impaired through intoxication, cerebellar damage or stroke. Complications from intravenous drug use can present as superficial and deep vein thrombosis, subacute bacterial endocarditis, nail fold infarcts, splinter haemorrhages, Osler's nodes and Janeway lesions. There may also be gum disease and dental caries. Chronic obstructive pulmonary disease (COPD) may arise from tobacco and/or cannabis smoking, and cocaine smoking can present with 'crack lung'. Alcohol misuse may present with acute (e.g. Mallory-Weiss tear, rup-

tured oesophageal varices, hepatic encephalopathy or arrhythmia) physical problems or else with stigmata of chronic liver disease, hypertension and oral and gastro-intestinal malignancy, as well as with stroke. Falls are also a common presentation of heavy drinking in older people.

There may be neurological manifestations such as cerebellar damage and traumatic intracerebral or extracerebral bleeding. Thiamine deficiency is associated with Wernicke's encephalopathy, Korsakoff's syndrome and peripheral neuropathy.

99.2.6 Mental State Examination

Certain aspects of the mental state examination have greater relevance for older people with substance misuse. Delirium is associated with intoxication or withdrawal. Delirium tremens has a high morbidity and mortality and is treatable. Wernicke's encephalopathy may also present with or be mistaken for delirium or intoxication, and the opportunity for treatment may be missed. The 'classic triad' of oculomotor abnormalities, cerebellar dysfunction and altered mental state only occur in 20%. However, 80% of patients present with an altered mental state of mental sluggishness, apathy, impaired awareness of an immediate situation, disorientation, poor attention, agitation and hallucinations.

Low mood and anxiety accompany misuse of a range of substances, particularly depressant drugs such as alcohol, sedatives and hypnotics. It is not uncommon to find the presentation of substance misuse compounded by mood disorder and cognitive impairment or 'somatised' by presenting as physical symptoms such as lack of energy. Suicidal ideation is highly relevant for older people with depression who are known to be at high risk of suicide when accompanied by alcohol misuse.

Psychotic symptoms are associated with a variety of substances such as cannabinoids, stimulants and hallucinogens; withdrawal states accompanying alcohol and/or sedative/hypnotics are also associated with transient psychotic symptoms. Chronic use of stimulant and depressant drugs (e.g. alcohol) can manifest as psychosis.

Cognitive impairment may arise from alcohol brain injury, alcohol-related traumatic brain injury, benzodiazepine use, stroke or chronic subdural haematoma. Cognitive impairment may be assessed using the mini-mental state examination (MMSE) [38] and Addenbrooke's Cognitive Examination (ACE) [53].

99.3 Co-occurring Mental and Physical Disorders

Co-occurring mental disorders occur in as many as 66% or people with substance misuse [6]. Depression and cognitive impairment are the most common mental disorders, with the latter mostly alcohol-related brain damage.

Depression is common in alcohol misuse [5, 16]. Older adults with depression are up to four times more likely to have alcohol-related problems than those without [32] and are also at higher risk of suicide [28]. Depression is also associated with a higher risk of past-year cannabis and cocaine use [10]. Other mental disorders such as anxiety, antisocial personality disorder and post-traumatic stress disorder are associated with alcohol misuse in over 60s [14, 63, 78].

Older heroin and methadone use is accompanied by physical co-morbidity, with prevalence rates varying from 11% for diabetes mellitus to 54% for hypertension. Other co-morbid disorders within this range include arthritis, cirrhosis, hepatitis C, lung disease and cardiac disease [74].

99.4 Interactions Between Substances and Prescribed Drugs in Older People

99.4.1 Alcohol

Alcohol has a number of potential adverse effects when taken with both prescription and non-prescription drugs. This is relevant to older people, in whom polypharmacy is common. Up to 28% of older people in the United Kingdom take medica-

tion that has not been appropriately prescribed. The most common drugs implicated are benzodiazepines and amitriptyline [8, 40]. Potential interactions between prescribed drugs, as well as with food and drink, are detailed in Table 99.5.

Table 99.5 Interactions affecting blood alcohol levels

Drug	Interaction	Risk
Over-the-counter drugs	Multiple interactions	Aspirin ↑ risk of bleeding into the gut Heavy drinking ↑ risk of liver damage from paracetamol
Antibiotics	Disulfiram-like reaction	Flushing, headache, palpitations, vomiting
Food	Multiple interactions	Food and milk ↓alcohol absorption
Nicotine patches	Pharmacodynamic	Tachycardia
Psychotropic drugs	Pharmacodynamic	Amitriptyline, clozapine, Mirtazapine, olanzapine, quetiapine, trazodone and zuclopenthixol ↑ drowsiness
Opiate analgesics	Pharmacodynamic	↑ risk falls/ respiratory depression
Sedating antihistamines	Pharmacodynamic	↑ risk drowsiness
Anti-hypertensive drugs	Pharmacodynamic	Low blood pressure and falls
Warfarin	Pharmacokinetic	Acute alcohol intake: ↑ levels Chronic alcohol intake: ↓ levels
Anti-emetics	Pharmacokinetic	Metoclopramide ↑ alcohol levels
Anti-epilepsy drugs and mood stabiliser drugs	Pharmacokinetic	Carbamazepine levels ↓ by heavy drinking; blood alcohol levels ↑ by meprobamate

99.4.2 Other Substances

Buprenorphine, methadone and loperamide are inhibited by antibiotics (ciprofloxacillin, clarithromycin, erythromycin, itraconazole, ketoconazole and ritonavir), the anti-hypertensive diltiazem, grapefruit juice and the antidepressant nefazodone. They are induced by drugs for epilepsy (carbamazepine, phenytoin, phenobarbital), the antibiotic rifampicin and the herbal remedy St John's wort.

Oxycodone, codeine, dihydrocodeine and tramadol are inhibited by the antidepressants fluoxetine and paroxetine, the anti-emetic metoclopramide and the anti-arrhythmic drug quinidine.

Pentazocine is inhibited by the anti-arrhythmic drug amiodarone, the beta-blocker propranolol, antibiotics ciprofloxacillin and rifampicin, the antidepressants duloxetine and fluvoxamine, the antipsychotics olanzapine and clozapine and caffeine.

Morphine, naloxone and naltrexone are minimally affected by pathways involving the above opioid drugs and therefore have clinically insignificant drug interactions with non-substances.

Nicotine alone has few interactions with other drugs. Its metabolism is inhibited by ketoconazole, isoniazid and grape juice. Phenobarbital and rifampicin are associated with enzyme induction. Polycyclic aromatic hydrocarbons in tobacco smoke affect the same enzyme pathway affected by metabolism of the drug pentazocine. However, in this case, smoking is associated with enzyme induction or inhibition of the drugs affecting its metabolism. The anti-epilepsy drug carbamazepine is induced by chronic smoking.

99.5 Treatment

A systematic review including people aged 50 years and over [54] concluded that older people have equally favourable or even better outcomes than younger people. An updated systematic review using a similar approach [9] found that interventions for at-risk drinking, cigarette smoking and prescription drug misuse

were associated with positive outcomes. A third review [48] with broader inclusion criteria included studies with mixed ages where non-age-specific treatments were also delivered to older people, focussing mainly on alcohol. There was a greater response to treatment (with longer duration and intensity of interventions) and greater treatment adherence in older than in younger people.

99.5.1 Alcohol

99.5.1.1 Pharmacological Approaches

Most pharmacological agents should be used with caution in older people. There is no specific guidance on the use of acamprosate, naltrexone or disulfiram in older people [52]. Addiction psychiatrists initiating treatment in older people should therefore work jointly with older people's mental health and medical services. Treatment needs to take account of co-morbid physical problems such as neuropsychiatric disorders and hepatic complications (e.g. alcoholic liver disease and hepatitis C), as well as respiratory complications such as chronic obstructive pulmonary disease (COPD). Older people are also likely to be taking multiple medications, with the potential for adverse drug reactions.

Alcohol withdrawal may be more severe and more prolonged in older patients in general hospital settings, compared with a younger age group [19]. Benzodiazepines such as chlordiazepoxide are clinically effective in managing alcohol withdrawal and detoxification [95]. For older patients, a lower starting dose of chlordiazepoxide is advised, with an increase in dose if withdrawal symptoms are not controlled. A longer-acting drug may prevent seizures and delirium but could lead to accumulation.

A lower starting dose should be used in older people, with regular monitoring using the Clinical Institute Alcohol Withdrawal Scale [90]. Shorter-acting preparations are preferable [57]. Chlormethiazole is not recommended for older patients because of its effect on respiration, cardiovascular complications and the unpredictability of the serum levels achieved [18].

Likewise, carbamazepine has not been evaluated in older populations and is therefore not recommended. Acamprosate, disulfiram and naltrexone are all licenced for the prevention of relapse in abstinent alcohol-dependent adults [52]. However, less evidence is available for their use in older adults. A trial comparing naltrexone as a relapse prevention medication with placebo found that the group aged 55 years and over had longer drinking careers and greater physical disability. However, their greater rates of treatment engagement and medication adherence were associated with a greater likelihood of abstinence [59].

99.5.1.2 Psychosocial Approaches

Several studies using age-specific treatment have evaluated the impact of psychosocial interventions. A study using the Computerised Alcohol-Related Problems Survey (CARPS) at baseline and 12 months found that adding physician input to education was more effective in reducing the quantity and frequency of alcohol consumption than education alone [36]. A telephone disease management (TDM) programme for depression and/or at-risk drinking was more effective than usual care. At 4-month follow-up, response rates were better in TDM (39%) compared with usual care (18%).

A controlled clinical trial (Project GOAL: Guiding Older Adult Lifestyles) compared the impact of enhanced brief physician advice compared with usual treatment [37]. Older people receiving the physician intervention demonstrated a significant reduction in 7-day alcohol use, episodes of binge drinking and frequency of excessive drinking.

The Primary Care Research in Substance Abuse and Mental Health for the Elderly (PRISM-E) compared integrated treatment in primary care with enhanced specialty referral for older adult at-risk drinkers [49, 60]. Both interventions produced an overall reduction in drinking or binge drinking. However, the integrated approach was associated with greater treatment engagement, especially for those with greater problem severity.

In the Healthy Living as You Age (HLAYA) study, participants were randomised to either active intervention or a booklet on healthy behaviours [51]. At 3 months, intervention group participants reported drinking fewer drinks in the past 7 days and less heavy drinking and had lower risk scores. At 12 months, only the difference in the number of drinks remained statistically significant.

A naturalistic retrospective study in London, UK, followed up 108 people aged 65 years and over with alcohol misuse who were referred to an old age liaison psychiatry service over a 5-year period [65]. Of the 50 people who were managed by community mental health teams, 19 (38%) had achieved abstinence from alcohol or controlled drinking at 6-month follow-up. Treatment comprised assessment and brief intervention, accompanied by psychosocial support.

99.5.2 Opioids

The prescription of strong opioid drugs for non-cancer pain has increased over the past 25 years. There are no controlled trials extending beyond 4 months of treatment, so the long-term effectiveness and safety of prescribed opioids are unknown. Inconsistencies in definition of aberrant analgesic use, in objective measurement of medication consumption and in description of clinical outcomes, can make identification of those overusing analgesics difficult [24].

99.5.2.1 Intravenous Opioids

Ninety percent of heroin users initiate drug use before the age of 30, with only 3% initiating after 50 years of age [100]. It was once believed that illicit drug users 'matured' out of their drug use, but there is evidence that older heroin users do not reduce their use as they age [74]. In the United States, the proportion of older adults seeking treatment for substance misuse is increasing relative to younger adults, and the pattern of drug use is changing, with increasing consumption of heroin [4]. In the United Kingdom, the initiation of drugs such as methadone, buprenorphine and adrenergic pre-synaptic agonists (clonidine and lofexidine) is not licenced for management of withdrawal states in older people. There is therefore a dearth of research into the use of these drugs in older people.

99.5.3 Tobacco

Older smokers appear to be more motivated to stop than younger people. One study showed a 4% increase in likelihood of enrolling in a smoking cessation trial for every year increase in age [27]. One review of 13 RCTs examined the effectiveness of smoking cessation interventions among people aged 50 years and over. Nine of 13 studies found a significant intervention effect at one or more follow-up assessments, suggesting successful interventions with older adults are available and feasible. The best results come from interventions of longer duration. Most studies included counselling of varying intensity, and eight provided medication for smoking cessation [101]. The impact on reducing harm from cigarettes through 'vaping' remains to be seen.

99.6 Service Provision

Older people with co-occurring mental and physical disorders have specific needs. Mental health services for older adults should provide integrated care. This should involve input from alcohol and drug services, geriatrics and primary care, so that physical, mental health and psychosocial needs are met. Ideally this should also be community based.

Older people with alcohol addiction frequently have co-morbid mental disorders, and in the absence of specialist services, they are mostly under the care of older people's community mental health teams. In the United Kingdom, the combination of alcohol addiction and other mental disorders is commonly referred to as 'dual diagnosis' [31]. However, at an international level, the most commonly used term is substance misuse and co-morbid mental disorder (SMCD) [66].

Traditional service configuration for SMCD is delivered through sequential or parallel treatment. Sequential treatment results in patients receiving treatment for one problem at a time, with treatment for the other problem being deferred until the first is resolved or improved. Parallel treatment involves different providers from different services system treating the two disorders simultaneously.

Integrated treatment models offer comprehensive services for both mental illness and substance misuse from a multidisciplinary treatment team, thereby overcoming barriers to care and debate over which disorder is primary. Both disorders are case managed to improve health and social function within a single care plan.

Targeting service delivery for SMCD in older people requires consideration given to those at highest risk. Such groups include those older people at risk because of their previous history of mental illness or else bereavement, retirement, social isolation or physical problems as well as those with depression, anxiety and cognitive impairment. However, integrated approaches cannot be effective unless older people with comorbidity receive the treatment that they need.

An 'assertive' approach involves the use of outreach models such as a home-based model, particularly for housebound older people who cannot access traditional substance misuse services. This is critical to success in engaging older people with SMCD and incorporates crisis intervention, practical support (monitoring safety, food intake, medication management, benefits, arranging transport), monitoring of mental disorders, review of treatment, social engagement and family support. The final component is the largest in terms of time and resource allocation, covering harm reduction and relapse prevention.

Approaches to harm reduction will involve substituting substance use with alternative activities, including:

- Improving social networks
- Improving physical function
- Reducing risks such as adverse drug interactions, delirium and falls
- Encouraging new hobbies
- Brief intervention and brief advice
- Supportive psychotherapy and cognitive behavioural therapy
- Social skills training around refusal of alcohol
- Psycho-education (including family education)
- Detoxification
- Consideration of alternative housing

Once harm reduction has been implemented, relapse prevention will involve a longer-term perspective and involves expanding opportunities for social integration, attending self-help groups (e.g. Alcoholics Anonymous), increasing family support, maintaining healthy lifestyles and living environments and encouraging volunteering activities.

In the United States, the Treatment Improvement Protocol Consensus Panel [11] recommends incorporating integrated assessment and treatment for SMCD, which included:

- Outreach, screening and intervention by addiction specialists, nurses, social workers and mental health counsellors
- Specific settings targeted to the elderly, including health fairs, day centres, retirement communities and housing sites
- Working with community agencies to develop referral networks such as primary care, social, ageing and other service providers
- Screening protocols for misuse of alcohol, prescription medications, over-the-counter medications and illegal drugs, as well as depression and risk of suicide

In 2009, a strategic vision for all clinical services for older people with SMCD within London, UK was developed [71]. The main aim was to improve the detection, treatment and health outcomes for older people with dual diagnosis (SMCD). The following objectives were identified:

- Building on existing good practice improving access to services
- Creating new service options where possible
- Developing clinically effective care pathways

- Promoting robust partnerships with key stakeholders (including working with service users and carers)
- Building a skilled workforce to address unmet needs
- Promoting health education/prevention/early intervention

A recent study of this service has shown that 40% of older people with SMCD referred from medical in-patient settings achieved either abstinence or controlled drinking within the Mental Health of Older Adults Clinical Academic Group.

Older people with SMCD require a considerably different approach to younger people, focussing more on chronic physical disorders, depression, organic brain disorders as well as social aspects such as social isolation, bereavement, activities of daily living, mental capacity, safeguarding and carer support. Challenges also lie within the prevention of hospital admission and institutionalisation through the delivery of home-based services.

99.7 Legal and Ethical Considerations

Older people with drug and alcohol misuse may present with difficulties around capacity, consent and principles used to determine the best interests of a patient. There should be presumption that all adults have the capacity to make decisions for them, unless proven otherwise. Capacity may also vary over time with intoxication or delirium, or according to the time of the day. Any decisions should be put off until the person regains capacity, if practically possible. If a person is deemed to be 'lacking capacity', it means that they lack capacity to make a specific decision or take a particular action for themselves at the time the decision or action was taken.

Older people from black and minority ethnic (BME) backgrounds face major challenges in accessing drug and alcohol services. These may include language barriers, social stigma as well as cultural and family values. Individuals from some BME backgrounds have higher levels of alcohol misuse and resulting health problems than the general population, such as older Irish and South Asian (Sikh) male migrants to the United Kingdom [64]. Both alcohol misuse and ethnicity can contribute to social disadvantage.

Each racial/ethnic group is not homogeneous and may include many subcultures that may be influenced by cultural values such as traditional beliefs, family structure, lifestyle preferences, gender roles, degree of assimilation and religious belief. These need to be borne in mind by various health professionals and during service developments.

99.8 Alcohol-Related Cognitive Impairment

Alcohol is known to be associated with cognitive impairment (ARCI) through a variety of mechanisms [68]. In older people with ARCI, there is also likely to be accompanying cerebrovascular disease with or without a history of stroke or cerebellar damage as well as a history of traumatic head injury with or without a history of chronic subdural haematoma or intracerebral haemorrhage [76].

Mechanisms of alcohol neurotoxicity [69] include direct toxicity (frontal and hippocampal damage), malnutrition (Wernicke's encephalopathy/Korsakoff's syndrome), metabolite toxicity, electrolyte imbalance, hepatic encephalopathy/infection, inflammatory (e.g. tumour necrosis factor alpha) and modifying factors (e.g. Apo E allele/elevated homocysteine).

ARCI shows better performance on language tasks but poorer performance on visuospatial tasks compared with Alzheimer's disease [72]. Frontal lobe damage is particularly common in ARCI, which may explain the high rate of behavioural problems seen in ARCI [70]. Unlike other forms of dementia, there is partial reversibility of some people with ARCI such as in frontal white matter integrity, particularly for late-onset alcohol misuse [39]. Alcohol use disorders also frequently complicate primary dementia, increasing cognitive decline [69].

100 Treatment in Criminal Justice Settings; Mandatory vs Voluntary Treatment and Rehabilitation

Tim McSweeney

Contents

Abstract

The public health and community safety challenges associated with the use of illicit drugs have intensified in recent years, with the number of people using illicit drugs increasing globally and rates of fatal drug-related overdose rising considerably, particularly in North America and parts of Western Europe. Yet prevention efforts and treatment provision typically fail to meet levels of need and demand in many parts of the world. At the same time, 'drug-related' offending continues to be a significant driver of global prison populations and its associated costs. While a growing number of countries have implemented alternative policy innovations for dealing with drug-using suspects, defendants and convicted offenders using forms of depenalisation, diversion or decriminalisation, most continue to incarcerate and criminalise people for the possession or use of illicit drugs and rely on punitive sanctions, such as imprisonment, as the default response to 'drug-related' crime. This chapter draws upon international evidence for the effectiveness of 'coerced' and mandated forms of treatment (which are ordered, motivated or supervised by the CJS) as a response to 'drug-related' offending. It also highlights what this evidence base tells us about how different contexts and mechanisms

for implementation and delivery can hinder or enhance the effectiveness of these approaches.

Keywords

'Coerced' treatment · Diversion · 'Drug-related' crime · 'EMMIE' framework

100.1 Introduction

A range of diverse indicators suggest that the public health and community safety challenges and costs associated with the use of illicit drugs have increased in recent years. Official estimates suggest that in 2017 more than 270 million people worldwide (aged between 15 and 64 years) had used illicit drugs at least once in the previous 12 months. This is equivalent to around 6 per cent of the global population or 1 in every 18 people within this age range. The number of people using illicit drugs has increased by 30 per cent since 2009 when there were an estimated 210 million illicit drug users globally [74].

UNODC further estimates that there are 35 million people – around 13 per cent of all past-year users – who suffer from drug use disorders and require treatment services. While cannabis is by far the most commonly used illicit drug, opioids present the greatest harm to the health and wellbeing of users. There were over half a million global deaths attributed to drug use in 2017, with rates of fatal drug-related overdose increasing considerably in North America and parts of Western Europe.

However, prevention efforts and treatment provision typically fail to meet levels of need and demand in many parts of the world, with the UNODC reporting that only one in seven people with drug use disorders receives appropriate treatment each year. Findings from a recent systematic review [45] identified some of the most pronounced gaps between levels of need and provision existing in the Middle East and North and sub-Saharan Africa, where only around one third of the estimated regional population of people who inject drugs (PWID), for instance, have access to opioid substitution therapy (OST). Elsewhere, the proportion of opiate users in treatment varies considerably: from 28 per cent in Canada and the United States to 60 per cent in England and 76 per cent in France [59].

100.2 The Social and Economic Costs of Illicit Drug Use and 'Related' Crime

International evidence has consistently shown that rates of illicit drug use are significantly higher at all stages of the criminal justice system (CJS) – whether that be in police custody, through the courts and sentencing process, while subject to probation supervision or starting a prison sentence – relative to those found in the general population [10, 54]. Consequently, the CJS represents an important point for identifying, engaging and intervening with illicit drug users. Despite the challenges associated with generating reliable national estimates in this area of policy [53], illicit drug use is known to impose significant social and economic costs on societies, with considerable direct costs borne by the CJS [12]. These costs are incurred in response to a range of 'drug-related' crimes, such as drug:

- *Defined* (violations of legislation linked to possession or supply).
- *Induced* (committed while under the influence of drugs).
- *Inspired* (committed to generate funds to support drug use).
- *Systemic* offences (committed as part of the 'business' of drug supply, distribution and use, such as violence between rival dealers or supply networks) [26].

Globally, prison populations are estimated to have grown by 24 per cent since the turn of the century (a rate of growth broadly in line with population trends over the same period). During 2018, it is thought that there were over 10.7 million people held in various forms of detention throughout the world, either as pre-trial detainees/remand prisoners or having been convicted and sentenced [76]. These increases in the prison

population have occurred despite available police-recorded data from different countries worldwide pointing towards overall reductions in violent and property crimes between 2003 and 2013. By contrast, drug possession offences showed a marked increase, rising by 13 per cent over the same period [72]. These trends have led the United Nations to conclude that 'The global increase in drug-related crime is driven mainly by a rising number of offences related to drug possession, particularly in Europe and Africa… offences related to drug possession currently comprise 83 per cent of total global drug-related offences' [71: 6]. Consequently, one in five (20 per cent) of the global prison population in 2012 had been imprisoned for drug law offences, with the highest rates of incarceration for these offences apparent in Asia [72].

These punitive responses have been shown to disproportionately impact upon minorities and the economically marginalised in societies [2, 16, 63]. They are also associated with human rights abuses, including the extrajudicial killing of suspected drug dealers and users [3] and at least 35 countries and territories worldwide where drug offences were punishable by death in 2018 [24].

Recent estimates suggest that annual expenditure by European Union (EU) countries on drug law offenders in prisons is within the range of EUR 3.7 billion to EUR 5.9 billion [20]. The United States, by contrast, incarcerates more people per capita than any other country. Since the mid-1980s, state expenditure on corrections in the United States increased by 793 per cent: from USD 6.7 billion in 1985 to USD 59.8 billion in 2017. The United States held over two million people in its prisons and jails in 2017. At the federal level, people incarcerated following a drug conviction made up almost half (47%) the prison population during this period [69].

Despite its overuse as a response to 'drug-related' offending, prisons are acknowledged as being particularly ineffective and problematic settings, where detainees are especially vulnerable to drug use and exposed to heightened risks of HIV and hepatitis C transmission [29]. The presence of illicit drugs and associated markets within prisons can also have a destabilising effect on rehabilitative regimes, leading to increased rates of violence, self-harm and corruption [33]. In the few jurisdictions where monitoring regimes exist, these tend to show high rates of illicit drug use on both reception to and release from custody. In the United Kingdom, for example, the Scottish Prison Service identified not only high rates of illicit drug use on reception to custody in 2018/2019 (71 per cent), but as many as one in four (26 per cent) prisoners also tested positive for illicit drug use upon release [61].

100.3 A Shift in Policy Responses?

These pressures on and costs to the CJS persist despite legislation and policy existing in many jurisdictions which enables the diversion of drug-using suspects, defendants and convicted offenders, at different stages of the criminal justice process, to various forms of education and treatment [19, 35, 37]. While a small number of countries have recently implemented policy innovations for legalising and regulating production and supply of some drugs (such as cannabis in Canada and Uruguay, heroin prescribing in Switzerland, coca in Bolivia and some novel psychoactive substances in New Zealand), dozens of jurisdictions worldwide have policies in place for using alternatives to conventional criminal law responses to drug possession offences [17]. Some have adopted a de jure approach (where the changes are formally enshrined in law), while others have introduced de facto decriminalisation, by officially de-prioritising drug possession for law enforcement agencies.

A recent rapid realist review examined evidence and experiences of 9 of these countries and 158 published papers relating to 12 studies on alternatives to possession offences. While the authors identified advantages and drawbacks associated with each of the three models examined (depenalisation, diversion and decriminalisation), and did not find evidence that any of these approaches consistently increased the use of illicit drugs, they nevertheless concluded that 'research in this area is

complex, incomplete and not capable of providing definitive answers' [36: 4].

Most countries, however, continue to incarcerate and criminalise people for possession or use of drugs, and the use of punitive sanctions, such as imprisonment, prevails and typically remains the default response to 'drug-related' crime. This chapter draws upon international evidence for the effectiveness of drug treatment delivered in criminal justice settings, measured across a range of outcomes. It also highlights what this evidence base tells us about how different contexts and mechanisms for implementation and delivery can hinder or enhance the effectiveness of these approaches [55].

The discussion which follows is structured around the dimensions of the 'EMMIE' framework, developed in the crime reduction field [39], and presents existing evidence from key pieces of research in a format that helps users to access and understand it quickly. The elements of the framework are:

- *E*ffect (the impact of an intervention).
- *M*echanism (how it works).
- *M*oderator (where it works).
- *I*mplementation (how to do it).
- *E*conomic cost (how much it costs).

In keeping with much of the contemporary debate in the field, this chapter largely focuses on CJS-based treatment interventions targeting the illicit use of opiates and stimulants like cocaine. The links between alcohol use and crime, and CJS responses to it, are not explored. This terrain is avoided here simply because of constraints of space. That said, most of the themes and issues examined will have relevance to debates about treating alcohol misuse and dependence using the justice system. A prominent model of 'coerced' treatment – in the form of drug courts – is examined elsewhere (see Chap. X).

100.3.1 Effect

The evidence for the effectiveness of treatment for opioid dependence is both considerable and persuasive. In aggregate, the findings from this body of evidence point to the considerable benefits of retention in different forms of OST, and in particular methadone maintenance treatment (MMT), in contributing towards reducing (but not eliminating) the frequency and intensity of illicit heroin use. These reductions can in turn promote broader physical, social and behavioural changes and contribute towards greater social integration, with commensurate benefits for both the individual and wider community ([1]; see Bell [8] for a more recent comprehensive review of OST effectiveness and Strang, Groshkova and Metrebian [67] for evidence on the impact of supervised injectable heroin).

By contrast, our knowledge of 'what works' for treating cocaine dependence is far more limited. A meta-analysis of six reviews [21] found that antipsychotic medications appeared the most effective approach for reducing users' cravings for cocaine, while disulfiram was better (than placebo, versus anticonvulsants, and antidepressants) at retaining users in treatment. The reviewers concluded that these medications, when supplemented with other forms of effective intervention, such as psychosocial support and contingency management, may form the core components of an effective treatment intervention for cocaine users.

The case for using drug treatment as a crime prevention measure is however compelling: international research (e.g. [25, 28, 47, 68]) and meta-analytic reviews (e.g. [34, 58]) have consistently shown that exposure to different forms of drug treatment reduces the need for individuals to engage in crime by curtailing their use of illicit drugs. The impact on crime has been described as one of the 'most striking' benefits to arise from drug treatment [27: 301].

A key focus for policy makers and practitioners has been to understand the extent to which these positive outcomes might be diminished when drug treatment is 'ordered, motivated or supervised by the criminal justice system' ([49]: 471; citing [65]). Uncertainties about treatment effectiveness for criminal justice populations are further compounded by the range of ongoing conceptual [73], ethical [64] and practical [6] challenges presented by attempts to deliver drug treatment within a criminal justice context.

Conceptually, for example, there are no clear or universally agreed definitions of 'coerced' treatment. Instead, terms such as 'involuntary', 'incentive-based', 'legal referral' and 'compulsory' treatment have been employed interchangeably – often without any effort to directly assess the client's subjective perception of the referral process. And evidentially, there is little scientific research which documents improved outcomes related to compulsory diversion and treatment approaches [13], with some studies identifying potential harms [48, 75, 77].

It is 'coercive' treatment – distinct from involuntary or compulsory forms of intervention found in some jurisdictions, requiring patient consent and involving an element of constrained choice, which Stevens et al. [65] referred to as 'quasi-compulsory treatment' in the QCT Europe study. This research, involving 845 participants accessing support from 65 different services across 5 countries, found that those who enter treatment via the CJS can perceive greater external pressure to be in treatment, but that this does not adversely impact their motivation for change, relative to 'volunteers' accessing the same support via non-CJS routes. Many 'coerced' patients reportedly value the opportunity to access treatment via the CJS [66]. Results from the study showed that 'coerced' forms of treatment can be as effective as 'voluntary' interventions provided by the same services in terms of their ability to retain clients in treatment, reduce their self-reported substance use, and offending behaviours and improve health and social integration [60].

These findings are broadly consistent with those found by Jones [40] who examined outcomes for 1796 adult patients accessing 342 community and residential drug misuse treatment services in England during 2006/2007, as part of the Drug Treatment Outcome Research Study (DTORS). CJS workers were involved in referring 35 per cent of the DTORS sample to treatment [41]. The study found no negative association between referral source and levels of motivation or readiness for treatment; in fact, conditional referrals were positively associated with motivation at the point of treatment entry. Data from DTORS showed that coercion can positively affect treatment retention, and while changes in drug-taking behaviour were more strongly associated with level of intrinsic motivation, coercion was associated with cessation of offending among Class A (i.e. opiate and/or crack) users. Jones concluded that a coercive CJS referral is not detrimental to treatment success and may have particular benefits for specific populations.

However, the findings from systematic reviews and randomised control trials (RCTs) tend to be far more equivocal about the impact of treatment delivered via the CJS. A recently published review by Hayhurst et al. [32], for example, considered the results from 16 studies published between 1985 and 2016 on the effectiveness of both 'voluntary' and court-mandated community-based diversion programmes for criminally involved users of heroin and cocaine (including crack). The review identified:

- A small impact of diversion to treatment on drug use reduction.
- Problems retaining users of heroin and/or cocaine in treatment (compared to users of other illicit drugs).
- An uncertain impact on offending outcomes (due to a lack of outcome measure comparability and heterogeneity within the studies identified).

The authors noted that the poor methodological quality of the studies considered, and the focus of much of the existing evidence on US methamphetamine users, limited their ability to generalise the results from this body of work to other contexts and settings (see reviews by [9], and [43], who reach similar conclusions and also raise concerns about the range and quality of the existing evidence base).

Perry et al. [56] reviewed evidence from 14 RCTs which considered the impact of pharmacological interventions[1] for adult drug-using offend-

[1]The interventions considered as part of the review included (1) naltrexone in comparison with routine parole, social psychological treatment or both; (2) methadone maintenance in comparison with different counselling options; and (3) naltrexone, diamorphine and buprenorphine in comparison with a non-pharmacological alternative and in combination with another pharmacological treatment.

ers. The studies were published over a 45-year period (1969 and 2014) relating to outcomes for 2647 participants. Nine of the RCTs were US-based studies. While noting that their review was limited by the lack of information reported by the studies and that the quality of the evidence considered was deemed to be low, the authors found 'that pharmacological interventions do reduce subsequent drug use and criminal activity (to a lesser extent)…[but that there were] individual differences and variation between the degree to which successful interventions were implemented and were able to sustain reduction of drug use and criminal activity'. The review further found that agonist treatments were not effective in reducing drug use or criminal activity (when compared to non-pharmacological interventions) and there were no significant differences between the pharmacological interventions examined (i.e. methadone versus buprenorphine, diamorphine and naltrexone) on any of the outcome measures considered. The authors urged caution when interpreting the results of the review given the small number of trials which were limited mainly to male adult offenders.

A separate systematic review by Perry and others [57] considered the results from 9 RCTs (8 originating from the United States and 1 from Spain) relating to outcomes for 1792 female participants. The authors concluded there were too few published studies to evaluate whether the treatment setting (court or community) had an impact on the success of interventions for female drug-using offenders. It did however identify how psychosocial treatment (in comparison to treatment as usual) had an impact on reducing subsequent re-incarceration, but not re-arrest or drug misuse outcomes.

100.3.2 Mechanism

The justification for using 'coercive' forms of treatment is often premised on the utilitarian notion that diverting and engaging illicit drug users into a therapeutic intervention as they come into contact with the CJS will contribute towards addressing a key amplifier of their offending behaviour. Exploiting the coercive potential of the justice system in this way can provide a powerful mechanism for encouraging or incentivising illicit drug users to engage in a therapeutic intervention (including diversion to forms of education, advice and/or assessment) – using a range of both positive and negative forms of reinforcement [46]. Models in some jurisdictions draw explicitly upon constraint-based strategies which seek to remove or restrict opportunities for non-compliance by elevating the risk and severity of punishment. These constraint-based approaches can involve the use of formal controls such as drug testing, physical restraints like curfews and electronic tagging, or restrictions on associates and places to promote engagement and compliance. Sanctions such as fines and short spells of incarceration can also feature as constraint-based elements of 'coerced' treatment approaches. Hawaii's Opportunity with Probation Enforcement (HOPE) programme [31] and South Dakota's 24/7 Sobriety Project [42] are high-profile examples of such an approach.

Engagement and retention in forms of evidence-based psychosocial and/or pharmacological treatment, of sufficient duration and intensity, seeks to significantly reduce or eliminate the number and intensity of substance misuse-related problems. Within this theory of change, skilled workers can use techniques such as motivational interviewing to accelerate dependent users through the 'cycle of change' to a point where they find internal motivation to change their behaviour [30]. In tackling drug use, misuse and dependency, the treatment and support facilitated by forms of CJS-mandated intervention also aims to deliver commensurate reductions in any 'related' offending behaviours. This in turn generates wider benefits for communities and society (e.g. in terms of reduced rates of victimisation and antisocial behaviour).

To sustain any benefits and changes facilitated by the treatment process, 'coercive' approaches should ensure sufficient throughcare and aftercare arrangements are in place post-intervention, to encourage integration back into the community and allow for continuity of care. This can include onward referral to drug treatment ser-

vices and any ancillary support, or social care needs linked to issues like housing, or education, training and employment.

Some of these assumptions are illustrated in a theory of change for addressing drug dependence using 'coerced' forms of treatment, as set out in Fig. 100.1. Given the range and diversity of approaches available globally, it is intended to be illustrative rather than precise.

100.3.3 Moderator

Early evidence for the effectiveness and operation of mandated treatment was largely derived from the North American literature which emerge from the experiences of the California Civil Addict Programme (CAP) [4] and initiatives like the Treatment Alternatives to Street Crime (TASC) [38], and following the expansion of drug courts from the late 1980s [7].

Increasingly, studies outside the United States provide important insights to inform our understanding of the different contexts under which these interventions can operate more effectively. The findings from a recent large-scale review of interventions across Europe [44], funded by the European Commission, found that all 28 Member States (MS) reported operating at least one form of what the authors described as 'alternatives to coercive sanctions', or ACS. The study, which drew on insights from national experts, data from 178 interviews with stakeholders and extensive desk-based research, defined ACS as 'rehabilitative measures of treating, educating or reintegrating drug users as alternatives or additions to conviction or punishment…' [19: 1], which included '…measures that had some rehabilitative element or that constituted a non-intervention (for example, deciding not to charge or prosecute), as well as those used instead of prison or other punishment (for example, a suspended sentence with drug treatment)' [44: iii].

The review found that the most commonly occurring form of ACS in operation across Europe was a drug treatment order (offered by 17 jurisdictions). While there was considerable variation between different MS in their use of ACS, it was acknowledged that most forms were underutilised across the CJS. ACS appeared to be mainly offered at the latter (court and sentencing) stages of the CJS process, and there was considerable scope to expand its availability through diversion from arrest, prosecution or investigation. Though limited in scale and quality, the reviewers noted that there is a developing body of evidence about features that might make forms of ACS more effective (though again this was typically limited to drug courts and evidence originating from the United States).

The research identified several common factors which appeared to influence use and uptake of ACS options. These were strongly influenced by the individual beliefs of those stakeholders responsible for imposing ACS, such as prosecutors and judges. These beliefs tended to centre on issues linked to:

- The perceived benefits of treatment over incarceration (e.g. in relation to public protection concerns).
- A perceived lack of clarity around intervention objectives (e.g. what does success look like?)
- The relapsing nature of drug dependence and motivations of drug users (and the flexibility of the justice system to respond constructively to this).
- Levels of awareness about what ACS options are available (and their relative effectiveness).

Importantly, Kruithof and colleagues identified how the use of ACS is shaped by factors that can be influenced by policy makers. They highlighted how legislative changes can both increase the use of these measures (in the case of laws mandating their use in certain circumstances) and unintentionally curtail them (for instance, where legislation imposes restrictive conditions or narrow eligibility criteria).

There were a range of practical and administrative barriers identified too. These included the availability of financial resources to fund treatment; instances where the use of ACS was associated with lengthy and/or bureaucratic procedures; varying levels of partnership working within and

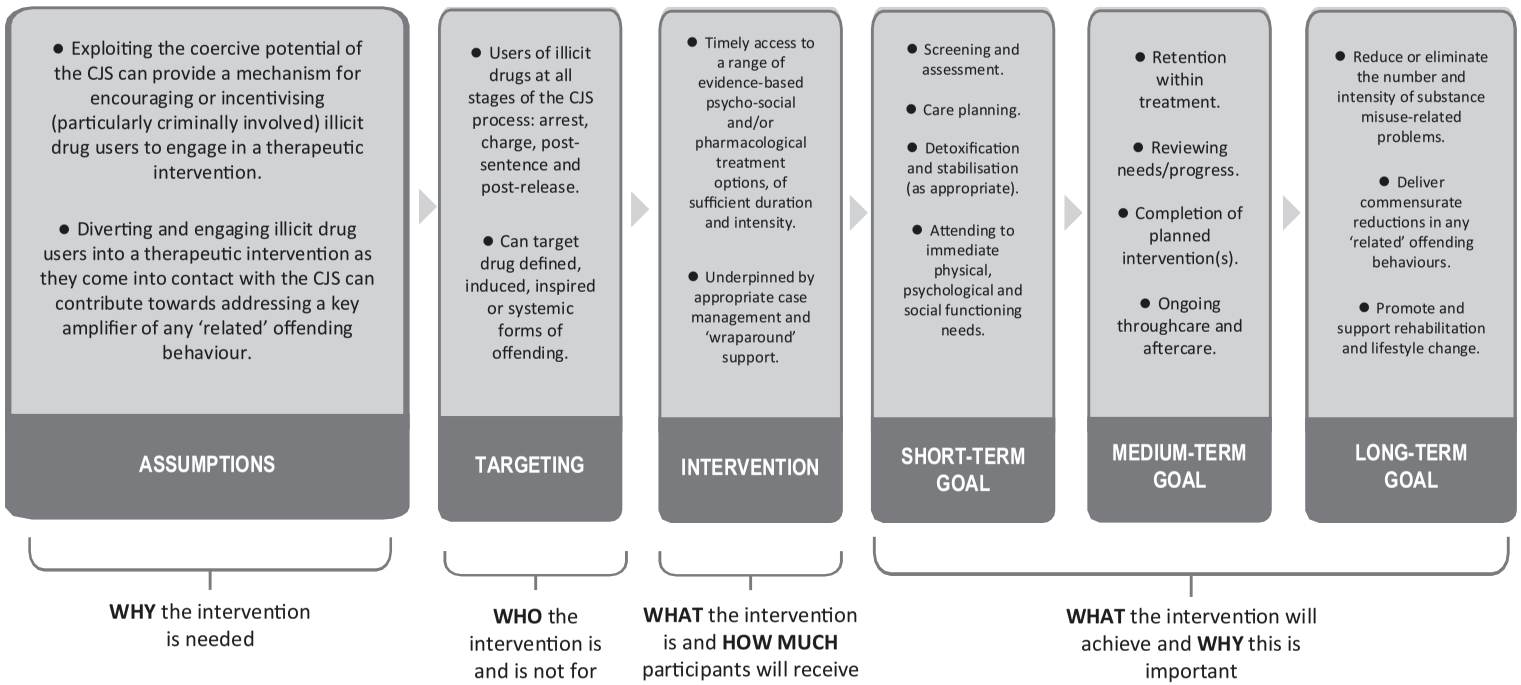

Fig. 100.1 A theory of change for 'coerced' treatment. (Adapted from Asmussen et al. [5]: 129)

between health, social care and justice systems; and problems ensuring effective forms of communication between those delivering treatment (e.g. health professionals) and those monitoring compliance (such as judges). In the absence of these elements, those imposing ACS may lack confidence in the quality, content and effectiveness of support, which may in turn serve as a significant barrier to their use.

A similar set of barriers and facilitators have been identified more recently concerning CJS responses to the personal possession and use of illicit drugs in Australia [36]. Key barriers to the uptake and expansion of diversionary approaches, identified using a mixed method approach which integrated insights from 24 professional stakeholders, included:

- The absence of a full range of programmes (e.g. with some jurisdictions only offering diversion for cannabis-related offences, but not other illicit drugs).
- Changes in drug trends (increasing use of methamphetamine and cocaine) and policing capacity.
- Narrow eligibility criteria employed by programmes.
- Lack of treatment access (linked to limited capacity and accessibility).
- Cultural resistance to diversion among (some) police sources.

By contrast, a range of key facilitators were identified. These included the establishment of diversionary options for all illicit drugs, in all states and territories, and for this to be underpinned by a supportive national policy framework which promoted the use of these measures. These efforts could be reinforced, the authors argued, in different ways: by introducing a legislative – or hybrid legislative – requirement to divert eligible offenders and integrating drug diversion into police performance monitoring systems. This would require greater streamlining of referral systems for police and improving feedback mechanisms to them about the operation and impact of drug diversion. There was considerable scope too for developing and testing innovative models of diversion delivery (such as online or using smartphones). Finally, investment in developing and improving the evidence base on 'what works' – including identifying the most effective or promising approaches and establishing their cost-effectiveness – could contribute towards building support for and increase the use of these measures.

100.3.4 Implementation

Despite some enduring reservations about the quality and range of evaluative evidence on 'coerced' or court-mandated interventions, the theories and principles underpinning effective drug treatment for criminal justice populations are, by contrast, well established [14, 23, 51]. These tend to highlight the importance of attending to a range of process and implementation issues, a focus which resonates with research findings pointing to service-level characteristics being better predictors of treatment outcomes than client-level variables [22, 50].

The results of a qualitative comparative analysis of best practice guidelines[2] for various diversionary programmes delivered in different parts of the world identified a number of distinct themes considered germane to effective implementation [11]. Achieving a consensus on *programmes objectives* was a key prerequisite identified. This included establishing and agreeing the overall aim(s) of the intervention – such as crime reduction or preventing future drug use. Clarifying the overall *treatment philosophy* for the intervention also emerged as an important best practice principle. This is concerned with whether the drug treatment component should be abstinence-based or harm reduction in focus and whether residential or community-based modalities would predominate, though the weight of

[2]Guidelines are usually systematically developed statements to assist and inform stakeholders in their decision-making about appropriate interventions for specific situations and circumstances. Typically, guidelines include a set of recommendations or steps that can be followed when implementing an intervention. Guidelines are commonly based on the available research evidence [18].

evidence suggests that, where possible, the full range of options should be available. There are inherent risks in adopting a 'one-size-fits-all' approach which privileges one treatment philosophy over another [70].

Establishing appropriate *eligibility criteria* for the targeting and identification of suspects, defendants and/or convicted offenders and observing *client rights* – gaining informed consent from participants and implementing ethical processes for securing this – were key areas highlighted by Bull's [11] review. Integrating a system for *compliance monitoring and judicial review*, which could include the use of sanctions and rewards, was another aspect of best practice identified. A focus on *reintegration* is an important consideration too, ensuring appropriate follow-up services and aftercare support – such as housing, education, training and employment – are in place to promote social integration.

Given the multidisciplinary nature of efforts which bring together public health and criminal justice practitioners, the review underlined the need for effective *partnership working* where the different stakeholders involved had clearly defined and demarcated *roles and responsibilities*. Regular *training* for different stakeholders such as the police, magistrates or judges, court workers and drug treatment providers should feature prominently, and approaches should be underpinned by appropriate *management and communication structures*, and informed using tailored and relevant *documentation* relating to all aspects of a programme or intervention (from referral, assessment, review, discharge, to monitoring and evaluation).

Bull's comparative analysis underlined the importance of *monitoring and evaluation*, establishing and imbedding at the outset requirements to routinely monitor throughputs, outputs and outcomes and independently evaluating (and re-evaluating) programme effectiveness. Finally, establishing and securing sustainable sources of *funding* for delivering all aspects of provision was an important best practice principle identified.

These best practice considerations linked to effective implementation are illustrated in Fig. 100.2.

100.3.5 Economic Cost

Research suggests that investment in drug treatment is likely to substantially reduce the economic and social costs associated with drug misuse and dependence. Official estimates from England, for example, suggest that in one 12-month period (2010–2011), drug treatment services may have prevented 4.9 million offences, leading to wider societal savings of £960 million during this period [52]. These estimates were derived from the multi-site, longitudinal DTORS study which reported a net benefit-cost ratio of investment in drug treatment in England of approximately 2.5 to 1 [15]. As noted above, more than one in three respondents to DTORS had been referred to treatment via the CJS [41].

Bright and Martire's [9] review of 'coerced' treatment approaches identified three studies which included an economic component: one produced mixed results, and another found that prison-based substance abuse programmes generated savings of between 1.8 and 5.7 times the cost of implementation, while a third study identified cost savings associated with drug courts.

While there is evidence from some jurisdictions which demonstrate the cost-effectiveness of diverting drug possession offenders [62], findings from systematic reviews of diversion and mandated forms of treatment have typically been unable to produce any economic or cost-benefit analyses based on the evidence assembled given the absence of data in this area [32, 43, 56, 57]. Therefore, the cost-effectiveness and value for money offered by 'coerced' forms of treatment still need to be quantified and measured.

100.4 Conclusion

While dozens of jurisdictions worldwide now have policies in place for using alternatives to conventional criminal law responses to drug possession offences, most countries continue to incarcerate and criminalise people for possession or use of drugs. The use of punitive sanctions prevails and typically remains the default response to 'drug-related' crime. Diverting and engaging

Fig. 100.2 Best practice principles for CJS-based treatment of criminally involved drug users [11]

illicit drug users into a therapeutic intervention as they encounter the CJS can contribute towards addressing a key amplifier of their offending behaviour. Engagement and retention in forms of evidence-based psychosocial and/or pharmacological treatment, of sufficient duration and intensity, can significantly reduce the number and intensity of substance misuse-related problems.

International research evidence from observational studies indicates that 'coerced' forms of treatment can be as effective as interventions accessed 'voluntarily'. These studies suggest no negative association between referral source and levels of motivation or readiness for treatment; that coercion can positively affect treatment retention; and that coercion at referral can be associated with a reduction in offending behaviour. This evidence points towards coercive CJS referrals as not being detrimental to treatment success and that this particular route may have particular benefits for specific populations. The findings from systematic reviews and RCTs, however, tend to be far more equivocal about the impact of treatment delivered via the CJS. These

studies consistently raise concerns about the range and quality of the existing evidence base.

This existing evidence provides some important insights to inform our understanding of the different contexts under which these interventions can operate more effectively. Comparative analysis of best practice guidelines points to the importance of achieving a consensus on programmes objectives; clarifying treatment philosophies; establishing appropriate eligibility criteria; observing client rights; integrating a system for compliance monitoring and judicial review; ensuring a focus on reintegration; the need for effective partnership working; clearly defining and demarcating roles and responsibilities of different stakeholders; the provision of regular training; appropriate management and communication structures; the importance of monitoring and evaluation; and establishing and securing sustainable sources of funding for 'coerced' treatment options.

The weight of evidence suggests that investment in drug treatment is likely to substantially reduce the economic and social costs associated with drug misuse, dependence and 'related' crime. That said, the cost-effectiveness and value for money offered by 'coerced' forms of treatment still need to be quantified and measured.

Drug Courts

Abstract

Drug courts provide judicially supervised substance use treatment and other indicated services in lieu of criminal prosecution or incarceration. Substantial research demonstrates that drug courts significantly reduce criminal recidivism, incarceration rates, and illicit substance use, improve the psychosocial functioning of persons involved in the justice system, and produce positive cost-benefits for taxpayers. Evidence has identified the optimal target population for drug courts and a range of best practices that are associated with improved outcomes in these programs. Although most studies have been conducted on adult criminal drug courts, emerging evidence reveals comparable benefits and best practices for other types of treatment courts, including mental health courts, driving under the influence (DUI) courts, and family drug courts. Emerging evidence is beginning to reveal positive benefits in European, Australasian, South American, and Caribbean nations as well. The challenge now is to extend the reach of drug courts and other treatment courts without sacrificing efficacy or safety.

101.1 Introduction

Approximately 60% of state prison and jail inmates in the United States and 40% of probationers and parolees have a moderate to severe substance use disorder [4, 58]. Approximately one-quarter to one-half of individuals in European, Australasian, South American, and Caribbean criminal justice systems misuse illicit drugs or alcohol [10]. Relapse to drug use is among the greatest predictors of criminal recidivism, increasing the odds of re-arrest by two- to threefold and the risk of multiple re-arrests by more than sixfold [14]. Completing substance use treatment reduces recidivism significantly [7]; however, the more a person needs substance use treatment and the higher the risk of recidivism, the less likely he or she will complete treatment [60].

Drug courts were created to reduce recidivism by improving compliance with substance use treatment. The drug court judge leads a multidisciplinary team of professionals that commonly includes representatives from the prosecution, defense bar, treatment agencies, probation department, and law enforcement. Team members meet frequently in staff meetings to review participants' progress in treatment and offer recommendations to the judge about suitable consequences to impose [45]. These consequences may include rewards such as verbal praise, reduced supervision requirements, or small gifts; punitive sanctions such as verbal reprimands, community service, or brief intervals of jail detention; or adjustments to the participant's treatment regimen. The consequences are administered in court during regularly scheduled status hearings, in which the judge discusses the matter with the participant or participant's legal representative. In pre-adjudication drug courts, the ultimate legal incentive is to have the criminal charge(s) dropped or withdrawn, and in post-adjudication drug courts, participants can avoid incarceration or reduce the length or conditions of probation.

The earliest drug courts were developed to serve adults charged with drug-related crimes. Eligible participants for these programs, referred to as adult drug courts, have a moderate to severe substance use disorder and are charged with a drug-related offense, such as possession or sale of a controlled substance, or another offense caused or influenced by drug use, such as theft or forgery to support a drug addiction. The success of adult drug courts spawned a variety of other types of drug courts, such as juvenile drug courts serving adolescents charged with drug-related offenses, family drug courts serving parents or guardians with substance use disorders accused of child abuse or neglect, and DUI courts serving persons charged with repeated instances of driving under the influence of drugs or alcohol. In addition, a broader range of treatment courts has been developed to address other social service needs commonly encountered in the court system, such as mental health disorders, homelessness, domestic violence, gambling, and prostitution.

The first adult drug court was founded in Miami/Dade County, Florida, in the United States in 1989. Currently, there are more than 3000 drug courts in the United States and more than 1300 other types of treatment courts [40]. Nearly 30 countries other than the United States have also established or are planning to establish drug courts, including Argentina, Australia, the Bahamas, Barbados, Belgium, Bermuda, Brazil, Canada, Cayman Islands, Chile, Columbia, Costa Rica, the Dominican Republic, El Salvador, England, Grenada, Ireland, Jamaica, Mexico, Norway, Panama, Peru, Scotland, Suriname, Trinidad and Tobago, and Vietnam [10].

In 1997, the National Association of Drug Court Professionals in the United States promulgated what are commonly referred to as the 10 Key Components of drug courts [45]. A few years later, the International Association of Drug Treatment Courts (IADTC) adopted the 10 Key Components and added three components focus-

ing on social reintegration of participants, ensuring flexible treatment for indigenous populations and ethnic minorities, and planning for aftercare recovery services. The IADTC principles are embodied in a document entitled the *13 Key Principles for Court-Directed Treatment and Rehabilitation Programs* ("13 Key Principles") (see below Box).

International Association of Drug Treatment Courts (IADTC)

13 Key Principles for Court-Directed Treatment and Rehabilitation Programs

1. The programs integrate substance dependency treatment services with justice system case processing.
2. Using a non-adversarial approach, prosecution and defense lawyers promote public safety while protecting offenders' due process rights.
3. Eligible offenders are identified early and promptly integrated into the program.
4. The programs ensure access to a continuum of substance dependency treatment and other rehabilitation services.
5. Compliance is objectively monitored by frequent substance abuse testing.
6. A coordinated strategy governs responses of the court to program noncompliance (and compliance) by offenders.
7. Ongoing judicial interaction with each offender in a program is essential.
8. Monitoring and evaluation measure the achievement of program goals and gauge effectiveness.
9. Continuing interdisciplinary education promotes effective planning, implementation, and operations of these court-directed programs.
10. Forging partnerships among courts directing treatment programs, public agencies, and community-based organizations generates local support and enhances program effectiveness.
11. Ongoing case management includes the social support necessary to achieve social reintegration.
12. There is appropriate flexibility in adjusting program content, including incentives and sanctions, to better achieve program results with particular groups, such as women, indigenous people, and minority ethnic groups.
13. Posttreatment and aftercare services should be established in order to enhance long-term program effects.

101.2 Effectiveness of Adult Drug Courts

101.2.1 Criminal Recidivism

Meta-analyses are advanced statistical procedures that calculate the average effects of an intervention across numerous research studies. Several meta-analyses conducted in the United States and Canada [2, 30, 34, 44, 55, 61] and national multisite studies in the United States [5, 52] concluded that adult drug courts significantly reduce criminal recidivism—typically measured by re-arrest rates within 2 years of entry—by an average of 8–14%, with the best programs reducing recidivism by 30–80%. Reductions in recidivism were determined to last for at least 3 years after entry [44], and in two studies, the effects lasted 15 years [15, 27].

Comparable effects have been reported in meta-analyses of DUI courts [44], family drug courts [62], and mental health courts [33]. Juvenile drug courts, in contrast, have shown small to statistically insignificant effects on recidivism [44, 61]. As will be discussed, this disappointing finding appears to stem from the fact that many juvenile drug courts are not following best practices or serving the appropriate target population of high-risk and high-need teens.

A meta-analysis in the United States concluded that adult drug courts also significantly reduce incarceration rates by an average of 8–12% [53]. Notably, however, this impact did not translate into less use of jail or prison beds. Although drug court participants were less likely to be incarcerated than comparable persons charged with the same crimes, participants who were unsuccessfully terminated from drug court ultimately served more jail or prison time. In other words, drug courts reduced the number of individuals who were sent to jail or prison but increased the length of jail or prison sentences for unsuccessfully terminated cases.

This finding could be interpreted as an indictment of drug courts because they may not reduce jail or prison overcrowding or overreliance on the most expensive correctional resources. An alternative interpretation, however, is that drug courts achieve larger crime reductions than other correctional programs without increasing jail or prison censuses. It is unknown whether crime rates would increase if drug courts reduced the consequences for unsuccessful termination. Some participants might be less likely to apply themselves in treatment if the consequences for program failure were less severe. Further research is needed to address this important question.

101.2.2 Cost-Effectiveness

In line with their positive effects on crime reduction, adult drug courts have also proven to be cost-effective. Meta-analyses of cost-effectiveness studies concluded that adult drug courts produced an average return on investment of approximately $2–$2.25 for every $1 invested [3, 12, 52]. These savings reflect direct cost offsets to the criminal justice system stemming from reduced re-arrests, law enforcement contacts, court hearings, use of jail or prison beds, and tangible impacts of crime victimization. When more distal cost offsets were also examined, such as savings from reduced child foster care placements and healthcare service utilization, studies have reported net economic benefits ranging from approximately $4 to $27 for every $1 invested, resulting in savings to local communities of roughly $3000 to $22,000 per participant [2, 15, 43].

101.2.3 Psychosocial Outcomes

The US National Institute of Justice (NIJ) funded a national study to examine the effects of adult drug courts on outcomes other than criminal recidivism, such as substance use, employment, family functioning, and mental health [52]. This study, the Multisite Adult Drug Court Evaluation (MADCE), compared outcomes between more than 1100 participants in 23 adult drug courts to those of a carefully matched sample of over 600 persons arrested for comparable offenses who underwent adjudication as usual. In addition to less involvement in crime, drug court participants reported significantly less use of illicit drugs and heavy use of alcohol at 6- and 18-month follow-ups, had significantly fewer positive saliva tests after 18 months, reported significantly greater improvements in their family relationships, and exhibited non-significant trends favoring higher employment rates and school enrollment. These findings confirm that adult drug courts produce substantial psychosocial benefits in addition to crime reduction. Comparable studies have not been conducted in other types of drug courts or treatment courts.

101.3 Effective vs. Ineffective Drug Courts

Meta-analyses indicate the average effects of an intervention; however, the results can mask substantial variability in the performance of individual programs. On the positive side, over three-quarters of drug courts included in the meta-analyses reduced criminal recidivism significantly; however, a substantial minority (roughly 20%) had no impact on recidivism, and about 5% were associated with increased recidivism [5, 34, 54]. A critical task is to identify prac-

tices that distinguish effective from ineffective drug courts and ensure programs apply those practices accordingly.

101.3.1 Target Population

A substantial body of research indicates which individuals are most in need of the full range of services embodied in adult drug courts. These are the individuals who (1) are addicted to or dependent on illicit drugs or alcohol and (2) are at substantial risk for criminal recidivism or failure in less intensive rehabilitative dispositions. Drug courts that focus their efforts on these individuals—referred to as *high-risk and high-need* individuals—reduce crime approximately twice as much as those serving less impaired individuals and return approximately 50% greater net cost savings [3, 5, 12, 34]. The same finding has been reported in DUI courts [49], juvenile drug courts [28], and family drug courts [37]. Unfortunately, evidence suggests that many juvenile drug courts are not serving the appropriate population of high-risk and high-need teens, leading to unimpressive outcomes and even increases in re-arrest rates [59].

These findings are consistent with a well-validated criminological paradigm referred to as risk-need-responsivity, or RNR [1]. According to RNR theory, intensive programs such as drug courts are hypothesized to offer the greatest benefits for high-risk individuals who have more severe antisocial propensities or treatment-refractory histories; however, such programs are often unnecessary or counterproductive for low-risk individuals. High-risk individuals have a relatively poorer prognosis for success in standard treatment programs and will often require intensive and sustained interventions to dislodge their entrenched negative behavioral patterns. Low-risk persons, in contrast, are less likely to be on a fixed antisocial trajectory and are apt to improve their conduct following a run-in with the law. Therefore, intensive interventions may offer small benefits for these individuals at a substantial cost. Worse, low-risk individuals often learn antisocial attitudes and behaviors from associating with high-risk peers, which can make their outcomes worse [35]. Providing intensive supervision or substance use treatment for low-risk or non-addicted individuals has been shown to increase rates of reoffending and substance use [32].

101.3.2 Best Practices

The key components of drug courts are hypothesized to include an ongoing schedule of judicial status hearings, a multidisciplinary team approach to managing cases, evidence-based substance use treatment services, frequent drug and alcohol testing, and contingent sanctions for infractions and incentives for achievements [45]. Each of these key components has been examined carefully by researchers to determine whether it is required for effective results.

Judicial Status Hearings Judicial status hearings are the defining ingredient of drug courts. Many correctional programs offer substance use treatment, drug testing, and sanctions and rewards for drug-involved individuals; however, only drug courts are led by a judge and require participants to appear frequently in court for status hearings. Evidence is exceptionally strong that judicial status hearings are a critical ingredient of drug courts, assuming the programs are treating the appropriate population of high-risk and high-need individuals.

A substantial body of research establishes the importance of scheduling status hearings no less frequently than every 2 weeks (biweekly) during the first phase of drug court. In a series of experiments, researchers randomly assigned drug court participants to appear before the judge every 2 weeks for status hearings or to be supervised by clinical case managers and brought to court only in response to repetitive rule violations. Results revealed that high-risk participants had significantly better counseling attendance, drug abstinence, and graduation rates when they were required to appear before the judge every 2 weeks

[13]. This finding was replicated in Australia [25] and confirmed in a prospective matching study, in which participants were randomly assigned to biweekly hearings if they were assessed as being high risk [39]. Similarly, a meta-analysis of studies of 92 adult drug courts [44] and a multisite study of nearly 70 drug courts [5] reported significantly better outcomes for drug courts that scheduled status hearings every 2 weeks during the first phase of the program. Scheduling status hearings at least monthly during subsequent phases of the program was also associated with significantly better outcomes and nearly three times greater cost savings [5].

Outcomes are also influenced by the length and quality of the judge's interactions with participants. Effects on recidivism are significantly greater when judges spend an average of at least 3 min, and as much as 7 min, interacting with participants in court [5]. Studies further find that drug court participants perceive the quality of their interactions with the judge to be among the most influential factors for success [19, 26, 48]. The MADCE reported significantly greater reductions in crime and substance use for judges who were rated by independent observers as being respectful, fair, attentive, enthusiastic, consistent, and caring in their interactions with participants [52]. A statewide study in New York similarly reported significantly better outcomes for judges who were rated by participants as being fair, sympathetic, caring, concerned, understanding, and open to learning about the disease of addiction [8].

A study of approximately 70 drug courts reported nearly three times greater cost savings and significantly lower recidivism when judges presided over the drug court for at least 2 consecutive years and thus had greater seniority and experience [5]. Significantly larger reductions in crime were also found when the judges were assigned to drug court on a voluntary basis and their terms were indefinite in duration. Evidence suggests most judges are less effective at reducing crime during their first year on the drug court bench [15]. Presumably, this is because judges, like most professionals, require time and experience to learn their jobs. For this reason, drug courts that annually rotated their judicial assignments or had participants appear before alternating judges had the poorest outcomes in several research studies ([15]; [48]). Participants in drug courts often lead chaotic lives and require structure and consistency to alter their maladaptive behaviors. Unstable staffing patterns, particularly when they involve the central figure of the judge, are apt to exacerbate the disorganization in participants' lives.

Multidisciplinary Team A controversial feature of drug courts is having professionals from different disciplines meet regularly to coordinate their functions as a team. Traditionally, judges, prosecutors, defense attorneys, and treatment providers did not sit down together to decide how to respond to defendants' behaviors. This practice has raised concerns among some commentators that drug court professionals might be sacrificing their ethical obligations of neutrality, objectivity, confidentiality, or zealous representation of their clients. Although anecdotal arguments abound, no empirical evidence indicates whether these ethical concerns are justified. Evidence does, however, confirm that a multidisciplinary team approach is necessary to improve outcomes. Studies reveal that the most effective drug courts require ongoing attendance at pre-court staff meetings and status hearings by the judge, defense counsel, prosecutor, treatment providers, program administrator, and law enforcement [5]. When any one of these professionals was regularly absent from team interactions, programs were approximately 50% less effective at reducing recidivism. Observational studies further revealed that when drug court judges did not attend pre-court staff meetings, they were often inadequately informed or prepared to deal effectively with participants in court [50].

Substance Use Treatment Substance use treatment lies at the heart of the drug court model. The core assumption of drug courts is that addiction fuels or exacerbates participants' criminal activity; therefore, treating substance use disorders is believed to be essential to reduce crime

and improve the psychosocial functioning of participants [45].

Studies confirm that the success of drug courts is attributable, in part, to the fact that they increase participant engagement in substance use treatment. The longer participants remain in treatment and the more sessions they attend, the better their outcomes [20, 55]. Outcomes are also significantly better in drug courts that offer a continuum of care for substance use treatment, which includes residential treatment and recovery housing where indicated [5]. The best results are achieved when participants meet individually with a treatment provider or clinical case manager at least once per week during the first phase of the program [5, 52]. Because many participants are unstable clinically and in a state of crisis when they first enter drug court, group sessions alone may not provide adequate time or opportunity to address their pressing clinical and social service needs. Individual sessions reduce the likelihood that participants will fall through the cracks in the early stages of drug court when they are most vulnerable to cravings, withdrawal symptoms, and relapse.

Better results have also been reported in drug courts that developed culturally proficient and gender-specific services for participants with specific clinical or social service needs, such as women with trauma histories or young African American or Hispanic males [41]. Finally, outcomes are better when programs deliver manualized cognitive-behavioral counseling that addresses participants' irrational criminal thinking patterns, improves their interpersonal problem-solving skills, and teaches them to consider the consequences of their actions before behaving impulsively [21].

Medication-Assisted Treatment Medication-assisted treatment (MAT) can significantly improve outcomes for persons with severe substance use disorders involved in the criminal justice system. Buprenorphine or methadone maintenance administered prior to and immediately after release from jail or prison has been shown to increase opioid-dependent inmates' engagement in treatment; reduce illicit opiate use; reduce re-arrests, technical parole violations, and reincarceration rates; and reduce mortality and hepatitis C infections [7]. These medications are referred to as agonists or partial agonists because they stimulate the central nervous system (CNS) via a comparable neural mechanism as illicit drugs. Because they can be addictive and may produce euphoria in non-tolerant individuals, they are sometimes resisted by criminal justice and treatment professionals. Positive outcomes have also been reported for antagonist medications such as naltrexone, which are non-addictive and non-intoxicating. Naltrexone blocks the effects of opiates and partially blocks the effects of alcohol without producing psychoactive effects of its own. Although research on MAT in drug courts is sparse, two small-scale, open-label studies reported better outcomes in drug courts for alcohol-dependent participants receiving an injectable form of naltrexone called Vivitrol [16].

A 2012 survey found that nearly one-half of drug courts in the United States did not use MAT [42]. One of the primary barriers was a lack of familiarity with the medications. For this reason, best practice standards published by NADCP require drug courts in the United States to learn the scientific facts about MAT, obtain expert consultation where available, and allow the use of evidence-based medications when prescribed by an addiction psychiatrist, addiction physician, or comparable medical professional who has personally examined the participant and will manage the case moving forward [47].

Drug and Alcohol Testing The success of any drug court depends on reliable monitoring of participant behavior. If a drug court does not have accurate information as to whether participants are abstaining from substance use and are compliant with other requirements in the program, there is no way to apply incentives or sanctions correctly or adjust treatment and supervision services accordingly.

The most effective drug courts perform urine drug testing at least twice per week during the first several months of the program [5]. Because the metabolites of the most commonly used sub-

stances are detectable in human bodily fluids for only about 2–4 days, testing less frequently leaves an unacceptable time gap during which participants can use substances and evade detection. In addition, drug testing is most effective when it is performed on a random basis. If participants know in advance when they will be drug tested, they can adjust the timing of their usage or take other countermeasures, such as frontloading on water, to elude the tests.

Although urine testing is the most common methodology in drug courts, other technologies that extend the time window for detection are becoming commonplace. Continuous alcohol monitors (CAM) are anklet devices that detect alcohol vapor in sweat and transmit a wireless signal to a remote monitoring station. Research suggests CAM can be effective at deterring alcohol consumption among recidivist participants in drug courts when worn for at least 90 consecutive days [17]. Similarly, ethyl glucuronide (EtG) and ethyl sulfate (EtS) testing extend the time window for detection of alcohol metabolites from a few hours to several days. At least one randomized controlled trial reported improved outcomes when a drug court employed EtG/EtS testing [18].

Graduated Sanctions and Rewards Drug courts administer gradually escalating sanctions for infractions and rewards for accomplishments. The nearly unanimous perception of staff members and participants is that sanctions and rewards are strong motivators for behavioral change [19, 31]. A randomized experiment confirmed that administering gradually escalating sanctions for positive drug tests and other infractions significantly reduced substance use and crime among drug court participants [22].

The use of jail sanctions in drug courts is controversial. Although some commentators have theorized that a realistic threat of a jail sanction provides the necessary leverage for drug courts to retain recalcitrant offenders in treatment, research on this issue is understandably sparse. It is difficult, if not impossible, to study the question in a controlled experiment. Few participants, staff members, or research ethics boards would permit jail to be imposed in a non-individualized and randomized manner. The most practical way to study this issue is to compare outcomes between similarly matched drug court participants who did or did not face the realistic possibility of receiving a jail sanction. Thus far, such studies have yielded mixed findings. One study reported better outcomes when participants faced a realistic prospect of jail [6], whereas another found no differences in outcomes [24]. Another method for addressing this question is to interview drug court participants. A consistent finding from focus groups is that participants viewed the threat of jail sanctions as a highly motivating factor to keep them engaged in treatment and committed to their sobriety [9, 19].

At least two randomized experiments investigated the effects of enhancing positive rewards for achievements in drug courts [38, 51]. The rewards were delivered in the form of payment vouchers or gift certificates for negative urine tests and other accomplishments. Neither study found improved outcomes, apparently due to a statistical ceiling effect. Outcomes were so favorable in both drug courts that it was difficult to improve upon them any further. In one of the studies, however, a pre-planned interaction analysis revealed a non-significant trend ($p = 0.08$) in which high-risk participants with more serious criminal histories may have performed better in the enhanced reward condition [38]. This preliminary finding suggests tangible rewards may improve outcomes for the most incorrigible participants in drug courts. Further research is needed to confirm this hypothesis.

101.4 Best Practice Standards

Armed with knowledge of what works and what does not, the drug court professional has an obligation to spread the word, raise the bar for all programs, and provide needed training and technical assistance to help programs comply with best practices. Until drug courts define appropriate standards of care, they will be held accountable, fairly or unfairly, for the worst practices in the field. Scientists will continue to analyze the

effects of weak drug courts alongside those of exceptional drug courts, thus diluting the average benefits of drug courts. Critics will attempt to tarnish the reputation of drug courts by attributing to them the most noxious practices of the feeblest programs. Only by defining the bounds of acceptable and exceptional practices will drug courts be in the position to disown poor-quality or harmful programs and set effective benchmarks for new and existing programs to achieve.

In 2013, NADCP released volume I of the *Adult Drug Court Best Practice Standards* [47]. Volume II followed 2 years later [46]. These landmark documents were the product of more than 6 years of exhaustive work by dozens of experts who painstakingly reviewed scientific research on best practices and distilled that vast literature into measurable and enforceable practice recommendations. Within 2 years of publication, more than 20 US states had already adopted the standards for purposes of credentialing, funding, or training new and existing drug courts in their jurisdictions. Comparable efforts are now underway in the United States to develop and test best practice standards for juvenile drug courts and family drug courts. Disseminating the standards widely and ensuring that all drug courts in the United States heed their provisions are the next great challenges facing the drug court field. It is too early to know whether other countries may adopt all or part of the standards to guide operations in their programs.

101.5 International Drug Treatment Courts

Rigorous experimental and quasi-experimental studies in Australia [25, 29] and Canada [30, 56] reported that adult drug courts—referred to as drug treatment courts in most other countries—significantly reduced criminal recidivism compared to traditional criminal justice programs and were cost-effective or cost-neutral. Similarly, a quasi-experimental study in London found that participants in a family drug treatment court engaged in significantly less substance use, were significantly more likely to be reunited with their children, and had significantly fewer recurrences of child abuse or neglect than matched parents in traditional dependency proceedings [23]. Finally, a quasi-experimental study in Vancouver, Canada, reported significantly lower recidivism for participants in a community court serving persons with co-occurring disorders compared to matched individuals undergoing traditional adjudication for low-level public order or summary offenses, such as public intoxication or disorderly conduct [57].

In other countries, most drug treatment courts are in the formative stages, and efforts to evaluate their outcomes have only recently been initiated. A survey conducted by American University on behalf of the Organization of American States (OAS) analyzed responses from criminal justice officials in Belgium, Bermuda, Brazil, Canada, Chile, Ireland, Jamaica, Mexico, Norway, and Suriname [11]. Most respondents reported that drug treatment courts in their country appeared to be reducing crime better than traditional criminal justice approaches, and approximately one-half reported achieving substantial cost savings. In 2010, the OAS Inter-American Drug Abuse Control Commission (CICAD) adopted the *Hemispheric Drug Strategy*, which, among other provisions, encourages member states to develop drug treatment courts and other court-supervised treatment alternatives to incarceration for individuals suffering from addiction who are charged with drug-related crimes. In 2012, representatives from Argentina, the Bahamas, Barbados, Canada, Chile, Costa Rica, the Dominican Republic, Jamaica, Mexico, Trinidad and Tobago, and the United States convened to develop an evaluation manual to guide evaluation activities for drug treatment courts in the Americas. The product of that work [36] includes a core dataset of performance indicators to be reported on a voluntary basis by member states and will hopefully guide drug treatment court evaluations in South American, Caribbean, and North American nations.

No studies have addressed the appropriate target populations or best practices for drug treatment courts in other countries. It is possible that the average risk and need level for drug court par-

ticipants may be substantially higher in some other countries than in the United States. Much of the increase in the US arrestee population has been fueled by drug possession cases, and in some US jurisdictions, individuals can be sentenced to jail or prison for simple drug possession. Because drug possession is less likely to receive a sentence of incarceration in many European and South American nations, drug treatment courts in those countries may serve persons facing more serious criminal charges. Future studies should address whether risk and need levels of participants differ significantly in other countries and, if so, whether this influences drug treatment court outcomes.

Virtually all countries surveyed by American University reported that they were providing services in their drug treatment courts consistent with the 10 Key Components or 13 Key Principles. It appears that many international drug treatment courts are exporting the model from the United States largely as designed and with modest adaptations. Future research will hopefully reveal what changes, if any, may be required to adapt the drug court model to the needs and traditions of other countries and peoples.

101.6 Conclusion: Going to Scale

Despite their proven efficacy, drug courts in the United States serve only a fraction (about 5–10%) of adults arrested each year who meet criteria for a moderate to severe substance use disorder [40]. The primary obstacle to expanding the reach of drug courts in the United States is a lack of resources and not an absence of judicial interest or public support [40]. Convincing lawmakers that they will recoup their investment and reap substantial economic gains by investing in drug courts is a primary goal of rational drug policy in the United States.

Other countries seeking to extend the reach of drug treatment courts face comparable challenges. The American University survey identified several barriers reported by other countries to implementing drug treatment courts. The most frequently reported barriers were a lack of funding (especially for treatment services), high rates of staff turnover, under-appreciation by policymakers of the serious problems faced by participants, inadequate services for teens and young adults, and insufficient availability of adjunctive services, such as child care and vocational training [11]. These barriers are virtually identical to those reported in the United States and do not appear to reflect unique problems encountered by Latin-American or Caribbean nations.

The major challenge for all nations is to extend the reach of drug treatment courts without diluting the intervention below effective levels. Any program can be made cheaper by reducing the dosage and providing fewer services to more participants. The difficult task is to maintain effectiveness in the process. Many interventions show efficacy on a small scale only to have the quality of implementation drift unacceptably downward as they are applied in day-to-day practice. The big question is whether the criminal justice systems in various countries will move in the indicated direction. Facing huge budget deficits, some governments are imposing across-the-board funding cuts to correctional and treatment programs. There is no need to speculate about the likely effects of such actions. If history is a guide, any cost savings that may be realized in the short term will shift the financial burden to a later date as the result of increased crime, drug use, and related impairments.

The appropriate course of action is to shift funds from costly and ineffective programs to those that are proven to reduce crime and conserve scarce resources. Rather than taking an axe to cost-effective programs, policymakers should reallocate funds away from inefficient programs, redouble their efforts to invest in evidence-based programs, and return net cost savings to taxpayers. Much is possible if lawmakers apply what works rather than what is expedient, familiar, or popular. If lawmakers do not rise to this challenge, all the research in the world will have little impact on public health or public safety.

Addictions in Physicians: An Overview

102

María Dolores Braquehais, Eugeni Bruguera, and Miquel Casas

Contents

Abstract

An estimated 10–14% of physicians are said to be at risk of becoming chemically dependent at some point in their careers. Defense mechanisms (as denial, minimization or intellectualization), greater stigma associated with mental disorders amongst doctors and easy access to self-treatment with licit drugs, added to specific individual risk factors, may account for this increased vulnerability. Substance use can appear as a an unhealthy strategy to cope with unpleasant emotional states, or it can be for recreational purposes. When it becomes an addiction, it poses risk both on the individual wellbeing and to their clinical practice safety. Among physicians, alcohol, sedatives and opioid misuse are the most prevalent substance use disorders (SUDs). In the last decades, Physician Health Programmes (PHPs) have been developed in several countries to address this problem. Although sharing some similari-

ties, they differ in organizational and clinical aspects. Addicted physicians in treatment prove significantly higher abstinence rates (70–80%) compared to other patients. However, concerns about ethical issues related to the treatment of sick doctors at PHPs, mainly in the USA, have recently arisen in public discussion and need to be carefully considered.

102.1 Introduction

Physicians are not free from the risk of developing substance use disorders (SUDs). Easy access to self-medication and delay in help seeking when they have developed an addiction are common features in this patient subgroup. Addictions in physicians are a cause a serious concern due to their potential impact on their patients' safety, the lives and careers of the affected physicians, and the socio-economic burden to the healthcare system as a whole.

The main aims of this chapter are to: (a) provide a brief epidemiological review of addictions in physicians; (b) analyze the psycho-social barriers that prevent doctors with SUDs from asking for help; c) outline some signs which can facilitate early recognition of affected individuals and some tips to promote help seeking; and, (d) to describe the main Physician Health Programmes (PHP)'s models of intervention with a discussion of their benefits and limitations from clinical and ethical points of view.

102.2 Epidemiology

Physician impairment refers to those situations where physicians are rendered unable to carry out their professional responsibilities adequately due to a variety of health issues, including a medical disease, psychiatric problems, SUDs or dual diagnosis [1]. Physician impairment due to addictive behaviours may be episodic or chronic, leading to psychosocial deterioration and, finally, becoming dangerous both to the physician well-being and to their patients' safety [2–4].

The prevalence of addictions among doctors is said to be similar to that of the general population. Therefore, an estimated 10–14% of physicians may become chemically dependent at some point in their careers [5]. Physicians are less likely to experiment with illicit substances (such as marijuana, cocaine and heroin) but more prone to using alcohol and self-prescription of controlled medications such as benzodiazepine tranquilizers, opioids and/or stimulants [5–10]. However, trends in drug addictions are changing among new physicians and should be adequately evaluated in the future.

Boisaubin and Levine [11] point out that medical students, like their peers outside Medicine, may be fascinated by drugs, during their early medical training, but tend to overestimate their understanding of pharmacology and underestimate, or fail to comprehend, what addictions really entail. They may even continue to use drugs throughout medical school and into residency.

Some physicians start using drugs during their residency training, when they first receive prescribing privileges. They may use them to relieve stresses generated during that time period (e.g. fatigue, early responsibilities, professional disillusionment, lack of emotional support, less time to spend with friends and family, etc.), for recreational purposes or as "performance enhancers" [12]. Hughes et al. [6] found that more residents reported lifetime usage of benzodiazepines (22.7% versus 19.6%) as well as barbiturates (8.5% versus 7.3%) but fewer of them reported cocaine use (29.2% versus 32.5%) compared to other college students. With regard to alcohol use, Flaherty and Richman [5] found that 20.3% of medical students met criteria for alcohol abuse or dependence in the 12 months prior to the interview.

Hughes et al. [6], in a mailed survey to 9600 physicians affiliated to the American Medical Association, reported that practising physicians were as likely to have experimented with illicit substances in their lifetime as their age and gender

peers in society, but less likely to be current users of illicit drugs. Physicians' use of prescribed drugs (e.g. benzodiazepines, barbiturates, minor opiates or amphetamines) was primarily related to self-treatment, while the higher prevalence of alcohol use could be related to other socio-economic determinants. Schneider et al. [13] also reported that Swiss primary care physicians tended to self-medicate with analgesics and tranquilizers.

In a nationwide, prospective and longitudinal study following young Norwegian physicians from internship through the subsequent 9 years, Hem et al. [14] found that physicians self-prescribed not only antibiotics (71–81%) or contraceptives (24–25%) but also analgesics (18–21%) and hypnotics (9–12%). Those suffering from mental disorders used sedatives or hypnotics as a form of self-treatment. In other studies, such as those conducted by the Galatea Foundation in Catalonia (Spain), both medical students and resident physicians were found to have higher problematic alcohol and sedative use compared to the general population [15, 16].

With reference to medical speciality, the reported prevalence of addictions among physicians is higher for anaesthesiologists, psychiatrists and emergency medicine/intensive care physicians compared to other specialities [6].

Particularly, anaesthesiologists and intensive care and emergency physicians are considered high-risk specialties because of their increased knowledge of and availability of highly addictive drugs [17–20]. As recently as 2005, the drugs of choice for anaesthesiologists entering addiction treatment were fentanyl and sulfentanyl. They also have an increased potential risk of misusing agents such as propofol, ketamine, sodium thiopental or inhalation agents. Prevalence rates of other SUDs, such as alcoholism, among them are not different from other physicians. Among anaesthesiology trainees, the main drugs abused are: intravenous opioids (fentanyl, in 64%), alcohol (35%), cannabis (14%), cocaine (12%), hypnotics (such as midazolam, 12%), oral opioids (10–14%) and anaesthetic agents (propofol 5–8% or inhalation agents, i.e. nitrous oxide, 2–3%) [19].

Hughes et al. [6] also found that general practitioners and obstetric/gynaecology physicians were more prone to using minor opiates, while anaesthesiologists, emergency doctors and chronic pain physicians tend towards self-prescribing major opiates. The trend was found to be similar among residents.

Psychiatrists were more likely to use benzodiazepines [6].

In a recent study [21], surgeons were found to be more likely than non-surgeons to enrol in PHPs because of alcohol-related problems but less likely to be admitted because of opioid use. However, they had positive treatment outcomes similar to those of non-surgeons.

In relation to mandatory treatment, McLellan et al. [8] reviewed the laboratory and medical records of 904 physicians admitted to 16 PHPs in the USA. Five specialities represented more than 50% of physicians: family medicine (20.0%), internal medicine (13.1%), anaesthesiology (10.9%), emergency medicine (7.1%) and psychiatry (6.9%). Alcohol use disorders and opioid abuse and dependence were found to be the most frequent conditions among physicians compulsory referred to PHPs [22].

The combination of affective and alcohol disorders is the most common form of psychiatric comorbidity among physicians [3, 23]. Some type II personality disorders, such as the narcissistic and/or the antisocial types, are often comorbid in physicians treated within specific programs for doctors under compulsory treatment [1]. In non-punitive programs [3], as well as antisocial traits avoidant and obsessive-compulsive ones are also present in doctors suffering from addictive disorders.

Increased suicidal risk has also been associated with the presence of addictions and dual diagnosis in doctors [3, 24, 25].

Smith DR [26] underlined that most developed countries had shown a steady decline in physicians' smoking rates in the last decades. The lowest smoking prevalence rates (less than 10%) have been consistently documented in the United States, Australia and United Kingdom [26, 27]. However, physicians in some developed

countries and newly-developing regions still appear to be smoking at high rates [28].

In summary, alcohol, sedatives and opioids are the drugs most commonly used by physicians with addictions, followed by cocaine, stimulants and cannabis (the latter, higher among younger doctors). Little evidence is yet available with regards to the use of new drugs and to behavioural addictions. However, they should also be considered whenever they may negatively affect both the individual wellbeing and pose risk to the safety of their practice.

102.3 Identifying and Helping the Sick Doctor

Doctors experience significant work-related mental health distress, as working long hours caring for others may be physically, emotionally and psychologically demanding. Other specific occupational factors may increase distress: high stressful situations, work-home time unbalance, conflicts with patients, injury or accidents at work, life-and-death decisions, etc. [29, 30]. Although some of the defense mechanisms for working as a doctor are initially adaptive, they become unhealthy coping mechanisms when physicians are in trouble [31]. In this situation, physicians may tend to self-medicate and will be at a higher risk of burnout or at an increased risk of self-harm behaviours, including suicide [32].

A high proportion of doctors show inadequate attitudes towards their general healthcare [14, 33], a phenomenon that has been popularly reflected in the old saying "the shoemaker always wears the worst shoes".

When it comes to SUDs, delaying help seeking will worsen their evolution [6], increasing the risk of developing comorbid conditions [14], their morbid-mortality [3], and the likelihood of having malpractice behaviours [8, 10, 34, 35].

Other reasons have been related associated with the tendency to delay help seeking: (1) the fear of licensure problems [36]; (2) the physician's identity construction, with an exaggerated sense of responsibility together with an increased sense of invulnerability; (3) their proneness to coping alone; (4) their survival mentality; and (5) their high level of self-doubt and insecurity [37].

In some individuals, barriers may be related to [38, 39]: high self-criticism; low self-esteem; poor bonding with relatives; competitive, humiliating and status-conscious work environment; and burnout symptoms related to high job demands.

In such situations, physicians may tend to self-medicate and will be at a higher risk of burnout and of self-harm behaviours, including suicide [32]. Alcohol use may become a "socially accepted" strategy to deal with stressful conditions [40]. The confluence of these factors with an increased vulnerability, due to factors unrelated to the profession, may lead to an addiction. Once the addiction pattern is established, it becomes even more difficult for the sick doctor to ask for help.

As some doctors with addictions do not ask for help, some direct or indirect signs may help their colleagues identify their problem [4, 11]. Some specific signs and symptoms appear when there is an intravenous drug addiction [17, 19] (see Table 102.1).

Besides professional impairment, some other personal and environmental problems can arise: (1) sexual, marital and/or financial difficulties; (2) driving convictions; (3) decreased involvement in family activities and commitments; (4) dependent children behavioural problems; (5) frequent arguments or unexpected mood shifts; (6) social isolation and/or loss of friends; and (7) cessation of hobbies and other interests (Bryson and Silverstein; [19]).

In fact, relatives or close friends may be the first to identify addiction problems and may encourage the doctor to seek help, although it is not uncommon to find the physician not accepting such recommendations.

Nevertheless, it is the peer-physician responsibility to identify alcohol-impaired or drug-impaired physicians in order to help them return to optimal functioning and to safeguard patients from the care of impaired physicians [4, 11].

Voluntary help seeking should be tried first. Some tips may be of help in this scenario: (a)

Table 102.1 Identifying physicians with drug addictions

	General signs and symptoms	Parenteral drug use
Indirect signs	Abnormal behaviour Loss of reliability Unjustified absences from work Frequent medical complaints Abnormal prescription (tendency to self-prescription) Mood changes Isolation from colleagues Staff concerns	Decreased performance Requesting extra shifts Preference to working alone Extra offering to colleagues for breaks, extra calls or wards Poor anaesthetic record keeping Offering to handle or manage drugs in exceptional environments Difficulty finding the person when on-call Suspicious or protective behaviour around locker or briefcase Using anaesthetic techniques without narcotics, falsifying charts, diverting drugs for own use
Direct signs	Smell of alcohol Somnolence Hyperactivity Disinhibition Ataxic gait Slurred speech Tremor Dishevelled appearance Depressed mood	Nasal rubbing/itching of drowsiness after drug "top-ups" Recurrent minor physical or facial injuries Favouring covered arms and feet to conceal injection sites Nasal discharge, yawning, tears, pallor, sweating, pilo-erection, feeling cold when abstinent from drugs Weight loss, pallor Gastrointestinal or pain complaints Frequent vague, unexplained complex illnesses

avoid "corridor" consultations; (b) find a quiet, private place to talk without interruptions, (c) try to be empathic and non-judgemental; (d) provide a comprehensive non-stigmatized model for addictions as mental disorders that can be successfully treated in specialized treatment settings; (e) underline the benefits of early help seeking; (f) focus on the physician-as-patient own strengths and competencies; and (g) offer support and advice of how and where adequate treatment or help can be provided. Refraining from working should be encouraged in this situation until the physician has demonstrated maintained abstinence and that s/he is not impaired from practising safely.

If the impaired physician does not accept to be treated, the senior doctor/manager or the regulator needs to be informed in order to avoid any danger to the public as well as to the physician. When found unfit for practice because of an addiction, the physician-as-patient may feel ashamed and/or fearful of the negative consequences of their misconduct. In some cases, this overwhelming distress may lead him/her to desperate solutions, including suicide [41, 42]. Providing easy and quick referral to adequate highly confidential treatment may help prevent this risk.

Some strategies specifically designed to prevent drug use among physicians should also be encouraged. Educational programs that identify and address the risk and protective factors related to addictive disorders in physicians help destigmatize and may change some unhelpful coping strategies among doctors. Safety measures inside and outside the workplace are also recommended. Careful record keeping, evaluation of use patterns and computerized record keeping and dispensing system in hospitals may decrease the misuse of highly addictive drugs such as opioids or other sedatives [17]. Systems that adequately and effectively monitor medical prescriptions may also be useful.

102.4 Treatment

Specialized programs to help doctors who are dependent on substances seem to provide the best available measures for protecting patients and for recovering physicians' careers and wellbeing [29, 43].

In the late 1970s, Physician Health Programs (PHPs) started to be developed in the USA in order to identify and treat impaired physicians involved in misconduct allegations as a conse-

quence of their mental disorders, mainly SUDs [35, 44]. PHPs were initially established with the primary focus on early detection and treatment of physicians with substance misuse but gradually expanded to address other mental disorders and even physical problems or disruptive behaviours. Similar programs were developed later in other countries such as Canada, Australia Spain and the UK [43]. In recent years, Ireland has launched a program similar to the UK´s.

In the US, physicians identified as having SUDs are referred to their state PHP to facilitate formal evaluation and assessment of treatment needs. US PHPs mainly follow a model which provides an active care management, monitoring and supervision (typically for 5 years) of physicians who have previously signed mandatory contracts with them. US PHPs refer addicted physicians to non-funded treatment resources where they start their rehabilitation process.

There is a close relationship between the treatment provider and the medical licensing boards, who may accept the PHP intervention plan instead of directly imposing disciplinary actions. Lapses during their treatment process lead to intensified treatment strategies. That also means bringing the physician back to the medical licensing board's disposal if necessary. In addition, those who refuse to sign the contract or continue to use drugs may end by losing the licence to practice. Nowadays, PHPs exist in 47 US states and in the District of Columbia ("Federation of State Physician Health Programs", 2018).

PHPs' clinically recommended interventions often include an intensive inpatient residential program lasting around 3 months followed by a less intensive outpatient substance addiction treatment, up to 1 year, which includes several group meetings per week [45]. After this intensive treatment phase, on-going care agreements are enacted with clients including meetings with counsellors and case managers, 12-step group attendance, support meetings for health professionals and 5-year random drug and alcohol screening (Brown and Bohler 2019; [46]). Follow-up interventions in US PHPs mainly adhere to the principles of Alcoholics Anonymous (AA), Narcotics Anonymous (NA) or other 12-step approaches [32].

The first national study of the state PHPs tracked 904 physicians from 16 PHPs over a period of 5 or more years, 78% of those who completed the stipulated contract were licenced and working, 11% had their licence revoked, 4% had retired and 3% had an unknown status [8, 46]. Although there were differences between each state PHP, the study described the core pattern of care management of all programs running at that time.

Similar results to the US PHP's model were reported by the Ontario Physician Health Program in Canada, where 71% physicians in treatment had no relapse during a 5-year follow-up and a total of 85% successfully completed the program. Most of them (66%) had been compulsorily referred to the program by their College of Physicians, and 16% had been sued for malpractice behaviours [22].

The Practitioner Health Programme in the UK, delivered by the National Health Service (NHS-PHP), is offered as a free, confidential, self-referral treatment service for physicians and dentists with mental and addictive disorders [47]. The national program is delivered through a central hub and has been led since the outset by a general practitioner with training in psychiatry. As such, the service acts as a hybrid between a mental health service and a primary care service. It provides what any standard mental health services do and also has access to residential rehabilitation services for patients with addiction problems [47]. The key difference from US PHPs is that the NHS-PHP deliberately does not have any formal links with the regulators (though it will meet and review treatment with them if the patient consents).

In 2018, the NHS-PHP reported that around 10.1% (n = 381) of all physicians attending the program suffered from addictive disorders. In 2017, they found a complete abstinence rate of 77.8% at 12 months or at discharge (usually >5 years) for 255 addicted doctors in treatment. Overall, 100 out of the 381 addicted doctors had been temporarily admitted to a specific inpatient unit for detoxification at the beginning of their

treatment process. Patients at the NHS-PHP receive a combination of psychological and pharmaceutical interventions (alcohol- or drug-assisted detoxification, antidepressants if necessary) and a case management approach. All addicted doctors are followed up, drug-monitored if necessary and encouraged to attend long-term mutual self-help meetings such as Narcotics/Alcoholics/Cocaine Anonymous or a specific group for addicted physicians ("Garden Group").

The Integral Care Program for Sick Doctors (PAIMM, in Catalan; PAIME, in Spanish) was created in 1998 in Barcelona and later extended to other Spanish Autonomous Regions [48, 49]. The PAIMM can be defined as a free, highly confidential, mental health treatment service whose main aim is to promote voluntary help seeking of physicians with mental disorders, including addictions, while safeguarding safe practice. In Barcelona, the programme is funded by both all Catalan Medical Council-Associations and the Catalan Department of Health. Patients in Catalonia are offered outpatient, day hospital or inpatient interventions in the Galatea Clinic depending on their clinical severity.

The Medical Council-Association mandates specific treatment measures as a condition for keeping the licence to practice only when there is evidence or risk of practice problems [40, 43]. In those cases, physician-as-patients voluntarily sign a specific contract where they commit to remain abstinent and to refrain from working if impaired by their mental disorder. Safety when returning to practice is adequately supervised by a tutor in the workplace. Physicians mandated to follow this type of therapeutic agreement are given all ethical and legal warranties to protect their rights both as individuals and as professionals. In Catalonia, the PAIMM mental health service model has been progressively extended to other health professionals whose practice needs to be regulated by a professional council-association (i.e. nurses, pharmacists, veterinarians, dentists, psychologists, social workers and physiotherapists).

At the beginning of the PAIMM, physicians with addictions followed long-term individual psychiatric and psychological treatment, regular drug screening and a case management approach. Since 2008, the PAIMM launched the Integral Treatment Program for Physicians with Addictions; the long term follow-up, drug screening and assessment were enhanced with an initial intensive psychotherapeutic phase followed by 2- to 5-year weekly group psychotherapy. All admitted physicians working in Catalonia completed the intensive intervention, and 87.3% kept being monitored afterwards. Mean length of treatment was 48 months. A total of 72.2% sick physicians remained abstinent at last contact. Good adherence to follow-up psychotherapy groups predicted both lower risk of lapse during treatment process and higher rates of abstinence at follow-up [50].

New PHPs are being estabilished place in other countries such as Argentina, Costa Rica, Uruguay and Chile following the Spanish PHP model. Since December 2017, a European Practitioner Health Provider Network (PHPN) has been formed in order to provide the opportunity to share practice, understand variance between different services and define a common Europe-wide service specification for practitioner health services. France, Ireland, Germany, the Netherlands, Belgium, England, Spain, Malta and Scotland have already joined the institution [47], although not all of them have set intervention programs yet.

In recent years, some concerns have been raised with regard to certain managerial and ethical questions related to US PHPs' procedures. In cases where physicians with addictions are mandated to treatment, two ethical principles are in conflict: a) the imperative to protect their practice safety ("social contract") and b) respecting of the impaired physicians' rights and autonomy [51–53]. Accepting treatment can be seen as an opportunity for impaired physicians to regain their professional standing [52]. Removing the financial barriers to being treated will help in this sense. Moreover, following unified national standards with periodical oversight of PHPs' activities will benefit the soundness and fairness of their practice [54].

Some programs, such as the Barcelona PHP, have addressed these ethical requirements by: (1)

offering free and easy access to all physicians working in Barcelona; (2) balancing the regulator's duty of preserving safe practice but also respecting the physician rights; (3) obtaining approval for big data analysis and reporting from a recognized Ethics Research Committee; (4) providing a highly confidential treatment; and (5) giving public visibility to the program.

Regardless of the country, physicians have a good response to addiction treatments when compared to the general population. Reports of several programmes reveal long follow-up abstinence rates for physicians with addictions to be around 70–80% [8, 11, 22, 43, 46, 50]. Results of follow-up studies support the need for and the efficacy of highly specialized programs for physicians with addiction problems [2, 11, 29].

Some keys to success of this "New Paradigm for Long-Term Recovery" of drug addicted patients are [2, 46, 55]:

1. Offering immediate and highly confidential intervention. Providing an appropriate, easy-access and confidential treatment as soon as the sick doctor seeks help is critical.
2. Addictions can be conceptualized as mental disorders with complex bio-psychosocial underpinnings. Careful and empathic presentation of the nature of the disorder may help avoid self-stigmatizing attitudes or responses.
3. Evaluation and triage at the appropriate facility where a comprehensive case management is offered. Treatment at outpatient or inpatient facilities will depend on the severity of their addictive disorder. However, an initial intensive treatment approach is recommended.
4. The treatment staff should be trained to deal with the particular occupational components and with the most common defence mechanisms of the impaired physician.
5. Peer-group therapies, formal group psychotherapy and/or mirror image techniques are useful in breaking through denial and overcoming the physicians' barriers to ask for help.
6. A non-interrupted, long follow-up program with extensively monitored and structured aftercare is a key factor to foster physician recovery.
7. Drug testing is a key component of adequate monitoring. Failure to attend screening is a prognostic indicator of imminent relapse.
8. Family involvement. Psycho-education with families and significant others as well as family therapy when needed should be part of the patient-tailored treatment.
9. Appropriate re-entry into practice when the impaired physician remains abstinent should be warranted. Supervision at work may become necessary in some cases.
10. Advocacy and a relapse contingency plan must be implemented when needed.

When back at work, some precautions are recommended. For example, resident anaesthetists who abuse parenteral drugs are usually encouraged to find another specialty. Practising anaesthesiologists allowed to re-enter medical practice must agree to certain conditions such as temporary avoiding access to the operation room, to calls or to handling opioids. For physicians with self-prescribed oral medications, adequate monitoring of prescription is desirable. Although careful long-term monitoring in the workplace is very important, it should never lead to discriminatory attitudes (Table 102.2).

Table 102.2 Treating physicians with addictions successfully

Key ingredients to treat physicians with addictions
SUD as a mental disorder with complex bio-psychosocial determinants
Immediate response, easy access and highly confidential treatment
Ethical guarantees during referral and assessment and along all treatment process
Case management approach
Specialized treatment setting run by expert care professionals
Initial intensive treatment
Uninterrupted long follow-up assessment and support
Long-term drug screening
Follow-up support through peer or psychotherapy groups
Family involvement
Supervised re-entry into practice when not impaired
Advocacy and relapse contingency plan

102.5 Conclusions

Addictions are said to affect 10–14% of physicians during their careers. This phenomenon is a matter of public health interest because of their negative impact on the physician's wellbeing and the potential risk of malpractice behaviours. Physician Health Programmes (PHPs) have been developed in several countries to address this issue. Abstinence rates of physicians in treatment in those programs are significantly higher than in the general population. Initial intensive treatment, long-term follow-up and drug screening, group therapy attendance and a case management approach are common factors that may explain the positive clinical outcomes of this new paradigm for long-term recovery.

Substance Use Disorders in Conflict-Displaced Populations

103

Nadine Ezard, Hussein Manji, and Anja Busse

Contents

Abstract

Forced displacement is at an unprecedented high. Globally, by the end of 2018, more than 70 million people had been displaced by conflict, the vast majority in low- and middle-income countries. Substance use is increasingly recognised as a major cause of morbidity and mortality in populations displaced by conflict. Alcohol use is the best studied; male gender, older age, multiple traumatic episodes and co-existing depression, along with environmental changes such as increased alcohol availability, have been associated with increased alcohol use disorder in displacement. Transitions in substance use appear to reflect a combination of pre-displacement and host population patterns of use and are influenced by exposure to trauma and adaptation to a new post-conflict environment. Theoretical models suggest that psycho-

logical distress, social stressors, changes in social norms and networks and growing poverty and inequality may underlie these transitions. Documented harm specific to conflict-displaced populations includes injection-related infection risks, HIV transmission, mental health problems, suicide and intimate partner violence directed towards women. Sudden interruption of substance consumption may precipitate acute withdrawal and necessitates rapid establishment of withdrawal treatment. Precipitation of withdrawal can also be experienced when treatment programmes are interrupted, such as with opioid agonist therapy. Resumption of substance use after prolonged interruption may result in decreased tolerance and increased overdose risk. The treatment literature is mainly limited to feasibility of screening and brief interventions in conflict-affected settings. Evidence-based and evidence-informed interventions should be adapted to local contexts and inclusive of displaced populations; more study of intervention effectiveness in displaced settings is needed.

103.1 Introduction

Forced displacement is at an unprecedented high. By the end of 2018, there were around 70.8 million people displaced by conflict [53]. The majority are fleeing conflicts in Africa, Asia, Latin America and the Middle East and remain within those regions. Almost 60% are internally displaced within their own countries and not entitled to international legal protection afforded to refugees [26]. Although many displaced people live in camps or collective settings, most are hosted among non-displaced populations, and more than half live in urban settings. New crises cause acute onset displacement, yet the majority of displaced people have been so for decades. Close to three-quarters of refugees are in so-called protracted situations of more than 5 years' duration [53].

Conflict-displaced populations are at risk of substance use disorders and related harms [24, 35]. Economic, psychosocial and cultural aspects of displaced contexts can promote vulnerability to newer and more hazardous patterns of substance use. Limited and disrupted access to health and social services can contribute to an increased burden of illness due to substance use disorder.

This chapter provides an overview of substance use among populations displaced by conflict and highlights key clinical practice points, with an emphasis on low- and middle-income countries. The majority of conflict-displaced people reside in low- and middle-income countries, where patterns, determinants and interventions will differ from high-income countries. Starting with an outline of the literature on substance use and changing patterns in displacement, it will then explore the literature on substance use disorder and substance-related harm among populations displaced by conflict. The chapter will conclude with a survey of the evidence for clinical interventions to respond to substance use disorder and highlight future directions to treat and care for substance use disorder among displaced populations.

This chapter is concerned with substance use among populations displaced by armed conflict. A widely used definition of armed conflict is that of the Uppsala Conflict Data Program, which defines an armed conflict as "a contested incompatibility that concerns government and/or territory over which the use of armed force between the military forces of two parties, of which at least one is the government of a state, has resulted in at least 25 battle-related deaths each year" ([40], p. 536). This chapter outlines a number of themes that may be common to other "Big Events" that can cause mass displacement such as natural disasters. For example, disruption to treatment services, alcohol and drug supply lines, community and social organisation, and changes in HIV risk behaviours have been associated with floods and hurricanes [36]. Furthermore, natural disasters can occur in situations affected by conflict (such as volcano eruption in eastern Democratic Republic of the Congo in 2002 or

tsunami in Aceh in 2004). Nevertheless, armed conflict brings with it a number of features that are distinct from natural disasters. These features include duration of displacement, often repeated displacement, ongoing internecine violence, experience of war-related trauma, war-associated social disruption and livelihood imperatives. The active involvement of at least one government of a state in the armed conflict introduces additional complexity. Taken together these elements may influence substance use and subsequent disorder in ways that are distinct from natural disasters.

103.2 Substance Use in Displacement

Use of a number of different substances has been reported from conflict-displaced populations. Globally, alcohol use is the most prominent, its use documented from a range of settings, including camps in Uganda and the Thai-Burma border [14] and among urban displaced in Colombia [44]. Khat use is prevalent among the most conflict-affected areas of Somalia among combatants and civilians [21, 39]. Opiate and cannabis use is common among displaced populations in Pakistan and Iran [13]. Documented use of other classes includes amphetamine-type stimulants, cannabis, glue and other inhalants.

Patterns of use also vary widely. These patterns can be characterised as an extension of pre-displacement patterns, a transition to host patterns or a mix of the two [13]. For example, frequent high-volume use of home-brewed alcohol has been documented among some men living in long-term conflict-displaced settings in northern Kenya, Uganda and Thailand [13]. Refugees from Somalia in Ethiopia describe a transition in patterns of khat use from celebratory and weekend use to daily use [21]. These patterns of use are considered an exaggeration and modification of pre-displacement use patterns. On the other hand, new-onset use, mirroring that of the host population, can occur. This is the pattern observed among some Afghan refugees in Iran, who have adopted the use of Iranian *kerack* (a concentrated form of heroin) and *crystal* (a predominantly methamphetamine preparation). Transition to injection use of opiates among Afghan refugees in Iran, Pakistan and Turkmenistan has been well documented; this practice was diffused on return

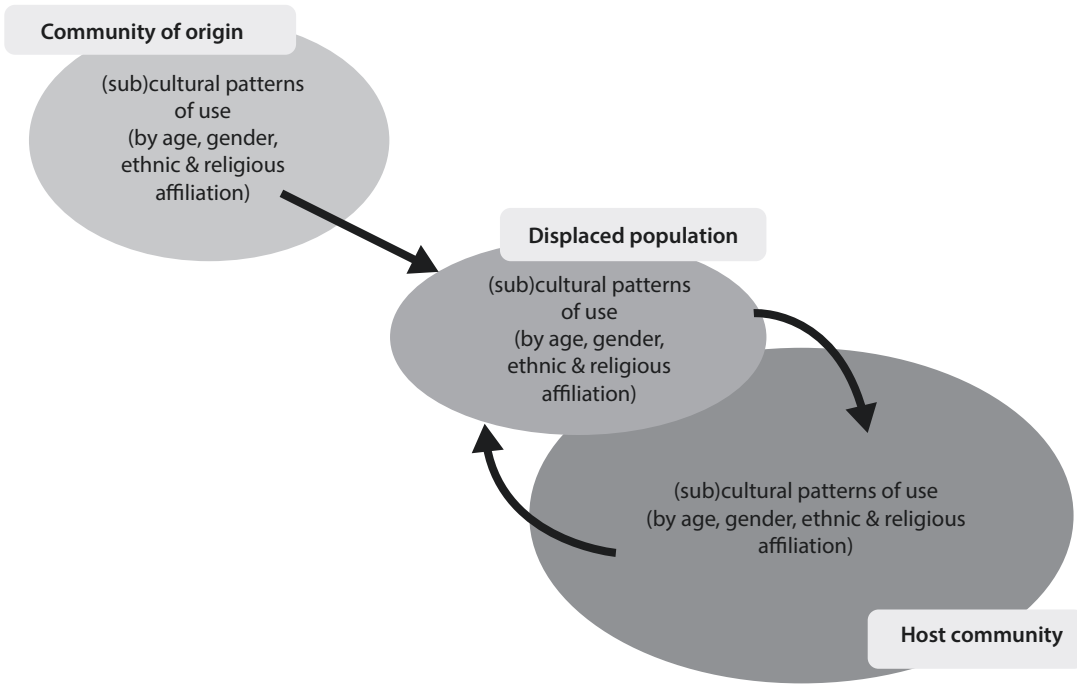

Fig. 103.1 Changing patterns of substance use in displacement [13]

and is now normalised in Afghanistan [51]. Figure 103.1 shows a diagrammatic schema for understanding changing patterns of use in displacement.

Supply factors will also influence observed patterns of substance use. Opiates, for example, are widely available and used among Afghani refugees, although believed to be less than among the host populations [13]. Grains supplied in food rations have been used to manufacture alcohol in long-standing displaced settings, such as refugee camps in Kenya and Thailand. Similarly transition to urban patterns of frequent heavy drinking – such as seen among some displaced populations – is believed to be stimulated by the more ready availability of alcohol [46].

Economic drivers underlie these observed transitions. Alcohol brewing and sale is an important source of income in settings where other livelihood options are constrained – such as in among camp-based internally displaced people in northern Uganda and refugees in north-western Kenya [13]. Arguably this may contribute to the availability – and use – of alcohol.

103.3 Substance Use Disorders in Displacement

Increased substance use in the face of trauma and social stressors may lead to the development of substance use disorder. Yet epidemiological data on the prevalence of substance use disorder are scant and subject to methodological limitations. A systematic review by Horyniak and colleagues showed that the prevalence of hazardous or harmful alcohol use ranged from 17% to 36% in camp settings in low- and middle-income countries [24]. Meaningful data on the prevalence of other drug use disorders are scant. The prevalence of drug use disorder among adult refugees from Liberia, Sierra Leone and Togo in a long-standing refugee camp in north-western Nigeria was around 20% [1]. Among camp-based Syrian refugees in Lebanon, the prevalence of drug use disorders was extremely low (less than 0.1%) [29].

There are a number of factors, which act at both individual and social levels, which may promote or protect from the development of substance use disorder. Individual trauma experiences, for example, have been hypothesised to promote substance use and the development of disorders. Among combatants, conflict exposure has been shown to result in increased substance use. Among conflict-displaced civilian populations, there is some (weak) evidence that male gender, older age, cumulative trauma event exposure and co-existing depression are associated with alcohol use disorder [35].

Gender emerges as an important determinant among alcohol use disorder populations studied in northern Uganda [44]. One study from the Thai-Burma border suggested that women in a long-term refugee camp drank very little alcohol, whereas around a quarter of men drank at risky levels [14]. This observation reflected social norms limiting women's alcohol use and promoting men's alcohol use. Nevertheless, women are not excluded from participating in substance use. Afghan women in Pakistan reported commonly using opiates in one study [13]. Refugee women in Kenya reported using alcohol to facilitate sex work [13].

Substance use disorders often co-exist with mental illness. Although post-traumatic stress disorder has been widely studied among conflict-displaced populations, its relationship with substance use disorder is inconsistent [28, 33]. (This is not to be confused with trauma exposure which has a more robust relationship with substance use disorder.) Mood disorders which are highly prevalent among conflict-displaced populations, such as depression and anxiety, may be associated with substance use as seen in non-displaced populations. Systematic review data suggests that depression is associated with alcohol use disorder in conflict-displaced populations [35].

There are a number of other factors associated with substance use disorder in displacement. Perhaps most importantly, a history of substance use disorder pre-displacement is likely to predispose an individual to substance use disorder following displacement. Individual socio-economic determinants are also important. For example, homelessness, unemployment and a lack of education are prevalent among opiate-dependent

Afghan refugees in Pakistan (and more prevalent than among the non-displaced hosts) [64]. Some population groups may be particularly vulnerable, such as sex and gender minorities (including lesbian, gay, bisexual, transgender and intersex people) [23].

Sudden interruption of substance consumption, including due to external circumstances, may precipitate an acute withdrawal syndrome in people with substance use disorders. In the case of people with alcohol use disorder who are not in treatment, this can be life-threatening. Reduced availability of substances consumed may also trigger transition from one route of administration to another, for example, from non-injecting to injection routes of administration of opioids such as observed among Afghan refugees in exile [50]. Abrupt and non-managed disruption of pharmacological treatments for opioid use disorders can lead to acute withdrawal in a similar way, such as discontinuation of methadone and buprenorphine supplies for the treatment of opioid use disorder during conflict [20]. Resumption of substance use after interruption (especially prolonged interruption) may result in overdose and related consequence due to decreased tolerance.

Various theoretical models can be applied to explain why substance use disorders may be prevalent among populations displaced by conflict. The self-medication hypothesis [31] proposes that psychoactive substances are used to relieve individual suffering, particularly among groups of people who are powerless and poor [49]. This hypothesis is shared by a number of displaced persons and observers. For example, research conducted among refugees from Sudan in Kenya explores the use of alcohol by refugees to manage thoughts of past trauma and the stress of confinement, hopelessness and powerlessness [13]. Similarly research from refugees from Somaliland in Ethiopia describes increased khat use to moderate guilt and emotional trauma [21].

Alternatively, the social stress model suggests that disruption of relationships between people and social networks may induce fear and anxiety and promote substance use [42]. It is likely that these social changes represent more than just psychological stress. Displacement can disrupt tight family and community networks and social hierarchies and replace them with new, expanded and unstable networks, removing pre-existing social controls on substance use.

Community-level changes in the physical environment may also increase the availability and accessibility of substances. This can in turn influence the prevalence of substance use disorder. One study of the "alcogenic" environment among internally displaced populations in Georgia showed an association between alcohol availability, advertising and pricing with alcohol use disorder [43].

Qualitative research conducted with refugees from Burma living in a long-standing refugee camp in Thailand explores how changing social structures influence changes in substance use [10]. Altered norms emerge, along with increased availability of alcohol, accompanied by transition to potentially more harmful patterns of substance use [16]. Social norms are likely to be at least as important as social stressors in mediating substance use [17].

Explanatory models have also been used to explain protective features of displacement. These include tight social networks developed and maintained in the face of conflict, such as theorised by McElrath in Northern Ireland [37]. Religious networks may also be protective, as suggested by Lopes Cardozo in Afghanistan [7]. Strong social norms proscribing excessive alcohol use, particularly for women, may persist in displacement such as seen in Thailand among Burmese refugees. Security, access to services and food rations, as well as hope for resettlement, as described in some camp settings may also protect against substance use disorder [10].

103.4 Other Harms Related to Substance Use in Displacement

Harms from non-displaced populations are well documented [9]. A number of health and social problems associated with substance use have been documented to be of particular concern

among conflict-displaced populations. These include communicable and non-communicable diseases, violence and economic impacts. For example, higher HIV seropositivity and lower tuberculosis treatment success have been documented among people who inject drugs compared with people who do not inject drugs in a conflict-displaced population in India [45]. HIV risk behaviours – unsafe sexual and injecting practice – were more common among refugees than host populations in Pakistan [64]. A similar pattern was observed among displaced refugees returning to Afghanistan [50]. Transition to injection may introduce HIV into communities. Molecular evidence from Afghanistan suggests a nascent epidemic of IDU-associated HIV infection in Hirat, with a similar strain of HIV observed in Iran, where the majority of people who inject opiates began injecting while refugees [48]. Indeed substance use is an important moderator of the relationship between HIV and conflict [30].

Compounding the health risks of alcohol consumption, the livelihood imperative to generate income from alcohol production by displaced persons may promote the addition of harmful chemicals. Qualitative research from Mae La refugee camp in Thailand explored community perceptions that consumption of artisanal alcohol may be dangerous as a result of poisonous additives [10]. Similar observations have been made in long-standing camps in African contexts. Nevertheless, although deaths have been reported from contaminants such as methanol or herbicides in poorly produced alcohol, it is the amount of ethanol and pattern of consumption of alcohol that pose the greatest threat to public health [34].

Other health problems include mental illness, which can be a cause or a consequence of substance use. Among some displaced populations, substance use is an important contributing factor to completed suicides. For example, alcohol has been implicated in the majority of suicides among war displaced in northern Uganda [32].

Substance use has been implicated in other forms of violence. Intimate partner violence against women is common and has been linked with men's substance use in camps in Iraq, Kenya and South Sudan [59]. In one long-standing refugee camp in Ethiopia, women whose male partners drank alcohol had twice the odds of experiencing intimate partner violence within the previous 12 months than those who did not [15]. Similarly in long-standing internally displaced camps in northern Uganda, women whose husbands use alcohol were 50% more likely to report intimate partner violence [3]. This connection has been made for other substances too – for example, violence against women was linked with their male partners seeking money for cannabis in a qualitative study in Pakistan [13].

Substance use has been observed to have important economic impacts at the individual, household and community level. These aspects have not been explored in depth. Household expenditure can be considerable – in refugee camps along the Thai-Burma border, 80% of households spent money on substances [6]. Theft, family conflict, poverty and child neglect among families with opium-dependent household members increased when the population was displaced away from traditional opium-growing areas in Laos [60]. Returning refugees to Somalia from Ethiopia promoted an increasingly thriving khat market, supported by third-country remittances [21].

103.5 Comparison with Non-displaced Populations

Although populations displaced by conflict are vulnerable to a range of factors promoting both substance use and substance use disorders, there are few studies comparing displaced to non-displaced populations. In community settings, no differences were reported in injecting drug use between Afghan refugees and Pakistani hosts [64] or in excessive alcohol consumption between urban displaced and hosts in Colombia [41]. In north-western Nigeria, the prevalence of alcohol use disorder was 13.5% among camp-based refugees ($n = 444$) and 19.0% among the host population (527, $p < 0.05$, not age or sex adjusted), and drug use disorder was 19.6% among refugees and

15.6% among hosts (no significant difference) [1]. Conclusions on whether displaced populations are more, or less, affected by substance use disorders post-displacement than pre-displacement are not possible; nor are comparisons with the host population. Indeed, mass trauma events in non-displaced settings in North America reveal contradictory findings regarding post-traumatic changes in the prevalence of new-onset substance use problems [38, 58], whereas resettled refugees have lower prevalence of substance use disorder when compared with the host population [47]. The lack of longitudinal data precludes further understanding of the relative contributions of *new-onset substance* use disorder following trauma or adaptation to the post-emergency environment and *exacerbation* of pre-existing substance use disorder. Such findings lend weight to the conclusion that any observation will be situation specific, and interventions must be guided by an assessment of the local context.

103.6 Treatment and Care of Substance Use Disorders

Experience of interventions to treat substance use disorders and reduce harm related to substance use among populations displaced by conflict is limited. The literature is limited largely to the assessment of feasibility of screening and brief intervention [18],

103.6.1 Community-Based Outreach

In non-conflict settings, community based outreach includes linkages to basic needs and primary care supports, needle-syringe programs, condom distribution, HIV and hepatitis C counselling and testing, hepatitis B vaccination, substance use education, overdose prevention (such as naloxone), and initial assessment, brief intervention and referral to specialist treatments [57]. Needle-syringe programs, counselling, psychoeducation, and naloxone distribution have been successfully implemented in Afghanistan among returned refugees with opioid use disorder from Pakistan and Iran [52].

103.6.2 Screening

For alcohol use disorders, the 10-item "gold standard" screening test, the Alcohol Use Disorders Identification Test (AUDIT, [5]), has been tested in a range of non-conflict settings and has been used in a number of conflict-affected settings including Thailand [12, 22] and Uganda [44]. The Alcohol, Smoking and Substance Involvement Screening Test (ASSIST) has been used to detect khat use disorder among Somali refugees in Kenya [63].

In low-resource settings, single-item screening tests may be useful to identify individuals who may benefit from further assessment and treatment. For example, the third question of the AUDIT *"How often do you have six or more drinks [equivalent to 10 g ethanol] on one occasion?" with at least once a month or more often over the last year as a positive* has been used for a rapid survey [13]. The short version of the ASSIST, the ASSIST-Lite [2] has been collapsed into a single question for each drug of concern*: "do you use [substance of interest] once a week or has anyone expressed concern about your use of [substance of interest]", with the answer yes considered positive.* Further assessment of sensitivity and specificity of these tests in displaced settings is required.

103.6.3 Brief Intervention

Stand-alone brief interventions for alcohol use disorder [5] by health workers have been shown to be feasible among Burmese refugees in Thailand [12] although impact on outcomes needs further testing. Among the same population, Haroz, Bolton and colleagues delivered a brief intervention for alcohol use disorder as part of a randomised controlled trial of a trans-diagnostic psychosocial intervention delivered by lay counsellors to a sub-sample of those screening positive for hazardous alcohol use ($n = 33$) and was underpowered to detect change [22]. A randomised controlled trial of a stand-

alone single-session brief intervention (n = 330) resulted in greater decrease in khat use and increase social functioning in the intervention group compared with the control group among Somali refugees in Kenya [63].

103.6.4 Specialist Treatment

Multi-component interventions including withdrawal and continuing care have been feasibly delivered on the Thai-Burma border [8]. The United Nations Office on Drugs and Crime implemented a combined community-based treatment and prevention programme among Afghan refugee women in Pakistan. This programme included home-based withdrawal, community-based continuing care and income generation [55]. Medication-assisted treatment with sublingual buprenorphine for opioid use disorder has been delivered in conflict-affected northeast India with 73% retention at 3 months (n = 713) [4].

103.6.5 Guidance Materials

In the absence of a strong evidence base, efforts have been made to develop consensus-based guidelines drawing on evidence from non-conflict settings. These guidelines usually address the initial response in resource-poor settings and are built on human rights and community development principles. Recognising that no universal response can take into account a broad range of historical, social, cultural and political contexts, these guidance materials attempt to identify core activities that are common to many situations. For example, the Interagency Standing Committee (IASC) Guidelines on Mental Health and Psychosocial Care in Emergency Settings [25] outlines minimum health services response to minimise harms related to alcohol and other substance use [25] (Box 103.1).

A number of rapid assessment guides exist for a range of settings. These guides have an intervention focus, use multiple data sources and emphasise community participation and understanding the social context. For example, the WHO/UNHCR *Rapid Assessment of Alcohol and*

Box 103.1 Minimum Health Services Response to Minimise Harms Related to Alcohol and Other Substance Use in Emergency Settings. (Adapted from [25])

1. Conduct a rapid assessment (guidance can be found at [54])
2. Engage men and women from the community in designing and delivering a multisectoral response
3. Train and support health workers and front-line staff in screening and brief intervention
4. Train and supervise community workers to target at-risk groups for additional supports
5. Provide information, education and materials to prevent harm related to substance use (condoms, needle-syringes, naloxone, thiamine for people who consume alcohol heavily)
6. Train and supervise heath workers to treat withdrawal (especially emergency management of life-threatening alcohol withdrawal; guidance can be found at [62].
7. Establish or re-establish opioid agonist treatment.

Box 103.2 Case Study: Rapid Assessment of Substance Use and Associated Health and Social Services in Refugee Settings, Uganda, 2018 [11]

Uganda has provided asylum to people fleeing conflict for more than five decades. The Government extends an inclusive

approach to refugee hosting to an estimated more than one million refugees from neighbouring countries, with a mix of protracted displacement and new arrivals. With growing recognition of the vulnerability to substance use disorders among conflict-displaced populations, context-specific information is required to design effective interventions.

UNODC commissioned a rapid assessment of substance use and associated health and social services in one rural refugee settlement and among urban refugees in Kampala, consisting of a literature review and rapid qualitative data collection (direct observation, focus groups and key informant interviews) conducted by a team of international and national researchers in April 2018.

Epidemiological data on substance use disorder among refugees were unavailable. This observation highlights the importance of and improved routine treatment data collection, survey data on problematic drug use and inclusion of refugees in data collection activities.

Qualitative data suggested that substance use was considered a growing concern in displacement. As for the Ugandan population, alcohol was the primary drug of concern among refugees. It is ubiquitous, cheap and readily available. Cannabis and khat were considered widely used in urban and rural settings. In the urban setting, in particular, heroin, cocaine and methamphetamine were also used, although less prominently, including injecting routes of administration. Substance use and related problems were gendered, perceived as more prominent among men than women. Urban life offered a greater range of opportunities and challenges, including exposure to an increasing range of substances and problems associated with them.

Some substance use behaviours were believed to have predated displacement, while others were related to integration with host communities. Consistent with the international literature [10], youth substance use patterns in particular were believed to be adapting to host community norms, in the context of weakening parental and community controls in displacement. As one respondent explained, "youth are lost, don't take advice from elders…. divert to other cultures".

Dominant rationalisations for substance use disorders were trauma, stress, idleness, limited educational opportunities, future uncertainty, discrimination and livelihood constraints. As one man explained, "I have no house, no job, sleep outside so I need drugs to cover inside". Another woman expanded, "I lost my husband, have three children, and need to support them so I am a sex worker. I use cocaine, marijuana, and alcohol with clients, sometimes inject". Groups perceived to be most at risk of substance use disorders were considered mobile young men and women without family financial support, particularly women sex workers and men *boda boda* (motorcycle taxi) drivers. Opportunities were seen by some as increasingly constrained with the duration of displacement, particularly in the rural settlement. These understandings are consistent with the international literature [10, 24].

Health concerns related to substance use included alcohol-related liver disease, dependence, accidents and injuries. One participant explained that substance dependence can be both caused by and enhance discrimination and social exclusion. In speaking of his own khat use: "I cannot enter the mosque, [I get] stress relief while chewing but lazy and irritated the next day, get annoyed easily … more discrimination, but the body needs to have it". Another man described an unpleasant experience of being acutely unwell with opioid withdrawal syndrome while incarcerated. One

woman explained: "Me I can't stop drinking even though I burnt my house and business. Why leave drugs when it helps you forget your pain? I have children, where can I get help? Nowhere to go".

There was a dominant perception among refugees that substance use and dependence may promote risky behaviours for HIV transmission while limiting testing and treating behaviours. As one man explained: "When you are intoxicated you don't use a condom". Similarly, this risk discounting was reported in the context of heroin dependence in the urban setting "when you are using [heroin dependently] you don't care [about HIV]" explained another man. These transmission risks are important in the context of a generalised HIV epidemic, economic constraints and cross-border and rural-urban population mobility and mixing.

Socio-economic concerns included alcohol-related domestic and family violence and disruption to child-rearing, household economy, livelihoods and education. Criminal justice consequences were of particular concerns to refugees – especially parents – as they had additional implications for refugee status determination.

Despite the limited scope of the assessment, there was no evidence to suggest that refugees in Uganda experience greater problems due to substance use than host Ugandan populations. Socio-economic and psychosocial vulnerability resulting from the displacement experience, particularly in protracted displacement, warrants additional resource investment. Given the context of free access to the public health-care system, the assessment findings suggest excellent opportunities to strengthen national primary and referral level treatment for substance use disorder as part of a broader prevention and treatment strategy, including for refugees. International response capacity could be strengthened by embedding substance use disorder in minimum standards for emergency responders.

Despite growing awareness of the importance of substance use disorders, consultations for alcohol and drug use disorders in refugee settings are low [27], suggesting the need to strengthen accessible, effective and affordable interventions. More implementation research is required, adapting interventions with evidence from non-conflict settings informed by contextual assessment [19].Yet it remains unclear whether displaced contexts are so vastly different in salient ways as to limit effectiveness. The gold standard of evidence-based interventions may not be realistic in settings of high population mobility, competing health and other priorities and resource constraints and with complex ethical dimensions. At a minimum, interventions should be theory based and show positive outcomes on monitoring or evaluation. More translational research is required.

Other Substance Use in Conflict-Affected and Displaced Populations field guide has been implemented in several situations of protracted displacement in Africa and Asia [13]. An example of how a rapid assessment may be used to guide interventions for treatment and care is given in Box 103.2.

Guidance for non-specialist clinicians in low- and middle-income settings is provided in the joint WHO/UNHCR *mhGAP Humanitarian Intervention Guide (mhGAP-HIG): Clinical Management of Mental, Neurological and Substance Use Conditions in Humanitarian Emergencies* (WHO 2015). These settings are typically challenged by competing priorities; limited time and resources; lack of access to specialists for training, referral, consultation and supervision; and disruption to supply of medications. More comprehensive guidance for non-specialist clinicians is provided in the WHO

mhGAP Intervention Guide [61]. In more stable settings, comprehensive interventions can be developed (see, for example, UNODC's Treatnet [56]); these have not been tested in conflict-affected populations. The addiction medicine specialist may have an important role in training and capacity building in these settings.

103.7 Conclusion

Substance use disorders among populations displaced by conflict are important but undertreated. This chapter has described how conflict can shape transitions in substance use and development of substance use disorders and outlines current approaches to clinical interventions. Although the evidence base is at yet underdeveloped, current approaches suggest adapting evidence-based interventions from other settings. Interventions should be based on an assessment of the biopsychosocial needs of men, women and children and their context and include at a minimum community outreach, screening, brief intervention and treatment of common co-existing disorders. Addiction medicine specialists will have an important role in training, supervision, referral and capacity building. Further context-specific implementation science-based research is required.

Key Points

- More than 70 million people are displaced by conflict at the end of 2018, most of whom are in low- and middle-income countries.
- Substance use is a major cause of morbidity and mortality among conflict-displaced populations.
- Transitions in substance use may be related to exposure to trauma, adaptation to a new post-conflict environment, pre-displacement and host patterns of substance use.
- Intervention design and delivery should be based on context-specific information and involve affected community members, including minority populations.
- Guidance materials for minimum responses exist, outlining community outreach (e.g. condoms, needle-syringes, naloxone, thiamine), primary care (e.g. screening, brief intervention) and specialist treatment (e.g. alcohol withdrawal, opioid agonist therapy).
- Efforts should be made to include displaced persons in health and social services delivered to host populations.

Children, Adolescents and Young Adults

Robert Milin and Kevin Gray

Children, Adolescents, and Young Adults: An Introduction

104

Kevin M. Gray

Contents

Abstract

Substance use disorders must be understood in a developmental framework. Substance use initiation typically occurs in adolescence or young adulthood, and earlier initiation poses a number of risks for adverse outcomes. Additionally, maternal substance use during pregnancy poses risks for the developmental course of the child. This section is intended to provide a comprehensive and timely update across a number of key areas. Epidemiology and characteristic features of adolescent substance use are reviewed, demonstrating both long-standing associations and dynamic trends. In light of the heterogeneous and often complex nature of adolescent substance use, tailored strategies for screening, assessment, and management are highlighted. Suicide, ranking among the leading causes of death in adolescents, is often associated with substance use. This relationship is examined in detail, with implications for integrated clinical strategies to prevent mortality. Risk and protective factors for adolescent substance use represent a critical area for research, given the clear implications for provision of prevention efforts. The latest advances in identifying psychosocial, genetic, and neurobiological risk factors, and their potential clinical applicability, are discussed. Finally, the array of developmental implications of maternal perinatal substance use for the mother, child, and mother/child dyad are highlighted, with a focus on practical clinical strategies to optimize outcomes. Overall, this section is crafted to synthesize the latest advances in understanding and addressing substance use in the developmental context of childhood and adolescence.

104.1 Section Introduction Text

Given its serious implications for the individual, family, community, and society, substance use has deservedly garnered increasing international attention and concern. Once highly stigmatized and derided as reflections of individual moral failings, substance use disorders are increasingly understood as both neurobiological and psychosocial in nature, and amid this awareness, a number of research advances have provided hope for improved clinical interventions and outcomes. However, while it is generally acknowledged that substance use initiation typically occurs during adolescence or young adulthood, relatively little work has focused on addressing substance use in its developmental context. Fortunately, emerging advances in this area provide a framework for clinicians working with children, adolescents, and families. This section is intended to leverage these advances and shed light on the developmental context of substance use disorders, spanning intrauterine substance exposure to childhood risk and protective factors to adolescent substance use epidemiology, potential consequences, and clinical strategies.

Olagunju, Milin, and Gray begin the section with a chapter focused on the characteristic features of adolescent substance use. Particular attention is paid to epidemiology, risk-vulnerability, developmental course, and comorbidity, all in the context of a biopsychosocial framework. Adolescent substance use is heterogeneous, with some individuals remaining abstinent throughout this developmental phase and others engaging in patterns of use that range from brief experimentation to continued intermittent use to escalating and eventually habitual use. Risks, such as motor vehicle accidents due to intoxication-impaired driving, span all facets of adolescent substance use and escalate with the degree of substance involvement. Adolescent substance use disorders pose both acute and chronic risks with potential lifelong implications.

Gray and Milin follow with a chapter that examines evidence-based strategies for adolescent substance use screening, assessment, and clinical management. Relying solely on previously established adult-targeted strategies may be insufficient and may in some cases be counterproductive. Instead, tailored strategies that acknowledge the developmental context of adolescence as well as the heterogeneity of substance use during this developmental phase are warranted. Guidance is provided on the current array of adolescent-specific evidence-based strategies, with an emphasis on practical implementation in clinical practice. Future directions for advances in care, particularly those that leverage advances in mobile technology and other platforms, are highlighted.

Shlosberg and Shoval provide a critical chapter on the associations between adolescent substance use and suicidal behavior. Tragically, suicide is among the most common causes of death among adolescents in the industrialized world, and its association with substance use necessitates clinical understanding of suicidal behavior as an inherent risk among substance-using youth. The chapter discusses important factors moderating this relationship, such as co-occurring mental disorders and demographic characteristics, to guide strategies for targeted and tailored interventions that address the potential for suicidal behavior among adolescents presenting with substance use.

Spechler, Ivanciu, and Garavan contribute an important chapter focused on risk and protective factors for substance use and addiction, a critical area of research that directly informs targeted prevention efforts. With advances in genetic and neuroimaging tools, as well as the advent of robust longitudinal studies of child and adolescent development, researchers are increasingly able to parse important psychosocial, genetic, and neurobiological factors that influence adolescent substance use and its subsequent life course. These efforts are focused on elucidating potential biomarkers to inform mechanistic models, with implications for precision in delivery of prevention and intervention services.

Velez, Jordan, and Jansson provide a comprehensive chapter on the relationship between prenatal substance exposure and neurodevelopmental outcomes. Importantly, perinatal substance use

has serious implications for all involved: mother, child, mother/child dyad, and family/community. Neurodevelopmental alterations that arise from intrauterine substance exposure may affect developmental, behavioral, cognitive, and adaptive functioning at a variety of life stages, and adverse effects may be compounded by unstable environments that often accompany chronic substance use. The authors parse a complex interplay among these factors, introducing important clinical strategies for screening and interventions for families affected by perinatal substance use.

Together, these chapters frame substance use in a developmental context, with implications spanning the full life course and across generations. The predictors, outcomes, and heterogeneous nature of adolescent substance use are elucidated, and this information is translated into practical strategies, based on an advancing evidence base, for clinical and population health approaches to enhance outcomes. Additionally, strategies for further research leveraging novel technologies and analytic techniques are highlighted, indicating that this important area will see ongoing advances to reduce associated morbidity and mortality.

Adolescent Substance Misuse/Use Disorders: Characteristic Features

105

Andrew T. Olagunju, Robert Milin, and Kevin M. Gray

Contents

Abstract

Substance use disorder (SUD) in adolescence is a serious mental health and social problem with its significant association with morbidity, disability, and mortality. Substance misuse has progressed from the more antisocial, risk-taking, and marginal groups of the population to the mainstream of society and dramatically to younger populations, reinforcing and expanding the boundaries of at-risk populations for SUD. Research in the area of adolescent substance use has expanded significantly over time, and while many studies have contributed to the growth of knowledge in this area, ongoing study remains important. Substance use may be seen through a developmental perspective progressing across adolescence into young adulthood. We have included the most recent studies and research findings on adolescent substance misuse and use disorders in this chapter. The chapter will focus on enhancing knowledge and comprehension of adolescent substance misuse in addressing the following areas: epidemiology, risk-vulnerability, developmental course, and comorbidity. The transitional period of ado-

lescence presents itself as an especially critical and vulnerable time for the onset of substance use with its impact on normal development, future SUD, and society as a whole. Adolescence is a period of major risk for the onset of SUD. The complexity of the risk-vulnerability for substance misuse and use disorders among adolescence is derived from the "addictive shared" effects of multi-domain factors including biological, environmental, interpersonal, socio-cultural, and psycho-behavioral factors. The changing pattern of use through adolescence and high rates of comorbid mental disorders among adolescents with SUD further emphasize the need for better understanding of the epidemiological trend, risk, and comorbidity to inform evidence-based interventions.

105.1 Introduction

The goal of this overview chapter is to present the current knowledge on the epidemiological burden, risk-vulnerability, and comorbidity for substance misuse and use disorders among adolescents. Research in the area of adolescent substance use has expanded significantly over time. While many studies have contributed to the growth of knowledge in this area, further research and study remain important. As such, we have included the most recent research and findings on adolescent substance misuse and use disorders in this chapter. As preadolescent substance use is uncommon, the focus of this chapter is on the adolescent population, an age group that faces major developmental, psychosocial, and cultural challenges including substance use. Substance use may result in serious mental health and social impairments with a significant association with morbidity, disability, and mortality. The onset of substance use disorder is particularly high during adolescence. Substance use has essentially become part of mainstream adolescent development and, over time, has become increasingly common among younger populations. Adolescence may be appropriately defined as a time of major risk in the development and onset of SUD.

105.2 Youth Substance Misuse

105.2.1 Epidemiology of Youth Substance Misuse

105.2.1.1 Epidemiology of Substance Use

Substance use among adolescents remains a public health issue of global significance in spite of some shifts in the pattern of use resulting from increasing use of cannabis and other substances relative to alcohol, albeit alcohol remains the most frequently used substance. The recent World Health Organization (WHO) estimates of current alcohol drinkers show high rates of use among adolescents aged 15–19 years across many countries including Luxembourg (86.4%), Australia (69.3%), the United States (59.9%), Canada (51.7%), Brazil (26.8%), and South Africa (19.5%). Notwithstanding the differences in the rates of use across the countries, there is consistency regarding male current drinkers being several folds higher than females [1]. Similar to alcohol use, experts have underscored a worrying level of substance use among adolescents globally regardless of the disparity in the rates of use across countries, arguably informed by differences in data quality, legislations, access, and economic and other psycho-socio-cultural variables.

Adolescence is a sensitive transition period characterized by major changes in physiological, psychosocial, maturational, and cultural expressions. It is therefore conceivable that age-related trends in substance use are critical to better understand epidemiological transitions in substance use among adolescents and the underlining factors. In this regard, the Monitoring the Future survey [2] provides a unique perspective as it has been mea-

suring the annual prevalence rates and trends in substance use in adolescents attending school across the United States in a nationally representative sample for more than four decades. Substance use (alcohol and illicit drugs) in general across the grades has shown a steady and measurable decline for some time led by a decline in alcohol use, though with some exceptions. The rate of binge drinking has remained a concern at 14% in 2018 for grade 12 students, and vaping is substantially becoming common.

Marijuana, in contrast, has shown a steady increase in use over the last several years affecting the rate of illicit drug use, whereas illicit drug use other than marijuana has more or less held steady or declined. The rise in marijuana use appears to mirror the lessening attitudes toward the perceived risk of harm associated with its use. The annual prevalence rates for 2018 for any illicit drug use in grades 8, 10, and 12 stand at 13.4%, 29.9%, and 38.8%, respectively, which remain relatively high. Substance use overall shows a marked increase in prevalence from grade 8 to grade 12. By far, the two most common substances used by adolescents are alcohol and marijuana, with current rates for senior high school (grade 12) students of 30.2% and 22.2%, respectively, in 2018. Marijuana has been the most common substance of daily use among adolescents by far for more than a decade, currently standing at 5.8%. Prescription drug misuse among high school seniors remains a concern at approximately 9.9% per annum, although higher proportion of use has been recorded for specific drug classes, particularly for pain relievers with as much as 19% [2]. Included in the prescription drug group class are narcotic analgesics (Vicodin and OxyContin), stimulants (Adderall and Ritalin) used for treatment of attention-deficit/hyperactivity disorder (ADHD), and sedatives/tranquilizers [3].

105.2.1.2 Epidemiology and Burden of Substance Use Disorders (SUD)

Prevalence rates of substance use do not provide one with comparable rates of SUD in general and especially in adolescents [4]. Substance experimentation among adolescents is highly prevalent, though the vast majority of these adolescents do not develop an SUD, even with some of these adolescents engaging in more regular use for a period of time, though the latter does increase the likelihood of developing an SUD [4]. These patterns of substance use, as it would relate to alcohol and marijuana use seen in adolescents, appear for some to be within normative behavior and part of the maturation process of adolescence but for others may lead to significant SUD [4, 5].

Substance use disorders are attributed with significant contributions to the global burden of diseases among adolescents, even though a lesser proportion of adolescent substance users progresses to meet the diagnostic criteria of SUD. Importantly, the 2017 Global Burden of Diseases estimates show an annual incidence of 907 per 100, 000 for SUD worldwide and a substantial contribution from SUD to disability-adjusted life years (DALYs) and years lived with disability (YLD) among adolescents aged 15–19 years [6, 7]. See Box 105.1 for some indices of global burden of SUD in 2017 [7].

Box 105.1 Annual Indices of Global Burden of SUD in Adolescents Aged 15–19 Years

Measures	Values	Rates/100, 000
Incidence (global)	5,595,270	907
Incidence (Africa)	1,051,388	800
Incidence (Asia)	2,601,609	725
Incidence (America)	1,340,886	1713
Incidence (Europe)	703,898	1264
Disability-adjusted life years (global)	2,157,907	350
Years lived with disability (global)	1,838,773	298

The US National Comorbidity Survey-Adolescent Supplement [8] has provided us with one of the most comprehensive general estimates of lifetime prevalence rates of SUD in this population. SUD at 11.4% and mood disorders at 11.2% represent the two most common categories of mental disorders with severe impairment in adolescents. It is important to recognize that

the prevalence rate of drug use disorders at 8.9% exceeds that of alcohol use disorders at 6.4% contrary to adult prevalence rates for SUD. Notably, SUD was found to be somewhat more common in boys at 12.5% than girls at 10.2%. The median age of onset for SUD was 15 years, with a steep increase in incidence thereafter. Notwithstanding the average rates just cited, higher SUD prevalence rates have been reported in a US community sample examining higher-risk groups of adolescents receiving public sector services including those receiving mental health services. The overall past-year prevalence rate for SUD was found to be 24% across all five public sectors [9]. This rate is being more than two times greater than the reported prevalence of SUD in the general adolescent population.

Emerging areas of concern include a defined minority of adolescents who engage in polysubstance use which may carry a greater burden of related problems and the rising misuse of prescription pain relievers by adolescents with evidence of significant use disorder liability [10]. One can also surmise that cannabis is the most telling and common substance of misuse in adolescents with alcohol being the predominant misused substance [5]. Overall, the prevalence of substance use and SUD in adolescents remains a major public health issue with drug use disorders being more prevalent than alcohol use.

105.2.2 Risks and Developmental Course

Levels of substance use have been found to increase from early adolescence to early adulthood (mid-20s) and decline thereafter. Despite the overall relative decline of substance use in adolescents, the prevalence remains high and is the greatest with older adolescents. Girls may exhibit higher levels of substance use than boys during early adolescence, whereas over time boys exhibit greater rates of change, resulting in high levels of substance use from mid-adolescence through young adulthood [11]. Adolescence is a time of major risk for the onset of SUD that shows a developmental trajectory [12]. The peak age of onset for SUD, both alcohol and drug use disorders, is in late adolescence/early adulthood, between the ages of 18 and 20 [3, 4, 12].

Adolescence, as seen from a developmental perspective, represents a time of convergence of significant neurobiological, cognitive, behavioral, emotional, and social changes with continuity of risk from earlier developmental stages, providing a unique period of heightened vulnerability and susceptibility for SUD [4, 13]. Brown et al. [4] reflect on these interrelated developmental factors, the changes that occur during adolescence, and its influence on individual alcohol use trajectories and risk for problem drinking. The authors' narrative highlights the growing evidence that adolescents are particularly vulnerable to the adverse effects of heavy alcohol use both in the biological and social domains and that the consequences of drinking appear to differ between adolescents and adults. They also identify that problem drinking has the potential to redirect the normative course of adolescent development in a manner that increases the risk not only of alcohol use disorders but also of mental health and social problems. This is particularly important as adolescents tend to binge drink consuming high quantity of alcohol per occasion. Notably binge drinking has a dose-response relationship with a range of acute alcohol-related harms, which may persist into adult mental health issues or chronic mental disorders [14]. In a broader sense, prospective studies suggest that early and more frequent substance use through adolescence is associated with, and may predict, later mental disorders in young adulthood [15, 16].

Schepis and coauthors [13] in their review of the neurobiological processes involved in the etiology of adolescent SUD emphasize the significance of maturational changes of the central nervous system that occur in adolescence, the foremost of these being synaptic pruning, myelination, and neurotransmitter system modification. In general, adolescents appear to have greater neurobiological bases for risk-taking behavior with attenuated suppressive and regulatory con-

trols on behavior. The authors surmise that the abnormal neurological markers of those at risk for the development of SUD may best correspond to disinhibition and/or negative affect. Adolescents appear more vulnerable to the effects of many substances that are most likely mediated by increased neuroplasticity, neurotoxic effects on cognition, and effects of stress. It is likely that substance-induced neurobiological changes enhance drug use behaviors. These attributes reinforce the progression to SUD in adolescents [16].

A range of risk factors have been identified in the prediction of SUD in adolescence/young adulthood. These risk factors may be conceptualized into four domains: (a) culture and society (e.g., laws and availability of substances), (b) interpersonal (e.g., peers and family including attitudes), (c) psycho-behavioral (e.g., early/persistent behavioral problems, poor school performance, rebelliousness, early onset of substance use, personality characteristics such as temperament and affect), and (d) biogenetic (e.g., familial or inherited susceptibility and psychophysiological vulnerability to the effects of substances) [16–18].

It appears that social factors, especially peer influence, are the strongest determinants of initiation of substance use, whereas psychological factors, biological vulnerability, and self-reinforcing effects of a substance are more closely associated with the progression to SUD [16].

There is not much evidence to assist in distinguishing the relative importance of risk factors and their specificity in the development of adolescent SUD. It is the number of risk factors, rather than any one factor, that is predictive of SUD. Many of these risk factors are shared with those related to the onset of other mental disorders in adolescents [17]. More recently, several converging lines of evidence favor the addictive rather than sole individual effects of risk factors to better explain the complex etiology of SUD in adolescents. For instance, the combined effects of several risk factors (such as family history of alcoholism, male sex, and impulsivity, among others) via mediating the pattern of alcohol exposure have been implicated to underlie the vulnerability associated with binge drinking and progression to alcohol use disorder [19, 20].

Protective factors are those that reduce the likelihood and level of substance use. Multiple protective factors have been identified including a positive temperament (absence of depression)/self-acceptance, intellectual ability/academic performance, supportive family/home environment, caring relationship with at least one adult, external support system (e.g., religion/church) that encourages prosocial values, and law abidance/avoidance of delinquent peer friendships [16, 18]. Again, it is not one particular protective factor but, rather, the number of protective factors that has the greatest influence on reducing the likelihood of developing SUD in adolescence. As such it has been shown that those adolescents with five or more protective factors are over 20 times less likely to develop cannabis misuse than the general sample. Protective factors also appear to have a moderating influence on the risk for drug use involvement with high protective indices being found to have the strongest effect on those at high risk for greater drug involvement [20, 21]. One factor that has been identified above others as protective of substance use is having early academic success [22].

The early initiation of substance use in adolescence predicts a considerably greater likelihood of developing later SUD with a more rapid progression to SUD, being of particular relevance for cannabis and alcohol. These findings are most robust for initiation of substance use by age 15 or younger; thereafter, other variables may come into play [23]. Adolescent SUD has been found to be a strong homotypic predictor (a disorder predicting itself over time) of young adult SUD [23]. A pattern of regular weekly use of cannabis in adolescence appears to be a threshold marker for the risk of cannabis use disorder in young adulthood [24].

A widely held concept reasons that there are developmental stages in the progression of substance use through adolescence into young adulthood. The sequence of stages defines a temporal relationship progressing from legal to illegal and softer to harder drug use, with each stage acting as a potential "gateway" to the initiation of the

next stage [25]. The use of one substance increases the likelihood of initiation of the second substance. For example, very few individuals who have tried cocaine and heroin have not already tried marijuana, the majority having previously used alcohol or cigarettes. However, the use of one substance does not invariably lead to the use of other substances. Many youth will stop at a specific stage and do not progress further or may return to an earlier stage of substance use [25]. It is relatively common to carry over substance use from one stage to the next. Adolescents who engage in the use of multiple substances increase their risk of developing an SUD into young adulthood [20, 23].

The causal application of the gateway hypothesis is more open to debate and specifically as it relates to cannabis use and other drugs [26]. However, a strong association has been established for cannabis use and the use of other illicit drugs. Further to this, regular or heavy cannabis use has been significantly associated with other illicit drug use and SUD. The relationship is especially strong during adolescence and declines with age. These findings add support to the potential causal role of cannabis use on the development of other illicit drug use disorders, though the actual causal mechanisms, whether direct or indirect, remain unclear [27]. Adolescents may show a greater likelihood of developing drug use disorder (cannabis) than adults across levels of use. Importantly, positive first reaction to cannabis in adolescence predicts later misuse, and regular weekly use of cannabis in adolescence appears to be a threshold marker for later SUD as well as the absence of a definition of what constitutes "recreational" use of cannabis [27].

Substance misuse, expressly cannabis, in adolescence is clearly associated with significant developmental impairment and negative consequences in multiple life domains including behavioral, psychosocial, and academic/vocational [4, 28].

In summary, the onset of SUD in adolescence with its biopsychosocial determinants is a serious mental health problem, with a serious impact on developmental tasks and a strong link to future SUD. Box 105.2 highlights few clinically meaningful points on risk factors and vulnerability to substance use among adolescents.

Box 105.2 Vulnerability and Risk Factors of Substance Misuse/Use Disorders

Risk factors spanning the course of substance misuse/use disorders are multidimensional and can be categorized into biological, environmental, interpersonal, socio-cultural, and psycho-behavioral factors
The "addictive effect model" is plausible to explain risk factors for the development, course, and prognosis of substance misuse/use disorders
Genetically mediated individual differences in response to early use of substance and the dose-response effects of substances are prognostic indices for SUD and acute and chronic harms of substances

105.2.3 Comorbid Disorders

The association of SUD with other mental disorders is well established. In clinical and treatment studies of adolescent SUD, elevated rates of comorbid mental health disorders have been found across clinical settings with prevalence rates ranging from 55% to 80% [29, 30]. Prevalence rates of comorbid disorders are significantly greater than community control samples of non-SUD adolescents. Adolescent SUD patients often present with more than one comorbid disorder. Clinical studies, however, may suffer from Berkson's bias where it is probable that an adolescent with a particular disorder such as SUD who is seeking treatment will have a greater likelihood of a second disorder, thus confounding the ability to generalize results. Only a handful of studies have examined the comorbidity of adolescent SUD in general community samples. Two such studies have found similar elevated rates of comorbidity as seen in clinical studies. Comorbidity rates were two to three times greater in adolescents with SUD than those without SUD for anxiety, mood, or disruptive behavior disorders (DBD). In comparison to adult studies, comorbidity rates of mental disorders are similar for lifetime SUD and may be higher for current

SUD in adolescents. These higher rates of psychiatric comorbidity in adolescents with SUD are most likely reflective of the number of DBD diagnoses made in adolescents that are either not applicable to or not routinely assessed for in adults. There is some evidence to support that comorbidity of mental disorders increases with progression of SUD and severity of substance use [8, 23]. The genders share far greater similarities than any meaningful differences with respect to comorbidity characteristics, especially when gender differences seen in the general population of such disorders as conduct disorder (CD) and major depressive disorder (MDD) are considered [29, 30].

Analysis of retrospective epidemiologic data has found the age of onset of DBD and anxiety disorders to precede the onset of SUD. The most common comorbid mental disorders seen in community studies of adolescent SUD are that of DBD, in particular CD, with these disorders showing a prevalence range of 25–50% and a median of four times greater likelihood of co-occurrence with SUD than without. The next most common comorbid disorder is that of depressive disorders with a prevalence range of 20–30% and a median of over twice the likelihood of co-occurrence [29]. These findings are relatively consistent with clinical studies, though there is a fair degree of variability in prevalence rates between studies of clinical population samples. On the other hand, SUD is a common comorbid disorder in clinical studies of youth that present with serious emotional problems or mental disorders. In this section of comorbidity, we will take a closer look at selected aspects of the relationship of the more prominent comorbid mental disorders and SUD.

105.2.3.1 Conduct Disorder

CD and SUD are strongly associated, with CD typically preceding the onset of SUD. CD imparts an increased risk for the initiation of substance use by age 15 and is a powerful prediction of SUD by age 18 [31]. As well, the severity of CD has been found to predict the severity of SUD. This relationship, however, appears to be reciprocal with each condition heightening the expression of the other. In such a manner, early-onset substance use has been associated with later criminality, and if substance use or drug dealing is reduced, there is a subsequent decrease in criminality [32].

Adolescents who present with CD may rapidly progress from substance use initiation through to substance use disorder, moving from one stage to the next in a matter of months, whereas early conduct problems have not been directly linked to the onset of SUD in adulthood [33]. Also, juvenile offenders with comorbid SUD have shown greater additional psychopathology than those without SUD [33].

105.2.3.2 Attention-Deficit/Hyperactivity Disorder (ADHD)

ADHD has been found to be a common comorbid disorder in clinical studies of adolescents with SUD, with large outpatient clinical studies reporting a prevalence range of 17–38%; however, similar findings have not been found in community samples [29, 30].

There has been considerable debate in the extant literature as to whether ADHD is an independent risk factor for the development of SUD in youth or whether the association is indirect and mediated by the presence of co-occurring CD or oppositional defiant disorder (ODD) [34]. What is now clearer on the balance of evidence is that childhood ADHD is a risk factor for the development of SUD in young adulthood, independent of co-occurring ODD/CD with the dimension of hyperactivity/impulsivity being of particular significance. However, the addition of ODD/CD and severity of ADHD further increases the risk for SUD in youth [31, 35]. Adolescents with ADHD have shown an earlier age of onset of SUD, a severalfold increase in the likelihood of SUD compared to matched controls, a more rapid progression of SUD, and a greater severity of SUD [36].

Considerable evidence exists as supported by a recent meta-analysis that treatment of childhood ADHD with stimulant medication does not increase the risk of SUD in adolescence or young adulthood [12, 21]. There has also been a certain

degree of evidence to suggest that stimulant treatment of ADHD may even reduce the risk of developing SUD in adolescence, though the effect appears to wane into young adulthood [16]. However, more recent research findings have not been supportive of a protective stimulant treatment effect for the risk of adolescent or later SUD [37, 38].

The relationship between ADHD and SUD remains complex in adolescence, and with the addition of CD, this grouping of disorders may represent a worse prognosis for the persistence of antisocial behaviors and substance use disorders. In spite of the consensus about the benefits of treating ADHD, clinicians need to be cognizant about the potential risk of misuse and diversion of treatment medications associated with these patients [35].

105.2.3.3 Depressive Disorders

Depressive disorders frequently co-occur with adolescent SUD and are the second most common comorbid disorder. The association of depressive and substance use disorder in adolescents is more frequent than one would expect and has been more widely studied than other comorbidities. It is also noteworthy that adolescents with a history of MDD show an elevated rate of SUD than those without a history of depression. Rao and Chen [39] in a comprehensive review of this topic proposed that common genetic, environmental, and neurobiological factors may possibly mediate the relationship between depressive and substance use disorder in adolescents, constituting a basis for their linkage. The authors recognized the limitations of the neurobiological findings and, by design, the selectivity of various risk mechanisms examined.

In clinical studies of adolescents with SUD, the onset of MDD most often follows the onset of SUD (secondary MDD). Secondary MDD is considerably more common than MDD preceding the onset of SUD (primary MDD) [39]. In the majority of cases, irrespective of whether it is primary or secondary, comorbid MDD in adolescents has not been found to spontaneously remit with abstinence and/or early treatment (excluding pharmacotherapy) by the third week. As would be expected, comorbid MDD has been found to be more prevalent in girls with adolescent SUD than in boys, with the girls showing an earlier age of onset of depression [40].

Adolescents with SUD and comorbid depressive symptoms on admission to residential treatment have shown poor substance use outcome [41]. Adolescents with depression are more likely to develop an SUD, showing an earlier onset and a greater severity of substance misuse. Comorbid SUD in adolescents with depression appears to have a negative impact on the phenomenology and course of illness with greater behavioral and CD problems, longer duration of depressive episodes, and increased psychosocial (school, family, and legal) impairment [39, 41]. A greater severity of substance use in adolescents with treatment-resistant MDD (without comorbid SUD) has been associated with increased severity of depression and comorbid ODD and CD. Adolescents with low substance-related impairment at the end of treatment for depression showed the best response [42]. Alternatively, achieving a positive response in the treatment of adolescents with MDD has been shown to reduce the risk of subsequent drug use disorders but not alcohol use disorders [43].

SUD in adolescents has been linked to an increase in suicidal behaviors including ideation, attempts (frequency, recurrence, and seriousness), and completed suicide. The prevalence rates of suicidal events or behaviors are clinically significant, and suicide is among the leading causes of deaths in youths-adolescents. Existing literature shows that as much as 50% of adolescents who died by suicide meet the criteria for a substance use disorder. However, the risk for suicide is most significant when comorbid with MDD [2, 44]. The comorbidity of substance use and depressive disorders appears to be interactive and has at least an additive if not a synergistic effect on the burden of illness of these disorders, with significant morbidity and mortality.

105.2.3.4 Psychotic/Bipolar and Related Disorders

Few studies report an incidence of comorbid psychotic and bipolar disorders in the adolescent

SUD population. This absence of reporting is quite likely a reflection of the severity of the illnesses, with those adolescents who experience the onset of these disorders being more likely to present to psychiatric services for assessment irrespective of whether they have an SUD or not. In that comorbid psychotic and bipolar disorders are not commonly or reliably reported in the adolescent SUD population, only a few selected comments will be made in this chapter. A strong association has been found for comorbid SUD with first-episode psychosis (FEP) and bipolar disorder (BD) in adolescents/young adults. The presence of comorbid SUD has been associated with exacerbation of psychotic or manic symptoms, a more debilitating course of illness, negative events including suicide, poorer clinical and treatment outcomes, as well as greater functional impairment in patients with FEP and BD (including evidence in first-episode mania and adolescents) than without comorbid SUD. SUD has been linked to an earlier age of onset of schizophrenia and BD with its significant negative clinical implication on prognosis. In the majority of cases, SUD typically precedes the onset of psychosis/schizophrenia, whereas the onset of BD may often precede that of SUD [42, 45]. The most common SUD is that of cannabis in FEP and first-episode/early-onset BD [46, 47]. Importantly, an effective evaluation of adolescents needs to recognize the bidirectional relationship of SUD with BD which can attribute as much as threefold risk increase in either direction and the likelihood of developing SUD in proximal to the onset or early phase of BD. Notably, history of recreational alcohol or marijuana use, immediate family history of SUD, poor treatment of BD, and the presence of oppositional defiant disorder tend to correlate with higher risk particularly.

Cannabis use has been found to be an independent risk factor for the development of psychosis/schizophrenia in young adulthood with a two- to threefold increase in risk. The risk for this outcome increases in a dose-dependent manner and is greater with the onset of use in adolescence and especially in vulnerable individuals. Cannabis-induced psychotic disorder has been found to be a cogent marker in the vulnerability for developing a primary psychotic disorder. In essence, adolescents and young adults should be counseled that cannabis use may increase their likelihood of developing a clinically relevant maniac symptoms or psychotic disorder or schizophrenia-related disorder [46, 47]. Box 105.3 summarizes some important points on comorbidity of SUB with BD/psychosis.

Box 105.3 Comorbidity of SUD in Adolescents

SUD is highly prevalent in comorbidity with BD
SUD share bidirectional relationship with BD with up to threefold increase in risk on either direction
Putative predictors of SUD include mood symptoms, inadequate treatment, recreational alcohol use, and familial factors
Comorbidity of SUD especially involving cannabis may act as a causal or exacerbating factor for BD and worsens overall prognosis
Clinical evaluation of adolescents with BD or psychosis should pay attention to SUD

105.2.3.5 Other Comorbid Disorders

There is considerably less extant literature on the relationship of other comorbid disorders in adolescents with SUD. Elevated rates of anxiety disorders, including social and generalized anxiety disorders and posttraumatic stress disorder (PTSD), have been noted in clinical studies [48]. From these studies, social anxiety disorders (SAD) and PTSD have been identified as the most clinically relevant of the anxiety disorders. SAD precede the onset of SUD and inherently may have an impact in SUD treatment that is oriented toward group therapy. Those with SAD may best be served initially through individual cognitive behavior-oriented SUD treatment. The relevance of PTSD in this population is significant, given the high rate of physical and sexual abuse (57% of girls and 31% of boys) identified in a clinical sample across treatment settings (residential, inpatient, and out-/day patient programs) [49]. In a cross-sectional community

sample of adolescents, a strong association was found for the comorbidity of SUD and PTSD with a significant impact on psychosocial impairment. The findings suggested multiple pathways leading to comorbid SUD and PTSD [50]. No consistent association has been found in adolescents for comorbid SUD and eating disorders (ED). There is some clinical evidence to suggest a possible relationship of SUD with bulimia.

105.2.3.6 Co-occurrence of Physical and Other Psychosocial Complications of SUD

Substance use and related disorders among adolescents are linked with a range of physical health morbidities and public safety, psycho-legal, and socioeconomic issues. In the setting of SUD, adolescents have perpetrated serious violence and criminal offences leading to significant public safety issues. Although not a major focus of this chapter, there is a body of literature evidence showing that SUD contribute or share important risk factors with violence-prone behaviors and chronic physical health morbidities (including chronic kidney diseases, hepatitis, human immunodeficiency syndrome, and cancer, among others) in adolescents contributing negatively to the psychosocial burden and prognosis of SUD [2, 5, 32]. The co-occurrence of physical health morbidities with SUD can impact clinical presentation including proneness to delirium and the choice and the outcome of treatment in this special "high-risk" population of adolescents.

105.3 Conclusion

In sum, substance misuse among adolescents has multiple implications on normal development, future SUD, and the society in general. Adolescence is a period of significant vulnerability and risk for the development of SUD; as such, substance misuse must be viewed from a developmental perspective. High rates of comorbid mental disorders, co-occurrence of physical health morbidities, public safety issues, and psychosocial problems among adolescents with SUD further emphasize the need for clinician to pay attention to substance use when dealing with youth and adolescent populations. The need for ongoing data collection to understand trends and shifts in initiation, pattern and course, and psychosocial sequelae of substance use cannot be overemphasized.

Adolescent Substance Misuse/Use Disorders: Management

106

Kevin M. Gray and Robert Milin

Contents

Abstract

While many aspects of strategies to address substance use in adolescents bear similarities to those employed with adult patients, developmental considerations merit modification to appropriately engage youth in effective care. This chapter seeks to provide an efficient summary of evidence-based approaches to screening, assessment, and treatment, with specific consideration of the heterogeneous nature of adolescent substance use. Suggestions are made for approaches to treatment matching based on clinical presentation and context of substance use. The chapter additionally indicates areas for further research and exploration as the field progresses to advancing clinical outcomes and life trajectories for this particularly vulnerable age group.

106.1 Introduction

Adolescent substance use is heterogeneous, spanning a variety of substances, constituencies, quantities, frequencies, contexts, and motives. General screening is necessary to identify poten-

N. el-Guebaly et al. (eds.), *Textbook of Addiction Treatment*, https://doi.org/10.1007/978-3-030-36391-8_106

tially high-risk cases, and after positive screening, careful assessment is necessary to match the adolescent with the appropriate clinical care modality and setting.

This chapter is structured to provide an efficient overview of strategies for screening, assessment, and treatment for adolescent substance use disorders. Priority is given to approaches with established evidence, though novel approaches are also highlighted.

It should be noted that adolescents are seen across a variety of settings (e.g., school, community, online/remote, general, and/or specialty clinics), and approaches discussed in the chapter can in many cases be delivered by an array of professionals. Most findings highlighted in the chapter are focused on clinic- and school-based strategies. Clinic-based strategies are the most common and therefore the default category. Other settings/contexts will be specifically mentioned if the evidence base includes them.

There is significant potential promise in incorporating mobile health technology to improve accessibility of assessment and treatment and to complement in-person services to improve outcomes [1]. This is a rapidly developing clinical research area worthy of ongoing attention by clinicians interested in adopting novel strategies.

106.2 Screening/Assessment

Substance use initiation typically occurs in adolescence. Effective tools may be used in primary care and other settings to screen for substance use-associated risks that would merit more thorough assessment and potential treatment matching.

Screening tools developed for adult substance use may not be developmentally matched for use with adolescents. For example, the CAGE (Cut down, Annoyed, Guilty, Eye-opener) screener has been shown to be ineffective in screening for problematic adolescent substance use [2]. The recommended approach is instead initiated with a general line of inquiry regarding frequency of use (e.g., never, once or twice, monthly, weekly, almost daily, daily) over the past year [3]. This process can be completed during a patient interview or submitted electronically for review by the clinician. For those adolescents indicating use in the past year, further inquiry can assess level of risk and impairment. The CRAFFT, also available as an online electronic tool, efficiently screens for problem use requiring more formal assessment and intervention [4]. Out of six items, a score of two or higher indicates the need for additional inquiry.

When the initial screening suggests problematic substance use and/or when a patient presents with substance use as the chief concern, careful assessment is necessary, given that substance use in adolescents is heterogeneous. A face-to-face discussion with the adolescent, without parent/guardian present, is critical in developing rapport and gathering details about use and associated behaviors. With agreed-upon terms of confidentiality, follow-up interview with the parent/guardian can yield necessary collateral information.

Based on information gained during patient and family interviews, an International Statistical Classification of Diseases and Related Health Problems tenth Revision second Edition (ICD-10) and/or Diagnostic and Statistical Manual of Mental Disorders fifth Edition (DSM 5) diagnosis (e.g., cannabis use disorder, mild) can be determined [5, 6]. The diagnosis reflects an array of symptoms indicating a pattern of use that persists despite associated impairments and consequences, and the severity is based on the symptom count.

The diagnostic assessment should be complemented by a functional behavior analysis, which frames substance use with associated antecedents and consequences, some of which can be modified to reduce the likelihood of continued substance use [7]. This is a critical component of assessment to identify the potentially highest-yield areas to target with psychosocial and behavioral treatments.

It is not generally recommended to serially conduct urine drug testing as a stand-alone screening approach – it should instead be strategically used as a complement to self-report [8]. Urine testing is imperfect, and in particular, in-office dipstick assays generally only provide a

qualitative (positive vs. negative) window into substance use with inconsistent ranges of detection, while self-report allows for more nuanced assessment of patterns and frequency of use. In addition, soliciting and clarifying self-report allow for rapport building and opportunities to understand patterns and aspects of use that can be approached in treatment. Regardless, urine drug testing does have a role in monitoring, particularly when trust has been eroded between patient and family and when negative results can be used as opportunities for contingent rewards during treatment.

106.3 Treatment

Considerable research efforts have been undertaken to yield efficacious interventions that are developmentally tailored for adolescents with substance use disorders. Across settings, the mainstay of care is psychosocial treatment, and a variety of modalities of both individual- and family-based interventions have been developed and tested. These vary from single-session brief feedback to intensive multimodal strategies; the treatment setting and modality/modalities are often chosen based on the clinical presentation (e.g., acuity, chronicity, risk).

Brief stand-alone treatments offer significant appeal, as they can be delivered in non-specialty medical settings as well as via mobile technology. These are generally employed in cases with relatively low clinical severity, as trials have indicated that when a substance use disorder is present, results are limited with Screening, Brief Intervention, and Referral to Treatment (SBIRT) [9], school-based [10], and motivational interviewing [11] brief treatment models. However, recent findings indicate that youth with *more* rather than *less* alcohol- or cannabis-related problems yielded benefit from a primary care brief motivational intervention [12], and in general, this approach yields reduced alcohol- and cannabis-related negative consequences 1 year later [13]. Delivery of brief interventions via mobile technology has yielded mixed findings; one meta-analysis indicated that text messaging interventions yielded a small positive effect size [14], while a recent feasibility study provided encouraging findings about computer-based delivery of SBIRT [15]. Recent research has demonstrated the feasibility of complementing school clinic-delivered SBIRT with a peer-delivered intervention [16].

Outpatient treatment for adolescent substance use has been the topic of a series of systematic reviews, most recently updated in 2018 [17]. In general, a number of interventions have evidence of efficacy at varying levels. The most established include ecological family-based treatment (including Multisystemic Therapy, Multidimensional Family Therapy, and Functional Family Therapy), individual cognitive-behavioral therapy (CBT), and group-based CBT. Motivational interviewing (MI) and behavioral family-based treatments are deemed probably efficacious. MI and CBT are commonly combined sequentially, both in five-session and twelve-session formats, to address adolescent substance use [18, 19]. The behavioral intervention contingency management (CM), in which desired behaviors are reinforced or rewarded (e.g., voucher for negative urine drug test), has been shown to enhance outcomes when added to psychosocial treatments [20, 21]. Positive findings for CM augmentation of MI have also been demonstrated in school-based treatment delivery [22]. In practice, elements of MI, CBT, family therapy, and CM are often incorporated into eclectic treatment, with variations based on adolescent and family clinical presentation, provider orientation and experience, and logistical considerations.

While Twelve-Step facilitation is commonly employed in adult substance use disorder treatment and relapse prevention, it has been less studied among adolescents. A recent trial tested an integrated Twelve-Step facilitation (iTSF) model, which includes both Twelve-Step facilitation and motivational and cognitive-behavioral strategies, versus established MET/CBT for adolescent substance use disorders [23]. While the treatment groups did not differ in rates of substance abstinence, the iTSF group had better

attendance and reported fewer substance-related consequences.

Medications are often used as adjuncts to psychosocial treatment for substance use disorders in adults, but this area has been less studied among adolescents [24]. The most established medication to date in adolescents is buprenorphine-naloxone for opioid use disorder [25]. Amid mixed findings overall, some positive trials have been conducted with sustained-release bupropion or nicotine patch for tobacco use disorder, *N*-acetylcysteine for cannabis use disorder, and naltrexone for alcohol use disorder (for review, [24]). Given the limited literature overall to date on pharmacotherapies, it is generally suggested that they be reserved for treatment-refractory or high-severity cases and always as an adjunct to evidence-based psychosocial treatment.

Recent clinical research efforts have focused on devising strategies to more precisely match patients to treatment approaches that are most likely to be successful based on their presentation and characteristics [26]. To date, treatment matching has generally been managed clinically based on patient/family preference, clinician availability, and determination of risk/severity. However, it would be reasonable to suggest that additional characteristics may potentially predict the most well-suited treatment case-by-case. Another avenue of investigation is the development and testing of approach avoidance training (AAT), a computerized cognitive bias modification paradigm designed to train adolescents to implicitly override their habitual bias toward substance-related cues [27]. AAT, which targets neural pathways distinct from those affected by established interventions, has demonstrated long-term relapse prevention effects in adults with alcohol use disorder [28, 29]. It may be particularly well suited to adolescents, for whom substance-approach tendencies are strongly relevant to substance use [30]. If successfully translated to adolescent substance users, AAT could be incorporated as a complement to established treatments to enhance outcomes.

106.4 Addressing Comorbidities

A recent study indicated that 64% of adolescents ages 13–17 with a substance use disorder also meet criteria for a co-occurring psychiatric disorder, demonstrating that comorbidity may be the rule rather than the exception [31]. Among the most common comorbidities are mood disorder, conduct disorder, and attention-deficit/hyperactivity disorder (ADHD). With substance use and psychiatric services often delivered by separate providers and/or in separate facilities, systems have frequently attempted to address comorbidities in series rather than in parallel. However, given increased understanding of the complex interplay between psychiatric and substance use difficulties, as well as the overlap in psychotherapeutic approaches relevant to these conditions (e.g., cognitive-behavioral therapy across mood, anxiety, and substance use disorders), recent efforts have focused on developing and implementing integrated treatments [32, 33].

Clinical trials of pharmacotherapies for psychiatric conditions traditionally exclude individuals with co-occurring substance use disorders, limiting interpretability of findings for youth with comorbidities. Recent work has advanced the field, indicating that pharmacotherapies for ADHD [34–37] and major depressive disorder [38–41] may be safely administered to adolescents with co-occurring substance use disorders. While efficacy findings are mixed across these trials, there are positive findings for extended-release methylphenidate formulations for ADHD [35, 37] and for fluoxetine for MDD [38] in adolescents with co-occurring substance use disorders.

106.5 Conclusions

Given the high prevalence and known associated adverse consequences of adolescent substance use, clinicians are encouraged to embed routine screening into longitudinal and acute care while being equipped to provide detailed assessment and treatment (and/or treatment referral) in cases deemed to be high risk. A

number of psychosocial treatments, with individual and family components, have demonstrated efficacy in addressing substance use disorders in adolescents, and contingency management can be used as a treatment complement to enhance abstinence outcomes. Pharmacotherapy may play a role as an additional treatment complement, though beyond a handful of medications with positive trials, the evidence base is limited to date. Ongoing work is aimed at broadening the content, scope, and reach of assessment and treatment services for adolescents with substance use disorders, and delivery of services via electronic interfaces and mobile technology is among the most promising avenues of this research.

lescents and pose substance use disorders as a major risk factor for emergent suicidal behaviors. This chapter reviews recent patterns and trends of substance abuse, focusing mainly on alcohol and cannabis, which are most prevalent among adolescents, and presents the existing evidence linking adolescent suicidal behavior and substance abuse. We address the role of salient moderating factors such as comorbid psychiatric pathologies, age, and gender differences on this relationship and highlight vulnerable subpopulations such as sexual minorities that are predisposed to be affected by this connection. Perspectives on recent as well as future basic science research studying the connection between adolescent suicide and substance use as well as substance use trends are discussed. Treatment strategies for substance use disorders as well as for suicidal behaviors are presented, arguing in favor of an integrated approach.

107.1 Introduction

Suicidality is a broad term encompassing a wide range of self-injurious ideation or self-inflicted harmful behaviors executed with at least partial intent to die. These behaviors are a major global public health concern since they are highly prevalent and associated with heavy mortality and morbidity in the immediate as well as in long term. This issue is intensified when child and adolescent suicidality is concerned, and therefore, a pressing demand for efficient prevention plans and novel treatment strategies yet remains.

Suicide is a complex behavior and various pathways lead to suicidality. Numerous risk factors associated with suicidality have been described [12] and are frequently divided into several categorical groups. This reductionism in classification of suicidality risk factors can be misleading and, in many cases, not clinically pragmatic. In real-life situations, these risk factors are much too often interwoven, are mutually effective in a nonadditive and unpredictable manner, and ultimately pose a methodological conundrum in the clinical assessment of adolescent suicidality. Nevertheless, in epidemiological studies concerning suicidality, several risk factors including substance use disorders (SUD) stand out more prominently than others.

Much epidemiological data has been gathered in the past decades elucidating the diversity and extent of adolescent substance use. The information accumulated has been extensively used recently by various health services as well as clinicians to yield a plethora of studies substantiating the impact of SUD on adolescent suicidality. In recent years, one can witness a gradual transformation of the harnessed data from the descriptive to the operative form; suicide risk assessments and odds ratios are being translated into operational plans and large-scale screening and intervention efforts in schools and health facilities. The applicability and efficacy of some of these measures are yet to be ascertained and validated by evidence-based studies.

Since the scope of this chapter cannot encompass the specific effect of all illicit as well as legal substances on suicidality, we will focus mainly on alcohol and cannabis as these are the substances which are most widely used and studied worldwide [60, 89].

107.2 Adolescent Suicidality

There are multiple levels of severity and injury burden within the construct of "suicidality." The scope of suicidal behavior constrained in this term ranges from *suicidal ideation* with or without a specific plan through *suicide attempt* which is a nonfatal, self-inflicted destructive act with explicit or inferred intent to die and finally the fatal act of a completed suicide.

Suicide is the second or third leading cause of death among adolescents in the United States and Europe [22, 62], and suicidal behavior represents one of the greatest public health issues for this population**.** Lifetime estimates of suicide attempts among adolescents range from 1.3 to 3.8% in males and 1.5 to 10.1% in females [10]. These numbers should most probably be considered to underestimate the true extent of this mal-

ady; a large portion of suicidal attempts remains unnoticed and unreported since most data rely on self-report or emergency department (ED) admissions. Indeed, ED visits in the United States due to self-inflicted injury are highest among the 15- to 19-year-old age group. In the United States, youth risk behavior surveys (YRBS) assessing health risk behaviors among youth and young adults have been conducted among representative samples of high school students biennially since 1991. The latest survey reports disconcerting data describing teenage suicidal behavior. During the 12 months prior to the last survey, 17.2% of students had seriously considered attempting suicide, 13.6% had formulated a suicide attempt plan, and 7.4% had reportedly attempted suicide one or more times [41]. Adolescent suicidality has been identified as a nationwide health improvement priority in the United States, and consequently, the "healthy people 2020 (HP2020)" initiative has proposed the objective of reducing adolescent suicide attempt rate by 10% (http://www.healthypeople.gov) by the end of this decade. Given a 27% decrease in adolescent suicide rate in the previous decade, this goal seems far from unattainable.

In light of the above figures and those of previous years, numerous suicidality detection and prevention strategies have been proposed and implemented to various degrees of success worldwide. Most adolescents presenting with suicidal behavior do not end up committing suicide; nevertheless, suicidal ideation in adolescence has been shown to be a harbinger of compromised adult functioning and future Axis I diagnoses [69], stressing the need for early suicidality identification regardless the obvious dire consequences of suicide itself. In their review of the available suicidality screening tools applied in educational and health-related community facilities, Horowitz et al. [36] suggest that the implementation of targeted suicide screening in schools and universal suicide screening in primary care clinics and ED may be the most effective way to recognize and prevent suicidal behavior [36]. The leading screening tool used today in school settings is the Columbia-Suicide Severity Rating Scales (C-SSRS). This free, simple, and brief questionnaire addresses acute suicidal risks across the full range of suicidal behaviors, is readily available in more than 100 different languages, and can be tailored to specific populations and settings. Those who screen positive in the initial screen are referred for further clinical evaluation of suicidality. Another screening tool that is not specific to suicide or substance abuse is the Strengths and Difficulties Questionnaire (SDQ) which has the advantage that it can detect adolescent emotional and behavioral difficulties that are not necessarily strictly DSM-based and therefore may be more sensitive to detect distress and psychopathology [78].

Recent encouraging data suggest a decrease in global adolescent suicide rate. A significant linear decrease in the prevalence of US adolescents having made a suicide plan has been noted in the past 20 years (18.6% to 13.6%), although no significant change occurred in the prevalence of actual attempts [41]. During the past two decades, the crude death rate from suicide and intentional self-harm among adolescents aged 15–19 residing in the OECD countries has also steadily declined by more than 10% [62].

107.3 Adolescent Substance Use

107.3.1 Alcohol Use

Adolescent alcohol use is related to the three leading death causes in the young [58], namely, accidents, suicide, and homicide, and is therefore related to most premature death cases in the young. The use of alcohol increases the likelihood of suicide death in both direct (acute intoxication) as well as indirect (loss of inhibition, increased impulsivity) means although most of the cases are usually related to the latter causes.

Alcohol has been shown to be associated with elevated rates and increased risk for suicidal behavior [17] even after the effects of depression, impulsivity, peer delinquency, and parental monitoring are controlled for [82].

Patterns of alcohol use can vary widely in terms of time (e.g., how many days in a month) and volume (e.g., how many drinks each time), and so it may be more appropriate to examine the association with suicidality in instances in which alcohol is consumed in excess. Consuming five standard alcoholic drinks or more in the same drinking session ("binge drinking" or "heavy episodic drinking") would cause most adolescents to reach at least some degree of intoxication. Although no global or cultural consensus exists to define an alcohol volume of a standard drink or how many drinks constitute a "binge," binge drinking can generally be viewed as a rapid consumption of alcoholic beverages with the intention of becoming intoxicated. On average, nearly half of the students in the United States (45%) and a third in Europe (35%) reported that they had been intoxicated in this sense at least once during their lifetime [21].

Binge drinking is most prevalent among teenage alcohol consumers and is associated with many poor health outcomes [80] and increased risk for suicidal thoughts and attempts, even when compared to current alcohol drinkers who do not binge [55]. This connection is strongly correlated to frequency of binging; those who binge on more than ten monthly occasions attempt suicide more than those who binge six to nine times (30% vs. 16%) and almost three times as much as those who binge once a month (11.9%) [55].

Binge drinkers also tend to explore the use of other psychoactive substances. Not only does heavy episodic drinking show a significant correlation to lifetime use of cannabis, it also carries an odds ratio (OR) of 5 for concurrent marijuana use as compared to alcohol drinkers who do not binge and much more than when compared to nondrinkers (OR = 60) [55]. Adolescents reporting concurrent alcohol and marijuana use presenting to the ED following alcohol intoxication display heavier drinking patterns as compared to those who report alcohol use alone, including increased binge drinking instances as well as elevated alcohol consumption on each drinking occasion [14].

Archie et al. [1] suggested that binge drinking raises the risk for suicidality in youngsters only when depression is present [1]. Using a survey delivered to over 17,000 adolescents aged 15–24 years, they show that binge drinkers and non-binge drinkers shared the same risk for suicidality when no depression was present even when using more stringent definitions of binge drinking (at least once weekly). When the effect of depression was tested, they found that depressed binge drinkers had an increased risk for suicidality as compared to non-binge drinkers who were not depressed (OR = 6.3) [1].

107.3.2 Trends in Alcohol Use

Adolescent alcohol use in the United States is steadily declining. In 2017, 60.4% of high school students reported they had ever drunk alcohol, a substantial decrease from 81.6% in 1991. A drop of almost 40% in the corresponding years has been demonstrated in youth reporting current alcohol use, from 50.8% to 29.8%. Data from the large-scale Monitoring the Future (MTF) study corroborate these findings. The latest report presents adolescent alcohol use has reached an historic low, from 93% lifetime prevalence of use in senior year high school students 30 years ago down to 58.5% today. The situation in European countries is quite different, though, as adolescent alcohol use has remained relatively unchanged in the past 15 years. The European School Survey Project on Alcohol and Other Drugs (ESPAD), which is based on data gathered from 100,000 European students from 35 countries, reports that for youth between the ages of 15–16 years, lifetime use of alcoholic beverages has dropped only slightly from 89% in 1995 to 80% 20 years later [21]. As can be expected, substantial prevalence differences were found between countries in this study. Although these figures probably reflect different social and cultural norms in drinking patterns, the different rates of decline in adolescent alcohol consumption might also reflect the utility of various alcohol

use prevention plans locally employed. Many educational and preventive policies aimed to reduce the harmful use of alcohol have been formulated and utilized worldwide in the past three decades [90], and the use of alcohol in adolescents as aforementioned is since on the decline. Furthermore, temporal trend reports of American senior binge drinking prevalence present a substantial decrease of more than 50% between 1998 and 2018 (31.5%–13.8%), perhaps reflecting the success of educational preventive strategies focusing on the behavioral aspect of alcohol use (highlighting negative aspects of "drunkenness" instead of "drinking") and not of restrictive strategies (e.g., increased legal drinking age). It is also debatable whether restrictive measures for alcohol use are applicable, alcohol is perceived by youth to be easily available, and 87% of senior year adolescents find it fairly or very easy to get hold of an alcoholic beverage. Strict policies may also lead to rebellious behavior and an increased prevalence of binge drinking. A study exploring the drinking pattern and drunkenness among mid-adolescents in 40 European and North American countries found a trend whereby higher prices and stronger alcohol controls were associated with a lower proportion of weekly drinking but a higher proportion of drunkenness [26].

Despite the abovementioned positive trends, alcohol remains the substance most widely used today by teenagers. Given the close association to suicidality, this should warrant continuing efforts to decrease adolescent alcohol use and not to rejoice over the positive statistical data reporting its decrease.

107.3.3 Cannabis Use

Cannabis by far represents the most prevalent illicit substance used by adolescents use today. Data regarding the prevalence of other illicit drugs can be found elsewhere [21, 41, 60] and will not be elaborated here in detail. Briefly, about 4% of adolescents aged 12–17 years in the United States report last year use of illicit drugs excluding marijuana. Of the several illicit substance groups whose prevalence has been annually monitored, the misuse of psychotherapeutics (including amphetamines, sedatives, tranquilizers, and pain relievers) remains second to marijuana, whereas hallucinogens, inhalants, and other drugs are far less prevalent [60].

The US nationwide MTF study utilizes national annual surveyed samples of more than 40,000 students gathered since 1975. In 2017, the percentages of students indicating use of cannabis in the prior 12 months (representing current users) were 10.1%, 25.5%, and 37.1% in grades 8, 10, and 12, respectively. Data concerning drug use in European countries has also been gathered in the past two decades and summarized in the ESPAD report which reveals a 7% prevalence of use in the past month for the corresponding tenth grade age group [21]. The National Survey on Drug Use and Health (NSDUH) obtains information from approximately 70,000 US residents aged 12 years and older regarding several categories of illicit drug use. In the latest report relating to 2017, about half (46%) of youths aged 12 to 17 reported that it would be "fairly easy" or "very easy" for them to obtain marijuana if they wanted to [60].

It is worth mentioning that temporal changes in patterns of adolescent substance abuse clearly exist, stressing the importance of ongoing efforts to monitor drug use trends. For instance, the use of nonmedical analgesic opioids has become second in prevalence to marijuana, surpassing the use of inhalants and hallucinogens [94]. This trend appears to have changed in recent years, and a steady decrease has been observable since 2013 [54], which was recently corroborated by prescription data as well [24]. Another example can be found in the prevalence of synthetic cannabinoids use which has become a source of major concern at the beginning of this decade and was first monitored in the United States in the 2011 MTF survey. A comprehensive national US ban enacted in July 2012 and other enforcement efforts that were initiated might have contributed to the dramatic decrease evident in the use of this substance class from 11.4% in 2011 to just 3.7% in 2017 among 12th graders. Recent years have

witnessed a global trend of cannabis decriminalization and legalization to various extents, and this has led to initial concerns and speculations that a resultant increase in prevalence of adolescent cannabis use will follow [13, 96]. This is yet to be confirmed by ongoing monitoring and evaluation schemes [74] in light of the fact that trends of adolescent rates of cannabis use disapproval have recently reached the lowest levels in the past three decades.

107.4 Substance-Related Disorders as a Risk Factor for Suicidality

The link between substance use and suicide among adolescents is well established by evidence from clinical and epidemiological studies [93]. Postmortem examination studies lend further proof to this relationship; one of these studies reported that in pediatric decedents tested positive for illicit drugs, 93% died from violent causes, and of these 15% died by suicide [58]. Most recently, Gobbi et al. [27] presented an exhaustive meta-analysis of data pertaining to the association of adolescent cannabis use and subsequent adult emergent suicidality and psychiatric disorders. They report an OR of 1.5 to develop suicidal ideation and OR of 3.5 to attempt suicide among cannabis users as compared to nonusers [27]. Importantly, the strength of this association appears correlated to the severity level of suicidal behavior. Adolescent suicide attempters, for instance, are more likely to be substance dependent than suicidal ideators, suggesting that substance use may in fact facilitate the escalation from ideation to behavior. In a large study among 15,885 French adolescents [37], the risk for suicide attempt among cannabis users as compared to nonusers was reported to be 30% higher for "heavy users" than "occasional users" and almost 50% higher for "occasional users" as compared to "former users," clearly strengthening the notion of a positive correlation between cannabis use patterns and suicide attempts. In light of the general opinion that the adverse psychosocial effects of cannabis stem from frequent use alone, the finding that the risk for suicidality is also related to occasional and even sporadic use is noteworthy.

Regarding drug use habits associated with "more of others" as contrary to "more of the same" pattern, polydrug consumption is highly correlated to increased suicide risk. In a large European sample of over 45,000 adolescents from 16 countries, the percentage of respondents who reported at least one suicide attempt increased sharply with the number of substances used. Logistic regression analysis revealed that the risk for suicide attempt was OR = 4.5 for users of two substances and continued to increase thereafter with the use of additional substances as compared to nonusers [45]. Quite contrarily to popular belief, regular cannabis use does not substitute or protect from the use of other illicit drugs or alcohol; rather, it is strongly associated with their later use ("gateway drug") in an age- and frequency-of-use-dependent manners [84].

107.5 The Moderating Role of Psychiatric Morbidity

SUD and suicidality are both highly associated with psychiatric comorbidity [27]. Unfortunately, the moderating effect of psychiatric comorbidity on the relationship between them is highly complex and difficult to clarify. For instance, adolescent SUD patients display high psychiatric comorbidity most commonly associated with externalizing disorders [2], whereas suicidal adolescents also tend to display psychiatric comorbidity though mainly with internalizing disorders [43]. The presence of a psychotic disorder also displays a moderating effect on this relationship; Shoval et al. [76] presented a significant and strong association between suicide attempts and the use of illicit substances among adolescent suicidal inpatients diagnosed with schizophrenia or schizoaffective disorder as compared to nonsuicidal patients [76]. The existence of personality disorders or traits may further intricate the assessment of this connection.

Not only the nature of the psychiatric disorder present but also the number of concurrent psychi-

atric disorders may increase the risk for suicidality. In a prospective study investigating suicidal behavior among 180 discharged adolescent psychiatric inpatients followed for up to 13 years, most of those who were suicidal during the follow-up period had concurrent depressive disorders, and many had also displayed disruptive behavioral disorders either alone or concurrently [31]. In the same line of evidence, Vander Stoep et al. [87] have shown that co-occurring depression and conduct disorder symptoms increase the risk for subsequent suicidality as compared to a single diagnosis of either of these [87].

107.5.1 Mood Disorders as a Model

An estimated 3.2 million American youths suffered from a major depressive episode during 2017 [60], and depression is the strongest known risk factor for adolescent suicide [9, 93]. Some data suggest that even subthreshold depression, which is highly prevalent and can be found in up to 30% of adolescents, is associated with increased suicidality risk [4].

Adolescent depression displays high comorbidity with alcohol and substance abuse [2]. Adolescents suffering from major depressive episodes (MDE) were found to be more than twice as likely than those without past year MDE to have used illicit drugs in the past year (29% vs. 14.3%) or to be heavy alcohol users in the past month (1.2% vs. 0.6%). This disparity increases when comparing rates of substance dependence or abuse [60].

The combination of adolescent depression and substance abuse elevates the risk for suicidality. This may be true even for mild to moderate substance abuse, subthreshold to diagnostic criteria of SUD [37].

The causative relationship between substance abuse, depression, and suicidality remains unknown. Studies that address this relationship face many methodological challenges. A fundamental impediment is that both depression and substance abuse are independently highly associated with adolescent suicidality, and their co-occurrence is the rule rather than the exception in adolescents. Large-scale prospective studies addressing this causative connection may aid the construction of suicide screening and prevention strategies. For example, Goldstein et al. [28] used post hoc analyses on data from the Treatment of SSRI-Resistant Depression in Adolescents (TORDIA) study to demonstrate that the level of substance-related impairments is reversely correlated to the response to antidepressive treatment [28], suggesting that treating substance abuse may by itself decrease depression and suicidality.

Data concerning suicidality in other mood disorders associated with substance use comorbidity are scarce in the adolescent population and usually hampered by a retrospective design. Most clinicians thus rely on adult studies and execute data extrapolation when considering risks and prevention plans. Nevertheless, the link between bipolar disorder (BD) and suicidality has been demonstrated in many retrospective studies [16, 18]. A study designed to assess predictors of prospectively observed suicide attempts among youth with bipolar disorder revealed a strong association of this disorder with high rates of suicide attempts [30]. This study utilized subjects enrolled in the Course and Outcome of Bipolar Youth (COBY) study and is the first prospective-designed study to test the BD-suicidality connection in adolescents. During the five-year follow-up period of 413 adolescents diagnosed with BD, 76 (18%) attempted suicide once or more. Of these, 31 attempted suicide more than once for a total of 163 suicide attempts during the follow-up period. Considering the early mean age of the study recruits (12.6 years), these figures may underscore the actual suicide attempt rate since most of these adolescents had yet to pass through the highest risk period for new onset of suicidal behavior which is in later adolescent years (see below).

The strength of the BD-suicidality connection may be correlated to the severity of suicidal behaviors. Brent et al. [8] described an extremely high prevalence of BD in adolescent suicide completers. The diagnosis of BD (either type I or II) in suicide completers (22%) was

found to be at least four times more prevalent than in suicidal inpatients admitted for attempted suicide or for having a suicidal ideation [8]. Surprisingly, suicide completers in this study did not display a higher frequency of the co-occurrence of mood disorder and substance abuse than non-completers. Though in a consequent larger sample study [9], they show that substance abuse is a more significant risk factor for suicide completion when comorbid with a mood disorder than when alone (OR = 17.0 vs. 3.3). Other studies describe the negative effect of substance use on suicidality in BD; Goldstein et al. [30] reveal a double risk for SUD and lifetime excessive drinking in BD-diagnosed adolescents who concomitantly performed a suicidal attempt as compared to those who did not. During the 8 weeks prior to the attempt, the risk for SUD was tripled [30]. The same group reported that in a large sample of bipolar adolescents in which lifetime prevalence of SUD was 16%, subjects with SUD demonstrated a significantly greater lifetime prevalence of suicide attempts as compared to those without SUD [29]. Interestingly, the effect of substance use and in particularly that of cannabinoids on suicidality in BD patients may be exacerbated by the emergence of increased psychotic features [93].

The psychological constructs underlying the relationship between substance use suicidality and mood disorders in adolescents are understudied when compared to the adult population and therefore less utilized in clinical practice. One model, for example, describes the constructs of adolescent behavioral disinhibition, which is frequently associated with self-injurious behavior, and ascribes personality traits such as impulsivity and sensation seeking as key structural elements [6]. In that line, a study utilizing a sample of adolescent self-reported questionnaires found significant associations between sensation-seeking behavior and depressive symptoms or the occurrence of substance use problems. Students with high sensation-seeking behaviors were three times more likely to have symptoms of depression or substance abuse than students with low sensation-seeking behavior [61]. Sensation seeking has also been shown to significantly increase risk for suicidality even when depression or substance abuse was controlled for [47, 61].

107.6 Gender Differences in Suicidality

The risk for suicidal behavior does not exhibit gender equality. This likely stems from multiple psychological, biological, and social between-gender distinctions that bear a dissimilar effect on mental states and behaviors associated with suicidal behavior. Trying to evaluate the moderating effect of gender on the SUD-suicidality connection is fraught with methodological challenges since gender is differentially associated with suicidality, depression, and substance use. For instance, female adolescents are more likely to be depressed; among American youth aged 12–17, females were more likely than males to have past year MDE (20% vs. 6.8%) or MDE with severe impairment (14.2% vs. 4.7%) [60]. Males, on the other hand, are more likely to use drugs and alcohol. On average, boys report illicit substance use to a larger extent than girls do (21% vs. 15% in Europe and 14.5% vs. 13.3% in the United States) [21, 41]. Adolescent males initiate alcohol consumption earlier in life, drink more alcohol, and report more frequent heavy episodic drinking [21, 41, 88]; additionally, females are more sensitive to alcohol-induced effects due to biological factors.

Regarding suicidality, adolescent females are more likely to have suicidal ideation, to make suicidal plans, and to attempt suicide [41, 49, 88], whereas males are more likely to complete suicide [73].

107.6.1 Sexual Minority Youth (SMY)

Adolescents belonging to sexual minority groups include mainly, but not exclusively, youths who identify themselves as lesbian, gay, bisexual, or transgender (LGBT). Among high school youth in the United States, more than 10% identify

themselves as nonheterosexual [42]. This population is gradually and increasingly being exposed to the public eye and to scientific studies that suggest that they suffer from increased rates of environmental stress which may lead to social isolation and interfere with normal adolescent development.

Assessing data regarding this subpopulation in the adolescent age group is not a simple task. Most SMY do not openly present themselves as such and many are not without doubt regarding their sexual preferences, and a substantial part of them go on to change their sexual orientation throughout this transitional period [59]. This task is made even harder when trying to retrospectively assess whether same-gender sexual affiliation was present, requiring the differentiation of self-defined sexual orientation from practiced sexual relationships which may or may not be in accordance to the sexual affiliation.

SMY display higher prevalence of binge drinking and report a higher rate of current marijuana use [41]. A meta-analysis exploring the connection between nonheterosexual sex orientation and substance abuse found an increased risk for SUD among SMY, including lifetime use of alcohol (OR = 2.23) and marijuana (OR = 2.58) [53]. Data gathered from a national longitudinal study of adolescent health in the United States revealed that SMY reported higher rates of suicidal ideation and suicide attempts than did non-SMY, even after controlling for race, gender, and age [79]. Risk factors analyses exposed different patterns of suicide-related risk factors for SMY. Problem drug use was more strongly associated with suicidal ideation among non-SMY, as was the association between depression and suicide attempts. The authors suggest that different treatment targets should be sought for this population following the elucidation of specific suicidal risk factors relevant to SMY.

A meta-analytic review comparing suicidality and depressive symptoms in sexual minority and heterosexual youth has also found increased suicidal behavior (OR = 2.9) and depressive symptoms in this population [52]. Of note in this analysis was the description of an increase in the level of disparity between both populations as the severity of suicidal behavior increased (OR = 1.96, 2.2, 3.18, 4.17 for suicidal ideation, intent, attempt, serious attempt requiring medical attention accordingly) stressing the need for health-care personnel to pay heightened attention to suicidal behavior when encountered in SMY and when performing a suicide risk assessment. In the United States, the most current surveys show that SMY have an almost fourfold risk for formulating a suicide plan and almost a fivefold risk for attempting suicide as compared to heterosexual peers [41]. Furthermore, SMY are more likely than their peers to have been victimized and threatened and to have been engaged in a variety of risky behaviors [41].

Prospective studies are in demand to promote the identification of distinct attributes concerned with suicidality in this population through their transition into adulthood and maturation of sexual preference as major risk factors such as depression remain elevated even in young adulthood [50]. In a large longitudinal study following a cohort of over 1000 children from birth to age 21, the sexual orientation was studied at age 21 retrospectively from the age of 16. The correlation analyses between sexual orientation and suicidality revealed a fivefold risk for such behavior in SMY through the cohort period. The risk for SMY substance dependence was almost double, although not statistically significant ($p = 0.086$) [23]. The prospective nature of this study allowed for the evaluation of social and familial backgrounds of the subjects, and indeed, some differences were found between SMY and other cohort members in their familial background, suggesting a more troubled childhood for SMY. Interestingly, controlling for these differences in the statistical analyses had a negligible effect on the unadjusted results and thus might reflect a need to focus on developmental and behavioral factors instead.

107.7 Age Differences in Suicidality

Zalsman [95] has speculated that the timing of onset of gene-environment interactions leading to adolescent suicidality is crucial. He postu-

lates that specific brain development time windows may be critical for this interplay to emerge as behavioral phenotypes [95]. Clinical observations of age influences on suicidal behavior are evident, and the risk for suicidal behavior has been shown to increase through the transition from childhood to adolescence in such a way that late adolescents (generally defined as over 15 years old) exhibit increased risks for suicidal attempts and completion as compared to early adolescents [92]. Indeed, in early adolescence, suicide is the tenth cause of mortality worldwide, and at age 15–19 years, there is a dramatic leap to second place [64]. In older adolescents, the perception of risk from using alcohol and marijuana is lower and the use of drugs and alcohol as well as practicing binge drinking is increased. For instance, in a study by Rey et al. [71], the lifetime use of cannabis tripled between ages 13–15 years and a further increase of about 60% occurred between 15 and 17 years [71]. Furthermore, late adolescents' suicidal behavior is more associated with increased alcohol and drug use [38] even though cannabis use [7] or heavy episodic drinking [3] may have a more prominent effect on suicidal behavior in school-aged children as compared to older adolescent users. These data clearly strengthen the notion that public health leaders should prioritize suicide and substance use prevention schemes directed at younger school-aged adolescents.

107.8 Future Studies

Whereas the epidemiological and clinical data linking substance abuse to suicidality are compelling, basic science research encounters many difficulties in establishing this connection. Several problems arise to hamper the fundamental demand to minimize heterogeneity in the studied variables. First, there is no consensus as to the exact age span of adolescence and to the transitional phases of childhood and young adulthood. Furthermore, adolescence encompasses developmental stages such as puberty and post-puberty, associated with dramatic hormonal and physiological changes (e.g., the menarche) which cannot be constrained by strict temporal limits. Second, adolescence is a period of a dramatic psychosocial transition from childhood to adulthood, and this change is anatomically supported by a profound increase in brain plasticity including rostro-caudal white matter increase (myelinization) and accelerated dendritic pruning [25] leaving few brain regions and neurochemical pathways unchanged. Suicidal behavior or even thoughts might turn out to variably modify brain activity and plasticity in a similar way as does substance abuse [15] or depression [83]. Trying to account for this variability in brain connectivity in time and space over the full adolescent period seems presently impractical. Third, for obvious reasons, studying human brain morphology and activity, particularly those of children and adolescents, should be undertaken by employing noninvasive means. These means are presently scarce, and thus, most studies rely on comparative neuroimaging techniques alone.

These methodological challenges are demonstrated in a comprehensive overview of the relationship between alcohol and suicide by Pompili et al. [67]. They describe this causal relationship as being inconclusive and highly suggestible at best in light of the many neurotransmitter systems which are affected by ethanol, with varying spatial and temporal modifications regarding target brain regions [67].

Nevertheless, in the molecular level, a substantial volume of research has been accumulated relating to neurobiological changes associated with suicidality in adolescents. While these studies present convincing data regarding a genetic predisposition to suicidality [95] as well as altered receptor and signal transduction pathways associated with suicidality [63], they seldom address the role of substance abuse as a modifier to these neurobiological changes.

Suicidality is undoubtedly a complex behavioral phenotype. Currently, researchers studying the heritability of suicidal behavior are increasingly concerned with endophenotypes or biomarkers [81] of suicidal behavior and less so with single genes, although in distinct cases, a direct

connection can be drawn between single genes and suicide-related features such as impulsivity [5]. A seminal workshop convened for the purpose of the identification of candidate biological and clinical endophenotypes associated with suicidality found the most promising endophenotypes to be aggression/impulsivity trait, early onset major depression, neurocognitive function, and cortisol social stress response [51]. Specific endophenotypes for drug dependence have also been described [20] as well as inherited alterations in regulatory mechanisms of the hypothalamic-pituitary-adrenal (HPA) axis in the development of alcoholism [75]. It has been recently suggested that these endophenotypes as well as others can and should be translated into animal models that will help elucidate how genetic and epigenetic factors contribute to emerging suicidality [32].

It will be interesting to explore how relevant are these newly defined endophenotypes and biomarkers to the adolescent age group and to what extent do they overlap in specific individuals. This might pave the path for early targeted detection of high-risk suicidal patients and enable the utilization of individualized biological-based suicide prevention schemes.

107.9 Treatment and Prevention

How effective are drug prevention programs? Recent surveys portray an optimistic dramatic decrease in the past decade in adolescent alcohol as well as illicit substance use for all substances tested excluding cannabis and including ecstasy, methamphetamine, heroin, inhalants, cocaine, and synthetic cannabis [34, 41, 46].

The increasing global trend to legalize or decriminalize cannabis-related products has also been raised as an issue of concern when considering the effect this might have on adolescent exposure and availability to cannabis products. Although studies addressing correlation trends to study the effect of cannabis decriminalization are scarce, a recent meta-analysis suggested that permissive medical marijuana laws do not lead to increased prevalence of cannabis use among adolescents [74]. Indeed, although adolescent perception of harmful effects of regular cannabis smoking has significantly decreased in past decade, the percentage of regular adolescent users remains the same [60]. The explanation for this positive trend despite growing public approval of cannabis is most probably multifactorial and can not only be the result of timely use of campaigns and programs addressing the negative effects of cannabis.

A straightforward example of a successful nationwide campaign to decrease the use and subsequent harm of substances can be seen in the effort of the US government to curb the opioid use epidemic in the recent years [40]. It is evident that widespread state- and federal-level legislations and interventions schemes have already resulted in favorable outcomes. In 2017, a 10% decrease in pain relief medication misuse was noted as compared to 2016 in adolescents aged 12–17 [60]. The percentage of senior year adolescents using narcotics has decreased from 13.2% a decade ago to an all-time low of 6% in 2018 as monitored since 1991. The ongoing funding and maintaining of large-scale surveillance programs to monitor and decrease prescription drug misuse are imperative as this recently highlighted that mode of substance use is also strongly associated with adolescent suicidality [33].

Despite the somewhat reassuring trend in substance use prevalence in the last decade, youth perception of drug prevention efforts is still far from encouraging. In the past 15 years, the percentages of adolescents reporting recent exposure to drug or alcohol use prevention messages through media and school sources have steadily declined, and also almost half of adolescents do not talk with their parents about potential dangers of substance use [60].

Efforts should also be directed to improve available treatment options since data from recent US surveys display dismal reports of severe undertreatment of adolescent illicit drug and alcohol use problems particularly in specialized centers. The most recent NSDUH report from 2017 reported that 770,000 adolescents were deemed in need for an illicit drug use problem

specialized treatment. Of these, only 7.3% received appropriate treatment, representing a significant decrease from the situation 6 years prior to that (10.5 percent) and a long-term negative trend displaying a lack of specialty treatment resources available to those youth who need it. This low availability of specialized resources further stands out when compared to adults who are more than three times likely to receive such treatments. The situation is very much similar for alcohol use disorders with only 8.4% of youth who are deemed to be of need for specialty alcohol treatment services actually receiving them [60]. These statistics are presumed to be even worse in many other countries due to stigma, underdiagnosis, and shortage of relevant clinical facilities or funding.

Treatment strategies for adolescent SUD are abundant, multidimensional in time and setting, and incorporate a variable degree of pharmacological, psychosocial, and behavioral tools in a wide spectrum of modalities. The full scope of the treatment options available is far beyond the scope of this chapter [56], and it has not yet been shown that adolescent SUD treatments have a suicide-lowering effect at all. The efficacy of substance use-targeted treatments in lowering suicidal rates remains largely unknown and demands a prospective controlled study sufficiently powered to capture these relatively infrequent events. Recently, a suicide-lowering effect has been shown for methadone substitution therapy in a mainly adult population seeking help for opioid use disorders [57]. Other reports imply that treating substance use may decrease suicidality for youth with comorbid depression ([28]).

Treatment options for alcohol disorders are markedly more abundant today than were in the past and are generally individual-focused, family/community centered or school-based in structure. In a review of the various assessment instruments and treatment options in use for alcohol use disorders in youth, Perepletchikova et al. [66] suggest Multidimensional Family Therapy (MDFT) and group-administered Cognitive Behavioral Therapies (CBT) in combination with brief individual Motivational Enhancement Therapy (MET) as the most evidence-based supported treatment strategies of adolescent alcohol use disorders [66]. Further meta-analyses of available treatment schemes suggested that behavior-based treatments are most beneficial in maintaining long-term changes [86] and that motivational-based brief interventions administered in health-care facilities offer the strongest proof of efficacy in alcohol use reduction [65]. Recently, school-based programs focusing on personality factors of targeted high-risk students seem promising in reducing alcohol use and transition to substance use disorders [19].

Suicide prevention programs and treatment strategies are also abundant, and a multidimensional approach is generally encouraged although hard to be implemented using evidence-based approaches. A major challenge to be overcome for the successful implementation of prevention and treatment strategies stems from the fact that most suicidal adolescents do not reach for help prior to their suicidal acts. Only 14% of young people in the United Kingdom who completed suicide were in contact with mental health services in the year prior to their death, and incidentally, 71% of these reported concomitant substance abuse [92]. Also, in a case-control study on the utilization of health-care services among Canadian adolescents aged 11–18 years prior to completed suicide, Renaud et al. [70] described that although 95% of suicide completers suffered from mental disorders, over two-thirds of them had no treatment contact within the month prior to the act, while only 12.7% were in contact with psychiatric services during that same period [70]. Psychoeducational suicide prevention programs have generally shown to positively affect knowledge and certain attitudes concerning suicide [68] although a paucity of large-scale controlled trials limits a clear-cut conclusion regarding their efficacy. Other prevention strategies, such as screening efforts, gatekeepers training, means restriction, family-based treatments, and cognitive- as well as dialectic-based behavioral therapies, have also been described [44] and their efficacy reviewed elsewhere [35]. An NIH Pathways to Prevention

(P2P) workshop was convened in 2016 to explore expert-led evidence-based means to promote adolescent suicide preventive measures. This governmental-funded workshop highlighted data systems improvement, data collection enhancement and improvement of analysis methods, and strengthening the research and clinical community as key strategies to enable improvement of current practice [48].

Finally, the exposure of youth to suicidal behaviors through the traditional and, more so in recent years, through social media may carry a substantial impact on the prevalence of suicidal behavior which should not be underestimated (suicide contagion or "Werther effect") [11, 77]. Despite this, media sources and particularly Internet sites and smartphone applications may also lend real-time, confidential, and easy-to-access sources for suicidality counseling and support and provide an accessible route for treatment referral [44, 72, 85].

107.10Conclusions

Although the act of completed suicide is extremely challenging to predict, many risk factors have been well established and studied. Efforts to further maximize the accurate assessment of high-risk individuals based on these should be encouraged. Reducing suicide attempts in these individuals remains a major challenge since it is not yet clear to what extent eliminating the associated risk factors will in effect result in the reduction of the risk for suicidal behaviors. In this context, efforts to strengthen anti-suicidal resiliency [39] through local or national initiatives have gathered interest, although their effectiveness remains to be proven.

It is apparent that both suicidality and SUD are highly prevalent in the young population and that both carry an increased risk for morbidity and mortality, increasing with older age. The counter-effect of these two complex behavioral states on each other increases the risk for suicidal behavior in adolescents with SUD as opposed to those without. This may largely be due to the fact that both are associated with decreased inhibition and increased impulsivity that lead to impaired decision-making manifested in risk-taking and reckless behaviors. In the proximal timescale, co-occurring SUD may facilitate the transition of ideation to action, whereas in the distal timescale, it may contribute to increased stress by adversely affecting the adolescent's environment and circumstances.

The ongoing efforts of large-scale initiatives that monitor teenage substance use trends and suicidality should also be supported. Relevant data gathered from these facilitate the analysis of global as well as local trends in substance use and their correlation with suicidality. Future clinical studies should follow these changes in temporal trends to provide rapid and relevant reports of the usefulness of prevention efforts utilized. To date, available treatment options only partially rely on evidence-based knowledge due to a lack of studies on the one hand and methodological difficulties on the other. Carefully planned large-scale prospective studies are in need to provide a stronger evidence base for assessing clinical benefits of prevention and treatment plans. A major goal for basic science research remains to discover a low-cost, minimally invasive, and highly specific endophenotype marker for suicide. Such a marker may be more pronounced or relevant in adolescents with SUD due to the strong association between the two phenomena.

In defined high-risk populations, such as the SMY, in which the SUD-suicidality association is more pronounced, efforts for early detection must be increased by the health system and careful evaluation of suicidality should be made based on validated assessment scales and established risk factors while avoiding stigmatization. Wide gaps appear between therapeutic strategies in different countries and even within countries. This may reflect the paucity of evidence-based proven efficacy of current therapies targeted either for SUD or suicidality. The association between SUD and adolescent suicidality is highly influenced by other psychiatric comorbidities, primarily but not exclusively mood disorders, which are most prevalent among these patients and confer an increased risk for additional psychopathology and completed suicide. SUD adolescents with suicidal behaviors are increas-

ingly diagnosed as suffering from "dual diagnosis" or "coexisting problems" without a concomitant referral to specialized treatment facilities. Regretfully, in most countries, the therapy for SUD is not part of the "mainstream" psychiatric health system, and this artificial dichotomy most probably hampers the integrative treatment effort which suicidal adolescents and their families require. We propose that for these patients, a holistic treatment approach is needed to be implemented in specialty facilities. SUD as well as other psychiatric comorbidities and emergent suicidal behaviors should be addressed concurrently as mutual effective connections between these conditions, although not yet well understood, are most evident.

Risk and Protective Factors for Substance Use and Addiction

108

Philip A. Spechler, Alexandra Ivanciu, and Hugh Garavan

Contents

Abstract

Studies on the predictors of substance use disorders have typically focused on psychosocial predictors, whereas the neurobiological predictors are still being elucidated. While psychosocial predictors such as peer influences and personality measures may be considered robust predictors of drug use, understanding neurobiological associations is crucial to uncovering biomarkers, which inform mechanistic models of addiction and treatment options. This review briefly surveys key psychosocial findings and focuses on the predictors of drug use identified from genetic and neuroimaging research. Special attention is given to cannabis use in adolescence, as cannabis is the most commonly used illicit substance, and adults with substance use disorders are likely to have initiated drug use in adolescence. This chapter concludes with a commentary on the future directions for substance use prediction studies.

108.1 Introduction

Problematic drug use is one of the most common and chronic behavioral health issues facing society [15], yet little is known about the neurobiological predictors of use. It is important to study the predictors of drug use within the context of adolescence as individuals who struggle with substance use disorders typically initiate use during this developmental period. An epidemiological survey estimated that 74% of young adults admitted to substance use treatment programs had initiated drug use by age 17 or younger [59]. Furthermore, early initiation of cannabis use is related to outcomes like lower socioeconomic status (SES) [22, 38] and jeopardized mental health including risk for mood disorders [25], schizophrenia, and other psychotic-like disorders [23, 40].

Despite known risks associated with its use, recreational cannabis use for adults is now legal or decriminalized in many parts of the United States and abroad. Global estimates indicate that cannabis use disorder is currently the second most prevalent substance use disorder behind alcohol [15]. In line with this finding, epidemiological studies of adolescent drug use indicated cannabis is also the second most popular drug (following alcohol) used by adolescents, surpassing cigarettes in 2011 [30].

In this chapter, we review what is known about the predictors that increase (risk factors) or decrease (protective factors) the likelihood of cannabis use in adolescence with a focus on the psychosocial and neurobiological changes that occur during adolescence. Special focus will be given to longitudinal neuroimaging studies reporting predictors and correlates of cannabis use in adolescence. The identification of these predictors will inform pathways to cannabis initiation, stratify risk in vulnerable adolescents, and supply targets for proactive interventions tailored to mitigate use and attenuate the consequences of use.

108.2 Psychosocial Risk Factors

The World Health Organization defines adolescence as the period of development between ages 10 and 19 (www.who.init) and is characterized by substantial psychosocial and neurobiological changes [51]. An increase in risk-taking and sensation-seeking behaviors is a common feature of adolescence. For instance, novelty-seeking personality levels typically peak during adolescence [35, 44] and are highly predictive of substance use [14, 26, 37]. Adolescents also tend to discount delayed rewards in favor of immediate rewards [57] and display insensitivities to the aversive properties of some drugs [9, 18, 46]. Together, these behavioral characteristics are thought to contribute to an adolescent's increased propensity for drug use.

Numerous studies have also identified relationships between environmental factors, such as traumatic and stressful life events, and risk for drug use in adolescence. Frequency of early life stress [5] and perceived level of stress [4, 17, 29, 61] are robust predictors of drug use in adolescence. While these findings predict drug use later in life for both sexes, physical and/or sexual abuse during childhood was more common in females than in males [34]. For males, severity of later-in-life drug use was inversely correlated with age at first abuse, such that younger males experiencing physical and/or sexual abuse showed more severe substance abuse problems later in life. This dose-response relationship was not evident in females, where any history of abuse during childhood strongly predicted substance use problems in adulthood [34].

Early life stress might promote the generation of maladaptive coping strategies including substance use. And while stress generally precipitates drug use [16, 49, 61, 66], the exact mechanism driving this association is actively being studied [39]. Drugs and drug-seeking behaviors may potentiate perceptual and biological reactivity to stress [11, 12, 19, 27] and drive self-medicating behaviors. Stress may impair the capacity for impulse control, which is thought to contribute to the maintenance of a substance use disorder [49]. Thus, while we might conclude that a variety of life stressors are reliable predictors of use, understanding the neurobiological mechanisms mediating the effects of these stressors remains an important research focus.

108.2.1 Peer and Parental Influences

A wealth of research supports the concept that parents' lifetime cannabis use predicts adolescent cannabis use [21, 31]. A recent paper by Sokol and colleagues reported that age of cannabis initiation was shifted 2 years earlier in children with a mother reporting any lifetime cannabis use, relative to children of cannabis-naive parents [50]. Furthermore, O'Loughlin and colleagues reported adolescents with *one* parent who endorsed any lifetime use were roughly twice as likely to use cannabis, while adolescents with *two* parents who endorsed any lifetime use were eight times more likely to use cannabis, relative to peers with cannabis-naive parents [42]. While many factors may contribute to parent-offspring transmission of drug use (e.g., exposure, drug availability), possible mechanisms include shared environmental factors as well as genetic and neurobiological predispositions.

An adolescent's peer group also influences cannabis use. Numerous studies indicate that an adolescent is more likely to use cannabis if their peer network uses cannabis [3, 20, 32]. Mechanisms contributing to this effect are thought to relate to the reinforcing properties of both the drug and the social context [8]. For instance, some adolescents may not find drug use itself pleasurable. Thus, the social context involved in cannabis use may prove reinforcing in those who may not find the cannabis itself rewarding. In contrast, some adolescents may not enjoy the social context, but it is a necessary means to obtaining the reinforcing drug. Evidence for both these scenarios are reported in the literature. Lee and colleagues reported that 26% of high school graduates who used cannabis endorsed social enhancement and bonding as their primary motive for cannabis use [33]. Buckner and colleagues measured the likelihood of cannabis use in different social situations and reported that adolescents with social anxieties avoided social situations where cannabis was unavailable [7].

In reviewing the preceding psychosocial risk factors for cannabis use, it should be noted that the research tends to focus on specific factors in isolation. As a result, much less is known about how risk factors accumulate or interact with one another to facilitate or impede cannabis use behaviors. For example, the likelihood of early life stress to confer risk for cannabis use might be moderated by differences in personality traits, peer, or parental influences. Further, although these psychosocial predictors inform pathways to drug use, they offer limited insight into the biological processes related to drug use. Next, the literature concerning the biological predictors of cannabis use will be surveyed starting with a brief overview of the genetic predictors identified from genome-wide association studies (GWAS), followed by human neuroimaging studies.

108.3 Biological Risk Factors

108.3.1 Genetic Associations

Genetic studies seek to identify preexisting genetic risk factors associated with a drug using phenotype. These studies require very large samples in order to detect and, ideally, replicate effects which are typically small in magnitude. Two GWAS studies on cannabis use failed to detect any single nucleotide polymorphisms (SNPs) that passed significance thresholds [2, 58]. Conversely, two other GWAS studies found significant genetic variants associated with cannabis use. The first such study identified three SNPs associated with cannabis use dependence [48]. One SNP was found on an antisense transcription region (rs143244591) whose function is unknown. The other SNPs were found on a gene coding for a protein that regulates extracellular calcium concentrations (rs146091982) and a gene coding for a protein that regulates neuronal inflammation (rs77378271). In another recent GWAS using a very large sample ($N = 184{,}765$), researchers identified eight SNPs that explained 11% of the variance in lifetime cannabis use. The three most significant SNPs were on a gene coding for CADM2, a cell adhesion molecule expressed widely in the brain. This gene has been previously linked to alcohol consumption and risk-taking behaviors [43].

It is hypothesized that different genetic profiles relate to the pharmacological actions of cannabis. For example, Agrawal and Lynskey proposed studying genes coding for various neurotransmitter receptors (CNR1, CB2, TRPV1, GPR55) and ligand enzymes (FAAH, MGLL) [1]. Spechler and colleagues used this approach as an exploratory analysis within the context of a larger machine learning prediction study (described further below) [54]. Here, the search for genetic associations with cannabis use was restricted to 108 SNPs chosen as they were previously reported to have relationships with substance use phenotypes. Results from that study yielded ten SNPs that modestly predicted cannabis use initiation in adolescence. Five of those SNPs were located on genes coding for the primary mu-opioid neurotransmitter receptor, three SNPs in genes coding for norepinephrine receptors, and two SNPs in genes coding for the D1-dopamine receptor. While these findings, like all genetic studies, require replication, they suggest that genetic variation on the opioid and catecholamine receptors might constitute a genetic profile conferring risk for cannabis use.

108.3.2 Neuroimaging Predictors

Structural and functional magnetic resonance imaging (fMRI) studies on substance-using populations typically use cross-sectional designs. Given the interpretational challenges posed by such designs, more studies using carefully controlled longitudinal and prospective designs are needed to make claims related to predictors of use. For example, Cheetham and colleagues studied gray matter volumes (GMV) in an adolescent sample pre- and post-cannabis use. Findings indicated that less GMV in the orbital frontal cortex (OFC) at age 12 predicted cannabis use by age 16 [10]. The OFC is commonly implicated in addiction. Early work by Volkow and Fowler reported converging evidence for hypoactivity in this region using fMRI and positron emission tomography (PET) to characterize individuals with drug dependence [62]. These studies suggest a propensity for drug use is partially predicted by differences in structure and function of the OFC, a region putatively involved in functions relevant to substance use, such as reinforcer evaluation [41] and behavioral regulation [6].

Jacobus and colleagues studied cortical thickness in a sample of adolescents before (age 13) and after (age 19) initiating alcohol-only, or alcohol and cannabis, and compared them to drug-naive peers. Less cortical thickness across many prefrontal regions, including the left precentral and superior frontal gyri, predicted the future alcohol + cannabis group relative to alcohol-only. Less thickness in right middle frontal gyrus predicted the alcohol + cannabis group relative to controls [28]. This study also included repeated measures on neurocognitive and mental health surveys. Results indicated that worse performance on working memory tasks and higher externalizing scores at baseline predicted the alcohol + cannabis initiating group relative to the others. These results suggest a preexisting working memory deficit is sustained (if not exacerbated) through prolonged cannabis exposure in adolescence. Consequently, a combination of behavioral and neuroimaging measures may yield a predictive profile of cannabis use in adolescence.

These two structural MRI studies suggest that less gray matter in prefrontal regions preceded cannabis use in adolescence. Normative adolescent neurodevelopment is characterized by volume reductions, so interpreting these effects is challenging. One possibility is that they might signal precocious development [24]. Hence, adolescents exhibiting less gray matter relative to their peers at the same age might indicate accelerated neurodevelopment – a possible marker of or risk factor for maladaptive psychosocial development and drug-seeking behaviors.

Prospective functional MRI studies investigating adolescent cannabis use are even more scarce than structural MRI studies. A forthcoming prospective report by Spechler and colleagues identified amygdala hyperactivity to threat signals (angry faces) in cannabis-naive adolescents predicted the level of cannabis use by age 19 [52]. This study informs previous work which demonstrated that amygdala hyperactivity correlated

with cannabis use by age 14 [55] and also suggests a dose-response relationship between pre-existing amygdala hyperactivity and future cannabis use.

In another prospective fMRI study by Tervo-Clemmens and colleagues, researchers scanned children at ages 12 and 15 using a working memory paradigm [60]. In children who were cannabis-naive at age 12, higher frontoparietal activations and lower visual cortex activations during high task load predicted cannabis use by age 15. A dose-response effect was also found in the cuneus, such that lower activations predicted heavier use. Additionally, lower spatial planning scores from a cognitive test battery (CANTAB) also predicted use. These results add to the literature despite being limited by a small outcome group ($n = 22$ future cannabis users): Replication with larger samples is needed. More refined predictive modeling strategies can be applied to larger samples, including cross-validation schemes testing for generalizability of models on external samples to further evaluate prediction accuracy [64].

108.4 Prediction Analyses with Machine Learning

Prediction analyses aim to yield models that accurately predict novel observations. As large longitudinal research projects like IMAGEN [47] and ABCD [63] become more prevalent, study sample sizes approach epidemiological levels and make external- or cross-validation procedures possible. These large research projects provide feature-rich characterizations of participants. Machine learning approaches may then be utilized to uncover multi-domain data-driven predictors of phenotypes, while testing the generalizability of a predictive model on novel observations using an external validation set or cross-validation [45, 64].

Despite recent large-scale projects, few studies have specifically identified neurobiological predictors of drug use. Whelan and colleagues used cross-validated regularized regressions to classify adolescent binge drinkers at age 14 and to predict binge drinking by age 16 from age 14 data [65]. These methods, applied to a wealth of neuroimaging, psychometric, and candidate SNP data, indicated highly significant classification (Area Under the receiver operating characteristic Curve (AUC) = 0.90) and prediction (AUC = 0.75). Hence, these methods yielded models that performed well in classifying and predicting independent samples.

Several features from the Whelan et al. [65] study both classified and predicted adolescent binge drinking: more frequent sexual life experiences, higher novelty seeking, disorderly and extravagant personalities, and lower conscientiousness. With regard to neurobiological features, lower activation in the left putamen and hippocampus during reward anticipation and less GMV in the ventromedial prefrontal cortex classified age 14 binge drinking. Lower activation in pre- and post-central gyri during failed response inhibitions predicted future binge drinking. In sum, the classification was driven by lower activity in regions serving appetitive processing, while the prediction was driven by lower activity in sensory motor areas during failed response inhibitions.

Spechler and colleagues implemented a similar approach using machine learning to generate cross-validated models that predicted cannabis use initiation in males and female adolescents [54]. Multi-domain data measured prior to any reported cannabis use were modeled together to uncover a sparse set of brain and behavioral predictors. Cross-validated prediction accuracy was robust (males AUC = 0.74; females AUC = 0.82). Psychosocial predictors observed in both sexes included higher lifetime alcohol or tobacco use, parental cannabis use, and novelty-seeking personality features.

Brain predictors from the Spechler et al. [54] study were found to be sex-specific. Generally, lower brain activations during a response inhibition task characterized future cannabis use in males and females, but the specific locations of these effects differed between the sexes. For example, males exhibited lower activation in the cerebellum, whereas females exhibited lower activation in prefrontal and temporal cortex, rela-

tive to their cannabis-naive peers. Brain activation during face processing and reward processing also predicted future cannabis use in females. The authors demonstrated that sex-specific predictors did not predict future cannabis use in the opposite sex, nor did they generalize to predict binge drinking in a related sample of same-sex adolescents. Lastly, hierarchical regressions demonstrated that the inclusion of each set of domain-specific predictors significantly improved model fits. Therefore, behavioral and brain data explain unique portions of the variance in future cannabis use initiation.

A caveat of the Spechler et al. [54] report was that the future cannabis users also reported future binge drinking. Even though the cannabis predictors identified in the 2018 report did not predict an independent sample of future binge drinkers, a stricter test of drug specificity would be welcome to help uncover the predictors unique to cannabis use. Therefore, in a forthcoming report by Spechler and colleagues, machine learning techniques were used to differentially predict future cannabis use vs. future binge drinking [53]. In that study, all individuals were cannabis-naive at baseline, but the comparison sample was chosen to be matched to the future cannabis-using group on their future binge drinking levels.

Results indicated prediction was still highly significant (males AUC = 0.63; females AUC = 0.66), although lower than when discriminating future cannabis users from cannabis and binge drinking naive controls. The identified predictors were also fewer in number. Higher rate of baseline cigarette use was the only feature that consistently predicted future cannabis use across the sexes. However, future cannabis use in males was also predicted by less negative feelings toward deviant behaviors and more regional GMV in the right inferior temporal lobe relative to future binge drinking peers. Future cannabis use in females was also predicted by a set of lower brain activations during response inhibitions, including the left middle frontal gyrus, right inferior temporal gyrus and right paracentral lobule during successful response inhibitions, and the left inferior frontal gyrus during failed response inhibitions.

Lastly, Squeglia and colleagues recently published a machine learning study predicting the initiation of alcohol use in adolescence [56]. In that report, researchers used random forests on data collected at age 12–14 to predict moderate to heavy alcohol use by age 18, relative to a sample of consistently alcohol-naive peers. Three separate models were generated by increasing the number of feature domains (demographics only; demographics + neurocognitive; demographics + neurocognitive + neuroimaging). Prediction accuracies increased with the inclusion of each domain, as indexed by sensitivity (0.60, 0.67, and 0.74, respectively) and specificity (0.64, 0.70, and 0.73, respectively) to alcohol initiation. The best predictors were from the neuroimaging data, including lower thickness of the left supramarginal gyrus and lower activations in the right posterior cingulate and superior temporal gyrus during a working memory task.

Aside from the neuroimaging data, sex, SES, and cognitive measures were also identified as predictors of adolescent alcohol use. The lack of consistency with Whelan and colleagues is likely due to differences in measurement (Whelan used voxel-wise data; Squeglia used regions of interest). Nonetheless, results indicated that the best prediction was achieved with a combination of behavioral and neuroimaging data. In keeping with the prediction studies by Whelan and colleagues [65] and Spechler et al. [54], machine learning approaches can be used to leverage multi-domain data, resulting in meaningful predictions and uncovering profiles predicting drug use in adolescence.

108.5 Discussion

Identifying risk for substance use and disorders is an active area of research spanning biological and behavioral domains. Uncovering risk for early initiation and problematic cannabis use is paramount in light of the prevalence of those who initiate as adolescents [30], the global estimates of cannabis use disorder [15], and the ongoing shift in legal status for adult recreational cannabis use. Generally, the psychosocial findings high-

light the role of novelty-seeking personality traits, alcohol and cigarette use, and peer and parental relationships as key predictors of drug use in adolescence. The neuroimaging studies, though still nascent, point to structural and functional differences in prefrontal regions as preexisting differences that increase risk for future cannabis use.

Machine learning approaches are novel and insightful tools for leveraging large datasets to identify predictors of drug use. Robust prediction models should generalize to predict independent observations and may identify predictors from multiple domains. Indeed, as demonstrated by Spechler et al. [54], modeling the combined psychosocial and neuroimaging predictors returned superior model fits relative to models containing only psychosocial data. Therefore, it is important to consider the contribution of risk from multiple domains in order to identify a comprehensive risk profile that can be used to infer etiological mechanisms and possible treatment strategies.

Of course, existing findings require replication, and future research should examine how predictors relate to each other. The majority of the research methods discussed thus far employed the general linear model, assuming a linear relationship among predictor variables. These methods also assumed predictors were independent from one another and their effects summed together to model a group average. Incorporating nonlinear interaction terms or other nonlinear modeling procedures might yield new insights into the joint contribution of multi-domain predictors explaining drug-using phenotypes. Therefore, new hypotheses to be investigated should model cross-domain interactions. For instance, some individuals may possess genetic risk variants, yet their personality traits or environmental factors moderate these effects to either magnify risk or protect against cannabis use. Moreover, researchers should explore the extent to which genetic and psychosocial features interact with neurobiology to influence the likelihood of drug use or substance use disorders.

One eventual goal would be for the findings of prediction studies to help develop and validate strategies that might disrupt a risk phenotype. Some of the predictors discussed in this chapter could be incorporated into treatments (e.g., augmenting executive control functions subserved by the OFC), whereas others may be incorporated by targeting the individual's environment including their parent and peers. As it stands, the psychosocial domain might be more accessible than the biological domain. For example, there is evidence for the efficacy of personality-targeted interventions [13] in reducing the likelihood of cannabis use in adolescents by targeting a sensation-seeking personality [36].

Central to all the research discussed in this chapter is the assumption that preexisting differences confer risk for drug use. However, it is worth noting that it would be incautious to assert that these preexisting differences caused drug use. Even with carefully designed and controlled longitudinal studies, it is difficult to assert causal relationships between risk factors and a complex behavioral phenotype. Treatment (intervention) studies are one method to approach causality if the modification of a risk factor is found to attenuate the phenotype. Conversely, if a protective factor is disrupted, say, by a shift in the social environment of the adolescent, that would also help illuminate causal mechanisms. The combination of longitudinal observational studies and experimental intervention studies should, in time, identify etiological mechanisms and identify which elements of those mechanisms are modifiable.

Abstract

Substance use disorders (SUDs) among childbearing-aged women are a significant public health problem. With advances in fields such as genetics, epigenetics, and neuroimaging as well as improved research methodologies, it is now established that prenatal exposure to psychoactive substances is a major preventable cause of disorders of fetal and infant/child growth and neurodevelopment. The effects of these neurodevelopmental alterations can appear at any time of the individual's life and can affect a variety of domains including developmental, behavioral, cognitive, and adaptive functioning. Problems related to prenatal substance exposure can be transient and start during the neonatal period (i.e., neonatal abstinence syndrome) or can appear at any age and compromise specific areas of functioning for a lifetime (i.e., deficit in executive functioning). Moreover, maternal chronic substance use can compromise the maternal neural circuitries that subserve executive functioning and regulation of stress responses, impairing their ability to appropriately parent. Expression of the teratogenic effects of perinatal exposure to substances can be exacerbated by a toxic or unstable prenatal and/or postnatal environment and ameliorated by a nurturing and stable one. Health-care providers play a crucial role in the prevention, early detection, and intervention for perinatal SUD. This chapter will describe the effects of maternal SUD on the mother, child, and mother/child dyad functioning and provide recommendations for screening and interventions for families affected by perinatal SUD.

Keywords

Prenatal substance exposure · Maternal substance use disorder · Perinatal · Parenting Child development · Intrauterine exposure

109.1 Introduction

The use and misuse of psychoactive substances among pregnant and postpartum women is of great concern for health professionals and policy makers. Prenatal substance exposure (PSE) affects more newborns than other common medical conditions and is linked to a variety of adverse outcomes for the pregnancy, the fetus/child, and/or the mother. Furthermore, an SUD can compromise maternal neural circuitries regulating stress responses and behavior, challenging her ability to care for the child and increasing risk for child abuse and neglect. The physiological, behavioral, and neurodevelopmental problems associated with PSE can appear in the fetus, at birth, or at any later age. These problems can be transient or persist throughout life, causing serious emotional and financial burdens to individuals, families, and society. The management of pregnant women with substance use disorder and their children is an opportunity and a challenge for the patients, their families, and their health-care providers. Failing to identify and treat this group of mothers and children comprehensively may bring undesirable consequences for the dyad and for society. The purpose of this chapter is to review the (1) scope of the problem, (2) challenges faced by pregnant women with SUD, (3) effects of substances on fetal/child neurodevelopment, (4) identification of pregnant women with SUD and their children, and (5) interventions to help this population of women and children.

109.1.1 Epidemiology at Different Developmental Periods Related to Perinatal SUD

The use/misuse of licit and illicit substances during pregnancy is a major cause of preventable disorders in fetal growth and neurodevelopment. Greater understanding of the epidemiology and factors contributing to substance use prior to, during, and after pregnancy, and of the mechanisms through which those factors exert their

effects, is a prerequisite to detecting and treating affected children and their families.

109.1.1.1 Preconceptional Period

In the US, 55% of childbearing-age women report alcohol use, with 24.5% reporting binge drinking in the past month. The use of tobacco among nonpregnant women aged 15–44 is 24%, and the use of illicit substances is 11.4% [42]. After marijuana use, prescription drug misuse/abuse is the most common type of problematic substance use.

Although pregnancy is frequently a motivation for women to decrease or stop substance use, a high percentage of pregnancies are unplanned, and late pregnancy recognition (≥7 weeks) occurs in 23% of women of childbearing age. In women with SUD, further failure to recognize a pregnancy can occur for many reasons, including chaotic lifestyles and amenorrhea associated with substance use, putting the exposed fetus at increased risk during a critical period of early brain development.

While the effects of maternal substance use on infant outcomes have been the focus of extensive research, the role of paternal substance use prior to conception has been limited. Epidemiological and animal studies indicate that chronic paternal substance use prior to conception may have a negative impact on the offspring's development [1]. Paternal alcohol, nicotine, cocaine, or opioid use has been found to influence infant birth weight, congenital malformations, and cognitive functioning, as well as increased risk for SUD in adulthood [35]. Although the mechanisms underlying the impact of paternal substance use on physical and developmental outcomes of the offspring remain unclear, preliminary studies suggest that paternal preconceptional substance use can produce heritable changes in genomic expression and phenotype in offspring via epigenetic transmission [15].

109.1.1.2 Prenatal Period

Tobacco, alcohol, marijuana, cocaine, amphetamines, opioids, and benzodiazepines are the most commonly used substances during gestation, with polysubstance use being more common than monosubstance use. The prevalence of disorders related to PSE varies by ethnicity, geographic location, and temporal and population factors. Globally, in a systematic review and meta-analysis published in 2017, approximately 10–15% of women consumed alcohol during pregnancy [34]. In the US, it is estimated that 9.4% of pregnant women use alcohol regularly with 2.3% reporting binge alcohol drinking, 15% smoking tobacco, and 5.4% current illicit substance use. Adolescents in particular are of concern; the rate of illicit substance use among pregnant women between 15 and 17 years old was 14.6% in 2012–2013 [42]. In a population-based US survey, 4.2% of women reported cannabis use during pregnancy and 6.8% after pregnancy [25]. Past-month cannabis use among pregnant women in the US increased up to 62% between 2002 and 2014 [6] and may continue rising with increased acceptance and efforts toward decriminalization and legalization. Concurrent use of cannabis and nicotine is also increasing. During the last decade, the overprescription, diversion, and misuse of opioid medications and subsequent increase in heroin use and fentanyl misuse have also become a major public health burden for maternal and child care. Finally, the use of benzodiazepines is estimated at 1–11% pregnant women, with 3.9% of a privately insured population of pregnant women being prescribed a benzodiazepine. Among pregnant women with opioid use disorder, 9.2% also reported concurrent benzodiazepine use [37].

109.1.1.3 Postnatal Period and Epidemiology of the Effects of PSE

Prenatal smoking is one of the most common preventable causes of infant morbidity and mortality. Approximately 5–8% of preterm births, 13–19% of term low birth weight infants, 23–34% cases of sudden infant death syndrome (SIDS), and 5–7% of preterm-related infant deaths are attributable to prenatal maternal smoking [11]. In the US, the proportion of infants developing neonatal abstinence syndrome (NAS) due to opioids increased fivefold between 2000 and 2012. The global prevalence of fetal alcohol spectrum

disorder (FASD) is 7.7 per 1000 population [26]. Within the US, FASD estimates range from 3% to 5% [34]. FASD risk is higher in disadvantaged groups, with rates of up to 68.0–89.2 per 1000 in the wine-producing regions of South Africa [30].

In addition to the effects of PSE on the offspring, resumption of maternal substance use following delivery is frequent and can further impact the infant via exposure through breast milk, as well as impair the mother's parenting abilities. Compared with use during the third trimester of pregnancy, cigarette, alcohol, binge alcohol, and marijuana use rates were higher in women with a child younger than three months of age [41].

109.2 Problems Faced by the Pregnant Women with SUD

In the mother, chronic substance use can lead to morphological and functional brain changes that produce compulsive craving and drug seeking, impairing daily functioning. Substance-induced brain changes result in heightened stress, which may amplify negative affect states and increase drug-seeking and neglectful or abusive parenting behavior. Drug use is further associated with impairment of memory and attention, inhibitory control, interoception, and self-awareness, all processes required to support the demands of adequate parenting practices, self-care, and healthy decision-making. Poor decision-making skills can lead to risky sex, violence exposure, higher stress, and homelessness. Many pregnant women with SUD seek prenatal care late or not at all even if they have chronic health concerns, further increasing the risk of poor perinatal outcomes. Dental problems are very common due to poor dental hygiene, lack of dental care, opioid exposure, and inadequate nutrition.

A significant proportion of pregnant women with SUDs have one or more psychiatric diagnoses, with comorbidity ranging from 45% to 75%, depending on the sample. Moreover, they commonly have histories of multiple adverse experiences. A past and/or current history of abuse (physical, sexual, or emotional), neglect, abandonment, and family violence is common condition. Many women with SUD grow up in multigenerational drug-using families with significant mental health problems or environments where multigenerational substance use, chaos, inconsistency, mistrust, and aggression are the norm. The perceptual, cognitive, and emotional capabilities of the mother and her parenting skills are built upon the scaffolding provided by her earlier life experiences. Life trauma may lead to maladaptive and recurring unhealthy behaviors that have a negative impact on general functioning and pregnancy well-being. Unaddressed maternal psychosocial issues can contribute to mother-infant interaction problems and alter developmental trajectories of children. Socioenvironmental problems have been found to affect the severity of neonatal abstinence syndrome expression in opioid-exposed infants [32].

109.3 Effects of Drugs on Fetal Neurodevelopment

The environment encountered in fetal and neonatal life exerts a profound influence on physiological function and risk of disease in later and adult life. The foundations of brain architecture and function are established early in pregnancy through dynamic interactions between genetic influences and the prenatal environment.

Most substances cross the placenta and have a longer half-life in the fetus than in adults, resulting in higher concentrations in fetal than maternal blood. Substances may affect biologic functions either through binding to receptors in the CNS or by affecting the release and reuptake of neurotransmitters. Neurotransmitters and neuromodulators appear early during embryogenesis, and their signaling serves key functions during neurodevelopment, including neurogenesis, neural progenitor proliferation, lineage segregation, and the migration and phenotypic specification of immature neurons and glial cells. Alterations in these processes can change neurodevelopmental trajectories via a variety of actions depending on the substance, timing and patterns of exposure, and the system affected. For

example, prenatal alcohol exposure alters gene expression and disrupts neural development by interfering with myelination, synaptogenesis, and cell migration and by enhancing cell death [50]. Similarly, opioid exposure disrupts neuronal maturation, alters the development of dopamine and serotonin transmitter systems, and suppresses myelination, resulting in reduced brain volume and connectivity [8]. While endogenous cannabinoid signaling tightly regulates neural development and migration during the prenatal period, exposure to exogenous cannabinoids (e.g., through marijuana) prenatally disrupts neuronal maturation, connectivity, and transmitter signaling [19]. Adverse prenatal environments created by substance exposures may result in long-term epigenetic modifications (i.e., heritable alterations in gene expression due to drugs, toxins, stress, and inflammatory responses), altered hypothalamic-pituitary-adrenal (HPA) axis activity, and elevated corticosteroid levels in the mother and fetus. These changes alter the programming of the fetal neuroendocrine environment and predispose the child to behavioral and emotional dysregulation, compromising physical and mental health and developmental trajectories.

109.3.1 Substance-Related Adverse Birth Outcomes

SUD during pregnancy is linked to perinatal complications related to the direct effects of the drugs or, secondarily, due to the environment associated with compulsive drug use and seeking. Substances used during pregnancy have been associated with adverse outcomes such as preterm birth (e.g., nicotine, alcohol, cocaine, benzodiazepines) and low birth weight (e.g., nicotine, alcohol, cocaine, methamphetamine) [49]. Medical and obstetrical complications associated with substance use include miscarriage, premature rupture of membranes, premature delivery, placental abruption, intrauterine growth restriction, chorioamnionitis, stillbirth, hypertension, and increased rate of infections, including sexually transmitted diseases. Intravenous substance use carries the additional risk of cellulitis and abscess formation, sepsis, endocarditis, hepatitis B, hepatitis C, and HIV infection. Small-for-gestational age rather than preterm birth is the main mechanism through which smoking causes excess infant mortality. Some studies suggest that infant mortality is 40% higher in infants exposed to smoking during pregnancy compared to those born to nonsmoking mothers, with variations by race/ethnicity [36].

109.3.2 Congenital Malformations

Malformations associated with prenatal alcohol use include the dysmorphic facial features (short palpebral features, smooth philtrum, and thin vermillion border) seen in fetal alcohol syndrome (FAS) or partial fetal alcohol syndrome (pFAS) and the congenital malformations seen in alcohol-related birth defects (ARBD), which include cardiac defects, eyesight and hearing issues, urinary problems, joint abnormalities, and skeletal problems. Reports from autopsies of infants with FAS and human imaging studies demonstrate abnormalities in overall brain size and shape particularly in the cerebellum, basal ganglia, and corpus callosum [28].

Aside from alcohol, which has a clearly defined pattern of birth defects, studies evaluating the correlation between congenital anomalies and other prenatal substance exposures are inconsistent [46]. While a few case reports, retrospective studies, and studies with small samples describe associations of some substances with particular anomalies, large-scale and prospective studies do not generally confirm these associations [4]. A systematic literature review of studies carried out between 1959 and 2010 found a significant positive association between maternal prenatal smoking and cardiovascular/heart defects, musculoskeletal defects, limb reduction defects, missing/extra digits, clubfoot, craniosynostosis, facial defects, eye defects, orofacial clefts, gastrointestinal defects, and undescended testicles [17]. However, these associations have not been reported by others. Minor physical anomalies such as true ocular hypertelorism and

severe epicanthus have been reported in heavy users of cannabis, but there is a lack of a definitive relationship between physical anomalies and prenatal cannabis exposure in general [2]. Congenital anomalies had been reported in some cocaine-exposed infants, but larger recent studies have not documented those associations [48]. Infants exposed in utero to PCP have been reported to display microcephaly and alterations in facial features [40]. Isolated cases of cardiac defects, cleft lip, and biliary atresia have been reported in neonates exposed to methamphetamine [33], but these findings have not been found in other samples. There has also been inconstant reporting on the relative risk of congenital anomalies (orofacial clefts) among infants exposed to benzodiazepines [23]. Recent meta-analyses of maternal opioid use reported mixed associations between prenatal opioid exposure and congenital malformations [29]. Cardiac defects and oral clefts may be more common in opioid-exposed infants, although results of larger meta-analyses are inconclusive [29].

109.3.3 Neurobehavioral Effects of Substance Exposures

Neonates prenatally exposed to substances are at increased risk for a variety of conditions that can make adaptation to extrauterine life a challenge for the neonate and caregivers and can negatively alter the mother-infant interaction and/or the trajectory of development if not recognized and properly treated. There exist several conditions associated with prenatal substance exposure that become apparent during the neonatal period, such as the neurobehavioral alterations associated with NAS in opioid-exposed pregnancies. Developmental effects secondary to disruptions in brain maturation may not become clinically apparent until later in life and can be produced in the fetus at dose levels that are relatively harmless for adults. Postnatal factors such as nutrition, socioeconomic conditions, parenting practices, and exposure to adversity can further alter gene expression and modify infant brain development. Regardless of mechanisms of harm, children exposed to substances during pregnancy are at increased risk for a variety of conditions that portend future consequences. It is easy to comprehend the wide variation in infant outcomes from substance-exposed pregnancies with the myriad factors at play in these pregnancies (Fig. 109.1).

109.3.3.1 Neurobehavioral and Regulatory Problems

Each newborn has a particular repertoire of physiological and behavioral characteristics that depend on the maturation, organization, and regulation of at least four different interactive systems: (1) sleep/awake state control and attention,

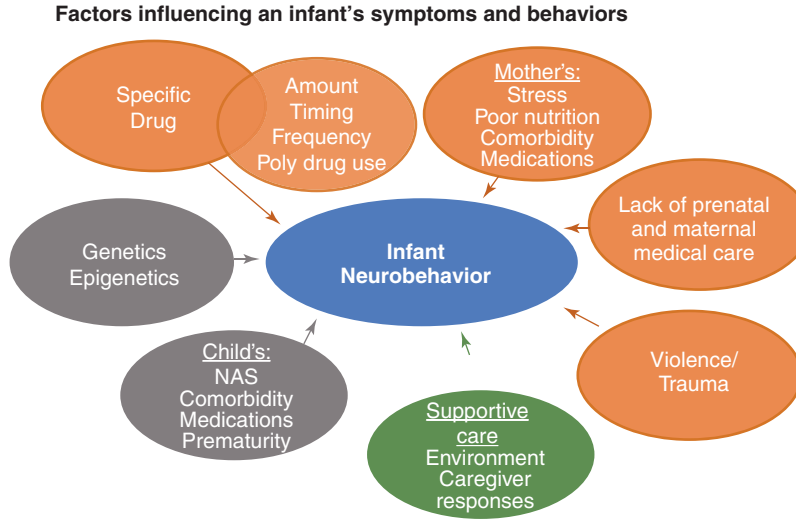

Fig. 109.1 Factors determining the effects of the prenatally exposed individual. These include maternal factors (drug use, medical care, stress), infant factors (including NAS and comorbid pediatric conditions such as preterm birth), and genetic/epigenetic and placental factors

(2) sensory integration, (3) motor/tone performance, and (4) autonomic control. The direct and/or indirect effects of substances on the fetus can negatively impact the newborn's functioning in one or more of these domains in an individualized way. The regulatory difficulties experienced by neonates can be assessed using the NICU Network Neurobehavioral Scale (NNNS) [45]. This scale, developed as neurobehavioral assessment tool for normal and at-risk infants, has been used to describe and evaluate how stressors, such as in utero substance exposure (cocaine, nicotine, marijuana, alcohol, methamphetamine, methadone, buprenorphine), affect infant self-organizing neurobehavioral capacities. Infants with compromised neurobehavioral functioning require early recognition and appropriate interventions for each domain of dysfunction to prevent problems related to feeding and organization of sleep-wake patterns, growth, acquisition of developmental milestones, and healthy child/caregiver interactions and communication. Such early recognition and intervention are crucial to facilitating a developmental trajectory toward more regulated, adaptive, and rewarding interactions.

109.3.3.2 Neonatal Abstinence Syndrome (NAS)

NAS is a group of signs and neurobehaviors experienced by the infant after discontinuation of gestational exposure to psychoactive substances taken by the mother. The symptoms associated with NAS include high-pitched cry/irritability, sleep-wake disturbances, alterations in motor tone and movement, feeding difficulties, gastrointestinal disturbances (vomiting, loose stools), autonomic dysfunction (sweating, sneezing, fever, stuffiness, and yawning), and failure to thrive. NAS is variable in its onset, severity, and types of symptoms presented, and typically associated with opioid withdrawal, yet other substances can produce an independent or synergistic withdrawal phenomenon (e.g., benzodiazepines). Opioid-induced NAS symptoms usually begin during the first four days of life with the clinical signs escalating over time as the drug is eliminated by the newborn. Polysubstance exposure, particularly opioids in combination with benzodiazepines, can result in more severe NAS expression that is induced by opioids alone [22].

109.3.4 Problems Related to Individual Substance Exposures

While consideration for the effects of individual substances may be important, most substance-exposed infants are polysubstance exposed, making these distinctions somewhat artificial. It should be noted that all of these substances pass through the placenta to the fetus, and all can be found in breast milk.

109.3.4.1 Alcohol

Alcohol is acknowledged as one of the leading human teratogens and is the top known cause of preventable neurodevelopmental disorders in Western society. Alcohol's effects vary depending upon timing of exposure, blood alcohol concentration, and patterns of maternal use. Although dose-related severity has been found, there are no evidence-based studies to suggest that any amount of alcohol use is safe during pregnancy. Women should be advised to abstain from drinking during pregnancy or while attempting to conceive, because it is not possible to predict which children will be affected by maternal alcohol use and how severely. The different categories of effects related to prenatal alcohol exposure are grouped under the nondiagnostic umbrella term "FASD." Four different groups of symptoms constitute FASD: fetal alcohol syndrome (FAS), partial FAS (pFAS), alcohol-related birth defects (ARBD), and alcohol-related neurodevelopmental disorder (ARND) (Fig. 109.2). If early detection and intervention for the neurocognitive and behavioral (e.g., self-regulation, adaptive, cognitive) deficits associated to FASD are not provided, secondary disabilities may arise during school/adolescence and adult life. In affected adults, the implications and effects of the disabilities resulting from prenatal alcohol exposure may involve troubles with the law, mental health problems, inappropriate sexual behaviors,

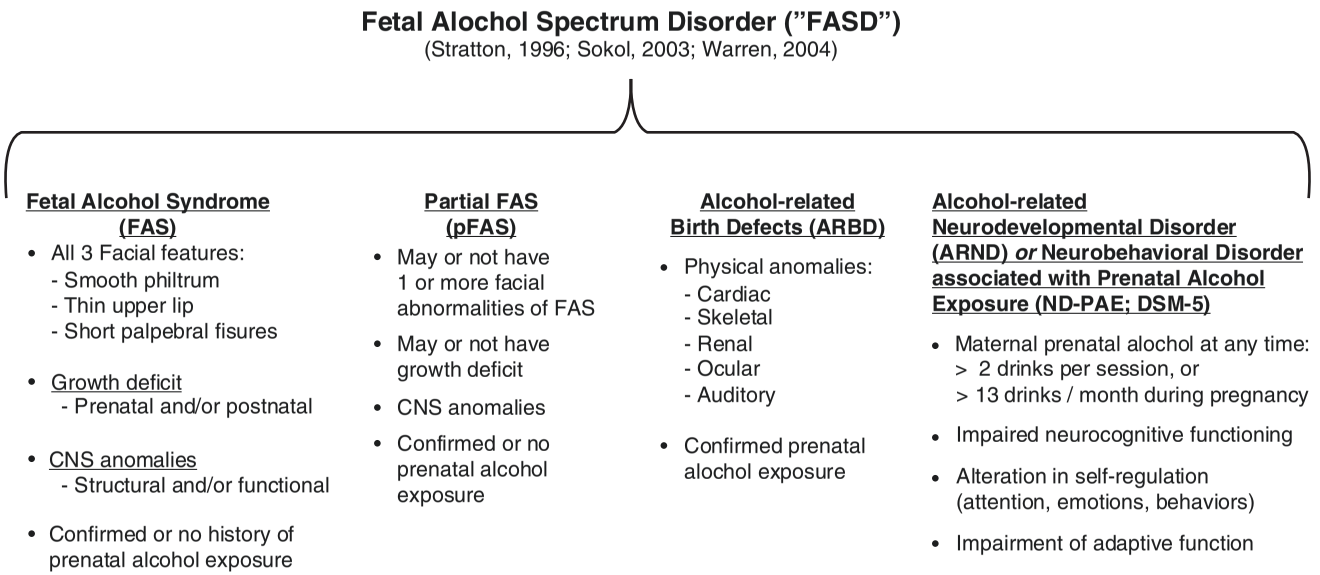

Fig. 109.2 Categories of effects related to prenatal alcohol exposure under the umbrella term of fetal alcohol spectrum disorder

SUDs, and problems with employment and dependent living. The magnitude of the health burden combined with the high prevalence of FASD makes the early diagnosis of and intervention for maternal prenatal alcohol use, in an effort to prevent damage to the developing fetal brain, a research and public health priority.

109.3.4.2 Cocaine, Methamphetamine, and PCP

Cocaine and methamphetamine are popular illicit stimulant drugs used recreationally worldwide, particularly among young adults in the US, Europe, and Australia. During the neonatal period, cocaine-exposed neonates display signs of disrupted neurobehavioral regulation including state lability, poor quality of movement and reflexes, hypertonia, deficits in orienting and attention, and increased irritability. Beyond the neonatal period, deficits in arousal regulation, hyperreactivity, and reduced emotional modulation and physiological responses to environmental stimulation during challenging tasks have been noted in cocaine-exposed infants. Other studies have reported behavior, language, cognition (including poor sustained attention), and motor function problems (for review, see Smith and Santos [39]). Some studies associate prenatal cocaine exposure with ADHD, oppositional defiance disorder, and future substance use.

Prenatal methamphetamine exposure has been associated with decreased arousal, increased physiological stress (e.g., difficulty maintaining normal respiration), and poor quality of movement. Neonates exposed to methamphetamine show reduced striatal and thalamus brain volumes and lower connectivity between the striatum, midbrain, orbitofrontal cortex, and limbic regions [48]. While research on the long-term effects of methamphetamine remains limited, similar to cocaine, ongoing longitudinal studies indicate that children at three and five years of age display more behavioral and emotional problems, including heightened emotional reactivity, anxiety, depression, and social withdrawal. Five-year-old children had more attention deficit-hyperactivity and externalizing behaviors, and by ages six to seven, methamphetamine-exposed children show reduced IQ and deficits in learning, memory, and motor coordination [39].

Neonatal neurobehavioral signs associated with antenatal PCP exposure consist of decreased attention, high-pitched cry, poor visual tracking, tremors, lethargy, nystagmus/roving eye movements, poor feeding, and altered reflexes [40]. Animal studies indicate that prenatal PCP exposure compromises neural proliferation and induces dysfunction in the brain's inhibitory GABAergic system, particularly in the prefrontal cortex, which may contribute to long-term behavioral consequences [44].

109.3.4.3 Nicotine

Neurobehavioral symptoms described in neonates exposed to nicotine include impairment of arousal, irritability and hyperexcitability, hypertonicity, and signs of stress/abstinence [27]. Smoking during pregnancy has been associated with increased risk of abruption, placenta previa, prematurity, low birth weight, and neonatal respiratory problems. Co-use of cannabis and tobacco smoking has been associated with smaller head circumference. Neurobehaviorally, prenatal nicotine exposure is linked to irritability and difficult temperament during infancy and poor self-regulation during childhood. Disorders of attention, externalizing behavior problems, and deficits in self-regulation, such as aggressive behavior and a higher risk of smoking, also occur in later childhood and adolescence [16].

109.3.4.4 Opioids

Long-term studies of children exposed to opioids are scarce, and most lack adequate control groups and have small sample sizes. Prenatal opioid exposure is linked to reduced brain volume in the striatum, thalamus, and cerebellum [38]. Hyperactivity and short attention span have been noted in toddlers prenatally exposed to opiates, and preschool children exposed to heroin demonstrated memory and perceptual problems. There is no consensus from available studies about the effects of opioids on cognition. Among infants born to women on methadone and buprenorphine treatment for opioid use disorder, no differences were observed in self-regulation or in sensory profiles compared to healthy controls [3].

109.3.4.5 Cannabis

Cannabis is the world's third most popular recreational drug used during pregnancy after alcohol and tobacco, and it is the most frequently used illegal substance during pregnancy in the Western world. Despite its popular use, there are few studies exploring the long-term effects of THC on the developing brain. Recent research has found that the endocannabinoid system plays a key role in prenatal and postnatal brain development, and activation by exogenous cannabinoids can permanently alter brain development. Use of cannabis during pregnancy is associated with low birth weight, increased need for neonatal intensive care, and abnormal infant cortical thickness [12]. Neonatal neurobehavioral effects of in utero cannabis exposure include changes in visual functioning, tremors, startling, jitteriness, difficulties with arousal, self-regulation, irritability, and excitability [10]. During the preschool years, deficits in verbal reasoning and short-term memory have been reported following prenatal THC exposure [9]. Adolescents prenatally exposed to THC may have impaired executive functioning (deficits in problem-solving, inattention, and impulsivity) [13].

109.3.4.6 Benzodiazepines

One of the most frequently prescribed classes of drugs during pregnancy, benzodiazepines also are commonly abused licit drugs, and exposure in infants often is unrecognized or ignored due to inconsistent screening policies. Signs of benzodiazepine withdrawal include hypoventilation, irritability, hypotonicity, and feeding difficulties, particularly after use in late gestation [37]. These symptoms can appear within a few days to three weeks after birth and can last for several months. Studies evaluating the neurodevelopmental effects on exposed children have yielded mixed results, with some reporting delayed motor development and neuropsychological symptoms [14]. More recently, protracted prenatal exposure to benzodiazepines (2+ trimesters) was associated with increased internalizing behaviors at 1.5 years and 3 years, suggesting long-term impact [5].

109.4 Identification of Pregnant Women with SUD

The periconceptual identification of the women with SUDs is necessary to provide SUD treatment and gynecologic/obstetric and other care as early as possible to prevent and/or mitigate the effects of substance exposures. The US Preventive Services Task Force, the American College of Obstetrics and Gynecology, and the American Academy of Pediatrics recommend that universal screening for substance use or misuse become a routine at any encounter with sexually active women and men of childbearing age. Stigma surrounding SUD creates enormous barriers to the treatment of pregnant women. Women often have difficulty acknowledging their problems with substance use, and professionals are reluctant to ask women about drug and alcohol use for many reasons, including lack of training or resources to adequately address an identified SUD. Pregnant women using substances are stigmatized by society and are perceived (and often view themselves) as having deviated from the traditional societal norms expected of women in their suitability as mothers and caregivers. Health-care providers may be explicitly or passively judgmental toward the woman causing her to be unreceptive to needed health care. Many states have punitive laws in place for pregnant women who use drugs. Such policies often contribute to patient unwillingness to admit substance use and missed opportunities for identification, education, support, and intervention. As a result, such women are likely to continue to use alcohol/drugs during their pregnancy, arriving at labor and delivery unregistered, with an increased risk of adverse maternal and infant consequences. Women face practical and financial barriers to accessing treatments that are gender specific, such as the need for adequate child care.

109.4.1 Identification of Women at Risk for SUD During Pregnancy

There are essentially two methods of screening for SUDs that can be used during the preconcep-

tion and prenatal periods: maternal interview/self-report and biologic specimen testing.

109.4.1.1 Maternal Interview Screening

All pregnant women, regardless of socioeconomic status and/or any perceived risk, should be asked about past and current licit and illicit substance use or misuse. A high index of sensitivity for substance use combined with an open-ended, nonjudgmental, and repeated questioning of pregnant women is therefore necessary to reduce reluctance to admission to use. There are several structured questionnaires that can be used during the prenatal period, although a majority are specific to alcohol (see Table 109.1). For example, the full AUDIT instrument, the abbreviated AUDIT-C, and single-question screening ("How many times in the past year have you had five [for men] or four [for women] or more drinks in a day?") have the best performance characteristics for detecting the full spectrum of alcohol misuse. Screening, Brief Intervention, and Referral to Treatment (SBIRT) is an evidence-based practice used to identify, reduce, and prevent SUDs in different settings.

Table 109.1 Screening tools for maternal substance use during the prenatal period

Instrument	Purpose
Alcohol use disorders identification test (AUDIT-C)	Screening for excessive alcohol use or alcohol use disorder
Cut down, annoyed, guilty, eye-opener (CAGE)	Potential problems with alcohol
Cannabis use disorder identification test (CUDIT-R)	Screening for excessive cannabis use or cannabis use disorder
Drug abuse screening test (DAST)	Screening for abuse of drugs other than alcohol
Michigan alcohol screening test (MAST)	Identification of heavy drinking or alcohol dependence
Pregnancy information program (PIP)	Assessment of stress, diet, alcohol, tobacco, and illicit drug use during pregnancy
Substance use risk profile-pregnancy (SURP-P)	Detection of alcohol or illicit drug use during pregnancy
Tolerance, annoyance, cut down, eye-opener (T-ACE)	Identification of risk drinking during pregnancy
Ten-question drinking history (TQDH)	Brief questionnaire for identification of alcohol abuse
Tolerance, worry about drinking, eye-opener, amnesia, K/Cut down (tweak)	Brief questionnaire for detecting alcohol problems during pregnancy
4P plus (parents, partner, past, pregnancy)	Screening for tobacco, alcohol, or illicit drug use risk during pregnancy

109.4.1.2 Biologic Specimens

The use of biologic specimens to screen for substance use or misuse has inherent difficulties. These methods do not give information about use patterns, are variably accurate depending on substances screened for and type of testing used, and can cause unintended legal consequences. Maternal and neonatal urine screenings obtained at the time of birth are most commonly used and have the lowest cost but only provide information about use in the last part of gestation (exceptions to this are chronic marijuana exposures; the metabolites of which can be excreted for as long as ten days in the urine of regular users and 15 or up to 60+ days in chronic, heavy users; and benzodiazepines, which can be present in urine up to 30 days), have low sensitivity, and have no role in mitigating the effects of substance exposures during pregnancy. Meconium analysis is more sensitive and supplies information about use in the second and third trimesters when meconium is formed but does not reflect periods of drug abstinence closer to delivery and as such may be harmful to women who access treatment and avoid use in the third trimester. Meconium may be difficult to collect and has high false-positive rates, and its passage may be delayed, particularly in premature infants, delaying the diagnosis. Umbilical cord testing is available but may be less sensitive than meconium [7]. Prior to testing, clinicians must be aware of legal requirements and the need for consent, which vary by state in the US. Hospital policies should comply with local laws and avoid discriminatory practices.

109.5 Identification of the Individual Exposed Prenatally to Substances

To date, there are no biologic markers to confirm or refute with certainty a syndrome or phenotype of children with problems related to PSE. This is a diagnosis of exclusion based on medical and alcohol/drug exposure history together with suggestive clinical signs. Infants with a suspected diagnosis of substance exposure and/or NAS should be evaluated using a scoring system such as the Finnegan Neonatal Scoring System (for opioid exposure) [24]. For children beyond the neonatal period, there are nonspecific situations that can indicate suspicion of PSE in the absence of known causes, which include developmental delays, sensory integration problems, emotional and behavioral problems, poor academic performance, or specific deficits in functioning of the child (Fig. 109.3). The diagnosis of problems related to PSE is complex. Because it carries life-long consequences, early recognition and treatment can result in a better outcome for the child that receives a diagnosis.

Underdiagnoses or overdiagnoses of any condition related to prenatal substance exposure are not beneficial for the child or the family. The clinician should rule out alternative or coexisting diagnoses of any suspected problem related to prenatal exposure to substances. Individuals with FASD are frequently misdiagnosed. There are other disorders such as ADHD, ADD, ODD that can have similar symptoms or can co-occur with any of the FASD categories. The formal identification of an FASD requires a qualified team and/or dysmorphologist. Individuals with an FASD group of symptoms require an early diagnosis to obtain the intensive and personalized services that may improve the outcomes and avoid secondary disabilities. For a review of guidelines for diagnosing FASD, see the recent update by Hoyme and colleagues [21].

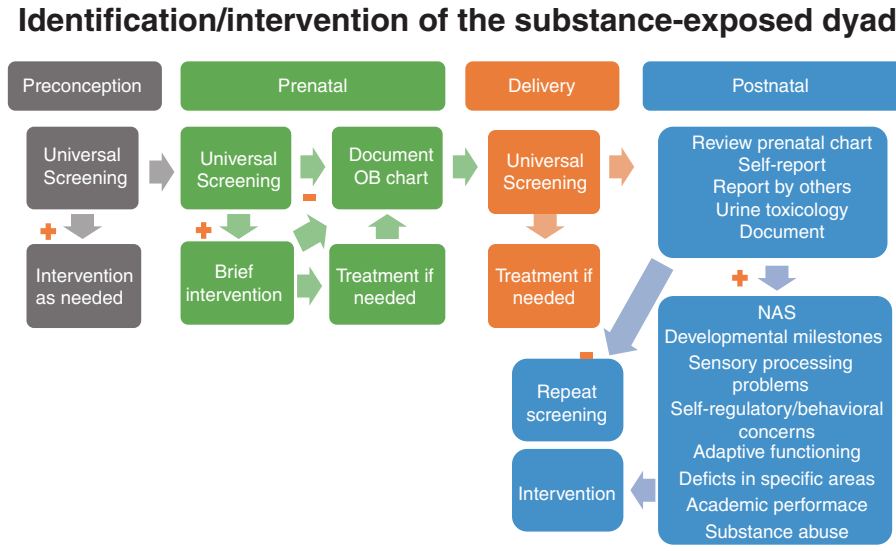

Fig. 109.3 Identification of the childbearing woman who uses/abuses substances should occur at several points during preconception, gestation, and at birth and be multipronged to include universal screening, review of the medical and social history, and maternal interview screening (Table 109.1), as well as evaluation of the infant/child

109.6 Interventions for Pregnant Women with SUD and Their Children

109.6.1 Preconception and Prenatal Counseling

Early pregnancy detection and first trimester prenatal care increase the chances of having a healthy pregnancy and baby. Women with a positive screening for substance use or misuse can receive brief intervention(s) or be referred to a comprehensive diagnostic evaluation and intervention. This process can be facilitated by using the principles of motivational interviewing. Brief interventions include short counseling sessions, feedback, advice, and goal setting conducted by health-care providers. Brief counseling has demonstrated efficacy in reducing the amount of drinking in pregnant women.

Pregnant women with SUD should receive a multistep management approach that includes comprehensive individual and/or group therapy concerning the adverse maternal and fetal/newborn impact of continued substance use. Referral to a multidisciplinary team for drug rehabilitation and a high-risk pregnancy specialist for ongoing fetal surveillance should occur; referrals may include counseling to deal with preexisting trauma and/or psychiatric comorbidity and assistance with other social determinants of health (e.g., housing; Fig. 109.4). Partner and/or family participation in prenatal care and SUD treatment is important to the woman's recovery; partner active drug use has been associated with delayed treatment time for pregnant women seeking care. Comprehensive care that is trauma informed and gender specific, including medical health care and developmental and behavioral assessments for existing children, should additionally be incorporated into the care plan for any parenting woman.

109.6.2 Treatment During Pregnancy

SBIRT gives health-care providers skills to discuss health behavior changes with their patients and can be effective at motivating individuals to

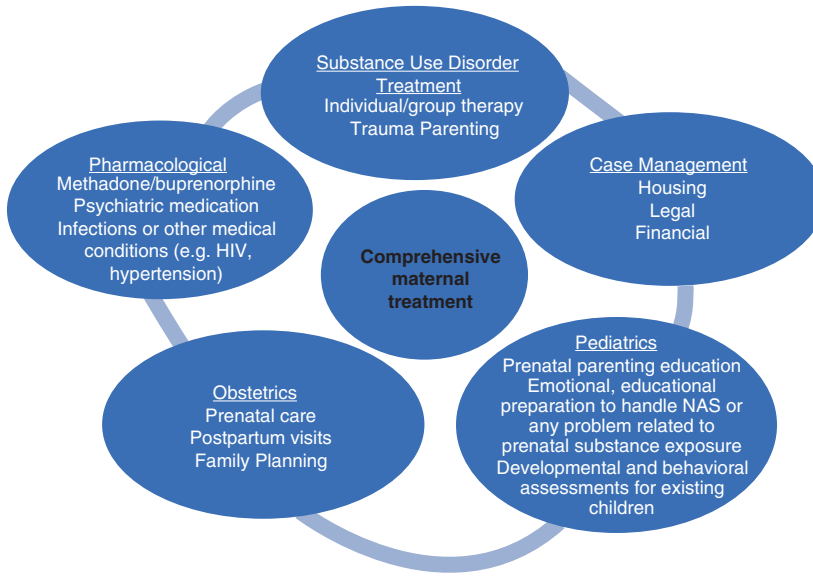

Fig. 109.4 Comprehensive treatment of the pregnant woman with an SUD. Treatment of the pregnant woman who uses/misuses substances should be comprehensive, trauma informed, and gender specific in nature and incorporate behavioral treatment; medical/obstetric/psychiatric care with pharmacologic treatment, including methadone or buprenorphine maintenance, as warranted; and the identification and provision of social support structures

change harmful substance use. SBIRT has three components: (1) screening to determine the severity of substance use, (2) brief intervention to build motivation through supportive conversation, and (3) referral to treatment directly linking the patient with needed services. Documentation of the interview and confirmation or not of maternal substance use should be recorded and transferred to appropriate health-care providers (i.e., anesthesiologist, pediatrician) to ensure a continuum of care.

Any pharmacologic treatment during pregnancy requires a clear and thorough discussion of the risk-benefits of the medication between the health-care provider, the mother, and the significant other when appropriate. Pharmacologic treatment for pregnant women with SUD includes medications for medical problems (i.e., HIV, hypertension), psychiatric comorbidities, and medications for opioid use disorders (OUDs). Daily methadone or buprenorphine treatment reduces the risk of relapse, increases retention in obstetric and SUD treatment, and may improve lifestyle for women with OUD by reducing criminal activity and avoiding risks associated with a drug culture, including those associated with drug seeking, overdose, and death. Both medications must be viewed as a central aspect to treatment but should be given as part of a comprehensive treatment approach that also includes obstetrical care, medical care, case management, life and parenting skills, and counseling. Although the benefits of treatment with methadone and buprenorphine are well known, many infants exposed to these medications develop NAS.

New non-pharmacologic treatment options for pregnant women with SUD have begun to emerge. These treatment options convey the advantage of not directly impacting perinatal development via exposure in utero or during breastfeeding, but studies to date are limited and efficacy remains to be demonstrated in large sample sizes. One such option is repetitive transcranial magnetic stimulation to the prefrontal cortex (rTMS), which has shown promise in the treatment of cocaine, alcohol, and nicotine use disorders [18] as well as depression during pregnancy [20].

Digital interventions, delivered via cell phones, computer software, Web pages, and "telepsychiatry" or social media, have also shown efficacy in reducing substance use [31], but these interventions have not yet been tested in pregnant women with SUD, and larger studies with adequate control groups are needed.

109.6.3 Postpartum Care of the Woman with an SUD

Comprehensive postpartum follow-up for pregnant women with SUD is necessary, with appropriate referrals to a primary care provider (OB providers for postpartum check and contraception, pediatric providers for the infant and existing children, and general medicine provider for the mother), psychiatrist if needed, and social services when warranted to ensure that the newborn has a safe home environment. While opioid overdose rates decrease during the second and third trimesters due to the availability of prenatal care for pregnant women with SUD, overdose deaths increase significantly within the first 7–12 months after birth, in part due to the paucity of health-care resources available for postpartum women as well as the stressors involved in caring for an infant. Working to ensure that women with SUD engage in safe sex practices and have acceptable contraception is a constant challenge; this population is disproportionately overrepresented among women with unplanned pregnancies and sexual violence.

109.6.4 The Mother/Child Dyad: Postnatal Period

All substance-exposed dyads should receive non-pharmacologic supportive management beginning at the time of infant birth and continuing throughout the hospitalization and beyond regardless of the infant's need for medication for NAS. These interventions are designed to (1) individualize the understanding and care of the infant, based on behavioral observations, with the goal of promoting organi-

zation, physiological stability, and competence; (2) modify the environment to support organized sleep/awake patterns and autonomic, sensory, motor, and attention/interactive development; and (3) encourage parental involvement with their infant [47].

An infant with opioid exposure should be hospitalized for a minimum of 72 hours for evaluation and identification of symptoms that may need pharmacologic treatment for NAS. This evaluation can be done using the Finnegan scoring system or a variant of it. These tools are applied every 3–4 hours for the infant's entire hospitalization. Medications most frequently used to treat the opioid-exposed infant are morphine sulfate and methadone. Breastfeeding is not contraindicated in many women with SUD who are able to access treatment, which may include methadone or buprenorphine maintenance, and who achieve sobriety and have no other medical contraindications to lactation. Each dyad should be individually assessed regarding their suitability for breastfeeding [24].

The primary care pediatrician has an important role in addressing PSE, which includes ongoing assessment of the infant, his caregivers, and his environment. This includes (1) assistance with maternal difficulties surrounding her substance use/misuse and awareness of how those difficulties impact the health and development of the child; (2) identification of infant/child difficulties related to exposures or parenting styles; (3) evaluation and interventions of the child for situations related to current or past parental SUDs such as violence exposure, relapse, and untreated psychiatric comorbidity; and (4) frequent and careful medical and developmental follow-up of the substance-exposed infant to child to teen. Mothers of substance-exposed children may be afraid to seek evaluations of the child when they have concerns (i.e., assessment for problems related to FASD) for fear of being labeled a "bad" or incompetent parent or due to her own difficulties dealing with guilt if the child's problem might be due to PSE. Judgmental or punitive health-care provider attitudes will cause further reluctance on the mother's part to engage in necessary health care. Neurodevelopmental, behavioral, academic, and emotional problems in childhood related to PSE can have both lifelong and intergenerational effects. Identifying and addressing these concerns early in life is essential, not only for the individual child and his/her parent(s) but to break the multigenerational cycle of SUD and victimization that often exists in substance-using families. In these cases, pediatricians must be able to step out of their traditional role as health-care provider to the child only to recognize and address the issues that are of critical importance to pediatric health, namely, issues that involve principally the parent and the environment created by parental difficulties with SUD.

Substance-exposed children and their mothers may have disabilities that can range from subtle to serious, with affected individuals presenting variable combinations of emotional regulatory deficits; deficits in memory, information processing, social skills (including pragmatic language and social communication skills), attention, and executive functioning; as well as significant emotional-behavioral and mental health issues. As a result, the interventions for a child, adolescent, or adult affected by prenatal exposure and his/her family vary according to these factors. Interventions designed to address neurodevelopmental problems associated with substance exposure require multidisciplinary assessment and care that is individualized and unique to the dyad, coordinated, compassionate, and comprehensive.

109.6.5 Parenting by the Mother with an SUD

The promotion of resilience in a substance-exposed child faced with the biologic vulnerability created by prenatal exposures depends upon the availability of parenting adults who can help children develop effective coping skills necessary to restore physiological and behavioral homeostasis and reduce disruptions in their developing brain circuitries. Essential to this process is the capacity of the parent to provide buffering protection for the children's developmental progress

through their own skills which include parental self-awareness, self-control, problem-solving, empathy, monitoring, and self-regulation. These skills areas are frequently underdeveloped or altered in one or both parents with SUD. The likelihood is, therefore, relatively low that these skills will be sufficiently strengthened by the simple education about child development or parenting recommendations. Training or coaching strategies that center on the parental skill set that includes executive functioning, emotion regulation, and social abilities offer a promising new direction that is worthy of investigation, especially for parents whose needs are not sufficiently addressed by existing support. An example of this mother/child model may be found in the "Mothering from the Inside Out" program [43]. In this model, mothers struggling to manage their SUD as they also parent their children participate in therapy focusing on problem-solving and coping emotionally with the everyday stresses of being a mother. This program is founded on an attachment-based intervention, which focuses on building reflective functioning in the mother and her capacity to attend to her own and her child's mental states, in order to promote secure attachment and emotional development in the dyad. These services are offered in conjunction with outpatient SUD treatment for the mother. Mother/child interaction is facilitated by a developmentally trained child care team, and the treatment center functions as a milieu that facilitates the dyad's regulatory functions.

109.7 Summary and Conclusions

In summary, the prevalence of use/misuse of substances among women before, during, and after pregnancy remains a major public health concern and constitutes one of the most common preventable causes of child morbidity. There are several key points the reader should take away from this chapter.

- PSE can disrupt fetal neurotransmitter systems, brain circuitry, and other important regulatory systems in ways that continue to influence physiology, behavior, and health at birth or decades later.
- It is of extreme importance to raise awareness of the impact of prenatal alcohol/substance use and to encourage the use of effective screening tools to reduce the incidence of problems related to PSE, which can profoundly impact not only the individual and the family but the health-care, education, and legal systems in our society.
- Any health-care professional in contact with a childbearing-age or pregnant/parenting woman and/or her child plays a critical role in screening for substance use during pregnancy and initiating appropriate interventions, as well as in the early diagnosis and ongoing treatment of children affected by PSE both biologically and environmentally.
- Although identification and intervention for women and children affected by PSE is critical, primary preventions (reducing the number of women of childbearing age who abuse legal and illegal drugs) and secondary preventions (recognizing and reducing the use of drugs substances among pregnant women) are also necessary. Inclusion of repetitive counseling to abstain from alcohol and other substances, including marijuana, nicotine, and misuse of prescribed drugs for women in the perinatal (preconception, pregnancy, parenting mother) health examinations is essential.
- Women of childbearing age and the general population must be informed that no safe level of alcohol or illicit drug consumption during pregnancy has been established and educated about the risks of misuse of licit substances.
- Services that enhance the mental health, executive function skills, and self-regulation capacities of vulnerable mothers should exist, with a focus on de-stigmatization. Few inclusive services exist, and such programs must include the child or at a minimum consideration for the child.
- A gold standard of care for the substance-exposed dyad must be established beyond the postpartum period, from the prenatal period through the first several years of the child's life. Only through the cooperative investment

of providers of all specialties in the well-being of the dyad can truly meaningful intervention take place for these high-cost, high-risk families. SUD treatment that is available, non-stigmatized, gender specific, and trauma informed that includes the child(ren) should exist for all pregnant women with SUD.

- Research funding should seek to prioritize the examination of optimal care for both mothers and children, examine the short- and long-term outcomes for the substance-exposed dyad, and establish effective measures to maximize healthy trajectories for both maternal recovery and the infant's neurodevelopment.
